**Unified International Technical Conference on Refractories (UNITECR) 18th Biennial Worldwide Congress on Refractories**

26th – 29th September 2023
Germany | Frankfurt am Main | Kap Europa

UNITECR 2023

Deutsche Feuerfest Industrie e.V. — DFFI

European Centre for Refractories — ECREF

# PROCEEDINGS

# THE CARBON CHALLENGE

**Steps and leaps to master the future**

# SPONSORS

We would like to thank the sponsors who made it possible to develop UNITECR 2023 into a very special event. Whether it's important conference elements such as pens, pads or the conference bag, the events, the Welcome Evening or the Conference Dinner, all of this has been prepared even better for you with their support.

### ADDITIONAL PUBLICATIONS IN „OPEN CERAMICS"

We have published a number of additional papers in a Special Issue titled „Ref-ractories for the Carbon Challenge" of the scientific journal „Open Ceramics". The Special Issue was edited by Prof. Olaf Krause (Koblenz University of Applied Sciences), Dr. Christian Dannert (Forschungsgemeinschaft Feuerfest e. V.) and Prof. Christos G. Aneziris (TU Bergakademie Freiberg). These papers are open access and can be viewed at **https://www.sciencedirect.com/journal/open-ceramics/special-issue/102HMR7RHH6**.

1

# WELCOME

**„The Carbon Challenge: Steps and Leaps to master the Future" is our motto at the UNITECR over the three days in Frankfurt – and for the coming years as we drive the transformation of our industry forward.**

During these days we will hear how the specialists want to further develop the path to $CO_2$ neutrality of our high-temperature industry, learn how we can reduce $CO_2$ emissions in the process and also give impetus to our customers. At UNITECR, experts, researchers and professionals from all over the world will come together to expand knowledge and find solutions to the challenges facing the industries.

An important aspect is the recycling economy to conserve limited resources and reduce the ecological footprint in the refractory industry. Regional value chains with close cooperation between suppliers, users and other stakeholders involved are essential. And there are already good examples of this.

There will be a leap in knowledge after this conference, which will be of enormous importance to all of us. We hope that you will experience inspiring presentations, exciting discussions and valuable networking opportunities during the conference. The UNITECR conference is known for its high-profile speakers and poster sessions. New are five panel debates on special topics that we have developed especially for this conference. Experience the exchange of opinions live and join the discussion.

Use this opportunity to expand your knowledge, exchange ideas with colleagues from the industry and discover new cooperation opportunities. We are confident that this conference will provide you with valuable insights and impulses for your work and research.

Prof. Dr. Christos G. Aneziris, as Vice-President of UNITECR 2023 and Chair of the Scientific Committee, and his team have ensured high quality and diversity. More than 250 papers will be presented in lectures or posters.

We both look forward to seeing you. Once again, welcome to the UNITECR Conference 2023. We wish you an inspiring and successful event.

We would like to thank all speakers, participants, exhibitors and organisers who have contributed to this event.

Dr. Andus Buhr

# 1  RAW MATERIALS

# DATA−BASED CARBON FOOTPRINT OF IMERYS SPECIALTY MINERALS FOR REFRACTORIES

S. Ranaivoharilala, N. Bunt, C. Wöhrmeyer
Imerys, Paris, France

## ABSTRACT

Refractory raw materials are the major contributor to the carbon footprint of unshaped refractories while for fired refractory bricks the firing process adds to the total carbon footprint. Significant energy and $CO_2$ emissions savings can be achieved by using monolithic refractories instead of fired bricks and a careful selection of raw materials can further reduce the total carbon footprint of refractory products. This paper will explain in detail the boundaries for the quantification of the $CO_2$ equivalents of Imerys specialty minerals for refractories. The analysis leads to product-specific scientific data-based $CO_2$ equivalents that allows a transparent calculation of the footprint of refractory products formulated with Imerys raw materials. This paper will concentrate on some Imerys specialty minerals and highlight the impact of different contributors on their carbon footprint, including the energy sources. Thanks to its effort to turn to low-emission energy supply, Imerys is capable of providing sustainable solutions and fulfilling its purpose to contribute to the decarbonization of the refractory value chain.

## INTRODUCTION

As part of its sustainability commitment, Imerys strives to develop minerals and expertise that deliver innovative, market-driven and sustainable solutions to society. For a few years now, a thorough assessment has been performed with the goal of understanding and further improving the sustainability profile of Imerys' existing and new solutions, including the specialty minerals manufactured for the refractory industry. First, this paper will detail the assessment methodology developed by Imerys, with a focus on the production step impact. Second, the evaluation outcomes of various minerals manufactured by Imerys, including chamotte, andalusite and white fused alumina, will be examined in view of the different carbon footprint contributors, namely the energy consumption. Advancing the sustainability goals of the refractory industry and their downstream users is one way Imerys is leading the challenge of caring for the planet through climate change mitigation by providing sustainable mineral solutions.

## IMERYS PORTFOLIO SUSTAINABILITY ASSESSMENT

Sustainability is anchored within Imerys activities, in a continuous improvement and long-term value creation approach. SustainAgility®, the program that structures sustainability within the Group, has been implemented based on the 2030 Agenda for Sustainable Development and major international framework agreements [1]. Delivering sustainable and high-quality solutions to its customers is one of the key ambitions of Imerys. SustainAgility Solutions Assessment (SSA) is the Group's methodology that screens and measures the sustainability of its portfolio and supports the development of its new solutions. Duly considering the World Business Council for Sustainable Development (WBCSD) guidelines for Portfolio Sustainability Assessments (PSA), it establishes a scientific, strong and reliable framework that considers the whole product's life cycle. The methodology results in a sustainability score, built on two specific factors called "Sustainable Value Creation", which is the balance between the economic value created and the environmental impact measured during the manufacturing stage, and "Market Alignment" which evaluates the sustainability benefits or challenges of the product in a specified application [2].

## IMERYS PRODUCT CRADLE-TO-GATE LIFE CYCLE ASSESSMENT

Life cycle assessment (LCA) is a technique used to identify, calculate and analyze the environmental and social impacts of a product or service over its life cycle. It takes into account the raw material production, acquisition, transformation, energy production, as well as the finished product use and end-of-life treatment. There are various manners to perform an LCA, including the conceptual, simplified or detailed approach. However, not all of the existing methods meet the ISO Standards. A conceptual LCA is the easiest technique as it only considers a limited qualitative inventory and results in qualitative findings focusing on the biggest impact contributors. A simplified LCA uses generic and standard data, and looks at the potential and/or most important life cycle stages and/or impacts. Conceptual and simplified LCAs are mainly used internally in order to support decision making, and their external use is meaningful provided that ISO Standards requirements are met. A detailed LCA is the more advanced approach and embeds a defined goal and scope, life cycle inventory or LCI (quantification of the inputs and outputs), life cycle inventory analysis or LCIA (understanding the importance of the impacts) and results interpretation (leading to the conclusions and recommendations) [3][4].

### Goal and scope

LCA is an integral part of Imerys' portfolio sustainability assessment. It has been used by the Group for many years, while ensuring continuous improvement, as a key instrument to measure and optimize the carbon footprint of its solutions [5]. As part of its SSA program, Imerys follows a detailed LCA approach and carefully aligns with the ISO 14040 and 1044 Standards on LCA "principles and framework" and "requirements and guidelines" respectively. This paper will look into the cradle-to-gate or manufacturing phase of the mineral, evaluated from the resource extraction and transformation ("cradle") until Imerys' gate ("gate"), meaning before the delivery step to the customer.

### Inventory: data collection

The cradle-to-gate system is modeled as exhaustively as possible with:

– primary data mainly: from Imerys quarries and factories' monitoring and measuring systems, which are the consumption and emission information related to the minerals extraction and transformation, and the packaging process,

– and secondary data: from external sources providing standard consumables and energy production and combustion data, as well as any other information not available at Imerys' level. The Group's main source of data is the ecoinvent database which is a repository that provides datasets on specific processes and their corresponding resource consumptions, emissions, products and wastes. The ecoinvent database covers multiple sectors globally and regionally and each dataset also contains LCIA results based on various assessment methods and impact categories [6]. The data, represented as input and output flows in the cradle-to-gate system are the:

– resources consumption (natural resources, consumables, energy),

– consumption of space (land occupation and transformation),

– production (products, coproducts, byproducts),

– wastes (mineral and process),

– emissions (to the air, water and soil).

Imerys also tracks energy-related indicators including: primary, non-renewable, renewable, fuel and feedstock energy.

**Inventory analysis: carbon footprint**
Imerys calculates and monitors a whole set of environmental and social impact indicators selected based on their relevance to the Group's activities, using a specific LCA tool. This paper will focus on the carbon footprint which evaluates the climate change impact by measuring the total amount of greenhouse gas (GHG) emissions generated by an individual, organization, event, service or product, over a 100-year time horizon. GHG emissions include carbon dioxide ($CO_2$), which is the reference gas, methane ($CH_4$), nitrous oxide ($N_2O$) and fluorinated gas (F-gases). Carbon footprint is expressed in $CO_2$ equivalents ($CO_2eq$) and is categorized into:
– scope 1: direct emissions from the company's factory, which are mainly the emissions from the fuels combustion or the carbon content of the raw materials,
– scope 2: indirect emissions from purchased energy sources, such as electricity or steam,
– scope 3: all the remaining indirect emissions from the whole value chain, including the raw materials upstream transportation or finished products downstream transportation, for instance.

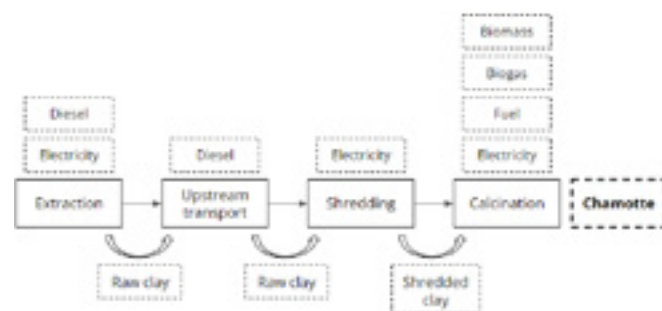
**Cut-off rules, exclusions, allocations**
A cut-off criteria determines the quantity of flows or the environmental importance assigned to a process or system that is excluded. Imerys takes into account all the available inputs and outputs, allowing a cut-off ratio greater than 99% based on a mass criterion. Some stages are excluded from the life cycle inventory because of their irrelevant or insignificant impact: capital equipment, closing and rehabilitation of quarries, impacts of human activities onsite. Allocation procedure, which is the repartition of the inputs and outputs to the different products, is avoided as much as possible by using the dataset associated with each product. When needed, physical allocation - in contrast to economic allocation - is applied.

**CARBON FOOTPRINT OF SOME IMERYS MINERALS**
Product carbon footprint will consequently depend on the overall assessment approach, implying the assumptions, modeling and calculation methods. However, it is also impacted by the different transformation processes involved and the types and quantities of resources used, these latters being also dependent on diverse factors such as the geographical zone. According to ISO Standards, in order to ensure comparability of results, it is imperative to determine a functional unit defined as a quantified performance of a product system for use, which will be a reference to which the inputs and outputs are related [3]. For monolithic refractories, the carbon footprint will mainly be influenced by the choice of the raw materials which are the aggregates, binders and additives. The raw materials carbon footprint will be based on the extraction, production and transportation methods. Furthermore, the footprint will also be impacted by the energy sources and quantities required by the processes, such as blending and drying. For bricks, the carbon footprint will also be linked to the raw materials and manufacturing techniques, which involve the shaping and high-temperature firing of products made from formulations containing the refractory minerals. This paper will focus on the raw materials, as illustrated by some minerals manufactured by Imerys.

**Chamotte - France**
*Manufacturing description*
Chamotte is a calcined clay with a high proportion of alumina used in refractory applications as it resists extreme temperatures, operating conditions and corrosive environment. This section will focus on one of the Imerys' chamotte grades produced in France. The kaolinitic clay is extracted from Imerys quarries and transported by truck to the Imerys plant located 20 km away. The extracted clay is shredded, using electricity, and calcined in rotary

kilns between 1400°C and 1600°C, using electricity, fuel oil, biomass and biogas (both from waste) (Figure 1).

*Fig. 1: Imerys Chamotte manufacturing process.*



*Data sources and results*
For this system, 2020 primary data from Imerys plant and secondary data from the ecoinvent library were used. This chamotte grade has a carbon footprint of **251 kg CO2eq / ton**. All the impact comes from the energy production and use, and the calcination step is the highest contributor (Table 1).

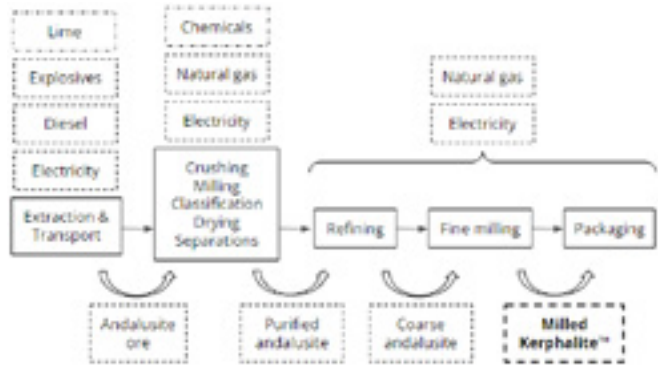
Tab. 1: Carbon footprint breakdown in the manufacturing of the Imerys chamotte (France).

| Impact contributor | Extraction | Transport | Shredding | Calcination |
|---|---|---|---|---|
| Electricity | 0.1% | - | - | 0.9% |
| Diesel | 8.5% | 1.3% | 21.3% | - |
| Fuel oil | - | - | - | 56.1% |
| Biogas | - | - | - | 9.9% |
| Biomass | - | - | - | 1.9% |
| Total | 8.6% | 1.3% | 21.3% | 68.8% |

In the calcination step, the energy contribution of each source is as follows: biogas (40%), biomass (19%), fuels (37%), electricity (4%). Consequently, the usage of biogas and biomass has a substantial impact on the total carbon footprint of this chamotte. Using these renewable sources translates into a reduction of the total product carbon footprint of almost 50%, compared to a system operating solely with the fuel. As part of Imerys' target to mitigate climate change, a replacement of fossil fuels with biomass or low-emission energy sources is a key priority. This will have an impact on the Group's activities emissions but also the carbon footprint of its products. We should thus expect an improvement of Imerys chamottes' carbon footprint, which is already relatively low.

**Andalusite - France**
*Manufacturing description*
Andalusite is a rock-forming aluminosilicate mineral with a high alumina content used in the production of refractories. Imerys andalusite minerals are ideal solutions for fired and unfired refractory bricks and monolithics, thanks to their outstanding creep and high thermal shock resistance, as well as resistance to chemical attack, slag and metal penetration. This section will focus on one of one of the Imerys' andalusite grades called Kerphalite™ mined and treated in France. Kerphalite™ is a unique product due the separation processes involved in the beneficiation of this mineral. The andalusite ore is extracted from an open pit with a blasting process using explosives and transferred to the treatment plant located one kilometer away. The plant mainly uses electricity and natural gas as energy sources. Coproducts composed of fine dust emissions are introduced back into the production process, improving the mineral resource recovery. The ore is crushed, milled and beneficiated through a refining process composed of a classification with magnetic, densimetric and electrostatic separations to remove impurities. The purified product is then further dried, milled and packaged (Figure 2).

*Fig. 2: Imerys milled Kerphalite™ manufacturing process.*



*Data sources and results*
For this system, 2021 primary data from Imerys plant and secondary data from the ecoinvent library were used. This milled Kerphalite™ has a carbon footprint of **312 kg CO2eq / ton**. Almost 80% of the carbon footprint comes from the energy production and use. The biggest impact contributor is the natural gas used in the process (Table 2).

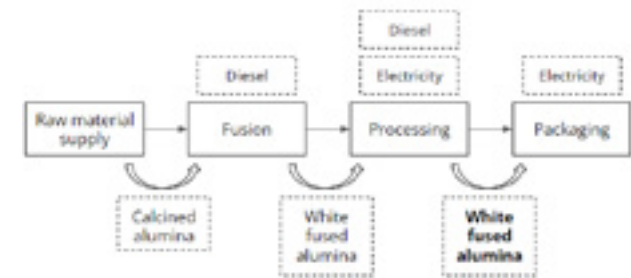
Tab. 2: Carbon footprint breakdown in the manufacturing of the Imerys milled Kerphalite™ (France).

| Impact contributor | Extraction | Crushing to separations | Refining to packaging | Other |
|---|---|---|---|---|
| Electricity | 0.4% | 5.0% | 1.5% | 1.1% |
| Diesel | 10.8% | - | - | 2.1% |
| Natural gas | - | 52.1% | 3.1% | 3.5% |
| Explosives | 6.3% | - | - | - |
| Lime | 7.8% | - | - | 1.0% |
| Chemicals | - | 0.4% | - | 3.1% |
| Packaging | - | - | 1.8% | - |
| Total | 25.3% | 57.5% | 6.4% | 10.8% |

Electricity accounts for more than 20% of the energy consumption in the system. However, its impact is limited by the emission factor of the French grid mix, which is among the lowest in Europe and worldwide [7]. The replacement of natural gas with a low-emission energy source would further reduce the carbon footprint of this andalusite grade.

**White fused alumina - Austria**
Imerys is the world's largest producer of fused alumina. Fused aluminas are used in different industries including refractories, thanks to their great resistance to shocks, as well as thermal and chemical stability. The manufacturing process of this white fused alumina model includes the production and supply of calcined alumina (90% sourced from Europe), as well as graphite electrodes from China used in the electric arc furnace. The calcined alumina is smelted by electrothermal fusion in the furnace at temperatures of around 2000°C, before being crushed, milled, sieved, blended and packed (Figure 3).

*Fig. 3: Imerys white fused alumina manufacturing process.*



*Data sources and results*
For this system, 2021 primary data from Imerys plant and secondary data from the ecoinvent library were used. This standard white fused alumina grade has a carbon footprint of **1113 kg CO2eq / ton**. Alumina feedstock production and supply to Imerys represent more than 80% of the total impact.

Tab. 3: Carbon footprint breakdown in the manufacturing of the Imerys standard white fused alumina (Austria).

| Impact contributor | Raw material | Fusion to packaging |
|---|---|---|
| Calcined alumina | 82.4% | - |
| Graphite | 0.6% | 1.0% |
| Raw materials supply | 7.7% | - |
| Electricity (hydro) | - | 6.9% |
| Diesel | - | 0.3% |
| Packaging materials | - | 1.1% |
| Total | 90.7% | 9.3% |

The calcined alumina production has been modeled using information from the literature [8]. Fossil fuels production and combustion are the biggest carbon footprint contributors in the calcined alumina manufacturing (Table 4).

Tab. 4: Carbon footprint breakdown in the manufacturing of the calcined alumina (Europe) [8].

| Impact contributor | Raw material | Processing |
|---|---|---|
| Bauxite | 3.2% | - |
| Heavy fuel oil | - | 32.9% |
| Natural gas | - | 33.1% |
| Coal | - | 23.8% |
| Electricity | - | 6.8% |
| Diesel | - | 0.2% |
| Total | 3.2% | 96.8% |

The impact of the fusion and processing of the white fused alumina is highly reduced thanks to the usage of hydroelectric power in this Imerys Austrian plant, accounting for more than 99% of the energy used in the process. Consequently, the white fused alumina carbon footprint is impacted by the calcined alumina production and origin, but it may also differ more or less significantly based on the electricity used in the furnace, which depends on the factory location and thus its power sourcing. For instance, China's electricity emission factor ranges between 250 and 950 g CO2eq / kWh according to the region [9], which is around five to more than 20 times higher than the average of the European grids. A simulation has been performed with the same system and energy ratio but replacing the Austrian electricity model with a Chinese model (State Grid Corporation of China - SGCC) [6]. The results showed that a white fused alumina produced with this Chinese electricity model has a carbon footprint of around 6000 kg CO2eq / ton, which is more than five times higher than the one produced in the Imerys' Austrian factory.

**CONCLUSION AND OUTLOOK**

Product carbon footprint is influenced by multiple factors including the LCA method, raw materials origin or energy sources used in the processes. We could particularly see the role played by energy throughout the life cycle. It is important to note that carrying out product carbon footprint comparison is only valid if a functional unit has been clearly defined. As the downstream industries or customers to the refractory industry push forward to decarbonize, the contribution the refractory industry brings to this decarbonization will be assisted by the ability of raw material suppliers to provide high-quality low-carbon footprint solutions. Imerys is well positioned to help the downstream actors like the iron and steel, aluminum, cement, glass and the hydrocarbon

processing industries achieve their sustainability goals and help reduce their overall greenhouse gas emissions. These sustainability goals will continue to help us minimize the negative impact of manmade climate change on the planet. Unlocking the sustainable potential of minerals in a responsible way, using science-based targets and methodologies, choosing renewable energy sources like solar, hydropower and biomass, and last but not least developing new innovative products and processes targeting higher efficiency in production and during use in refractories for the high temperature industries will allow Imerys to assist its customers in reaching sustainability targets and helping to preserve the planet.

# SINTERING AND THERMO-MECHANICAL CHARACTERIZATION OF A NOVEL REFRACTORY GRADE BAUXITE

Noronha, Luiz Gustavo.
Bautek Minerais, Caldas, Brazil

Muche, Dereck Nills Ferreira.
Universidade Federal de São Carlos, São Carlos, Brazil

**ABSTRACT**

The global market for refractory grade bauxite (RGB) has been supplied by few players located in China and Guyana, mostly because of the chemical and mineralogical restrict specifications required for this class of material. When considering the mineralogical phases of the refractory grade bauxite, the main phases present higher content of corundum, tialite and mullite. Recently, a new Brazilian bauxite mine, located in Barro Alto, State of Goias, is capable of producing bauxite with higher $Al_2O_3$, low $Fe_2O_3$ and lower $TiO_2$ contents, than those available in the market. Herein, the present work focuses on the processing of the Brazilian RGB highlighting 2 main fronts: i) Improving the sintering of the bauxite to be able to attain the benchmark properties for bulk density and apparent porosity, approximately 3,2 g/cm³ and 9% respectively; ii) Comparing it with the global benchmarks (Guyanese and Chinese Refractory Grade Bauxite) in terms of chemical and mineralogical composition, and mechanical performance. Preliminary results so far, have shown that the Brazilian RGB develops only the mineralogical phases corundum and mullite, without the presence of tialite, with a density of ~3,3 g/cm³ and an apparent porosity lower than 10%, showing to be a promising candidate for refractory applications.

## INTRODUCTION

Bauxites are widely used as a source of aluminum and alumina in global production, with this market accounting for a significant portion of global production. However, bauxite has various other applications known as non-metallurgical applications. Among the non-metallurgical applications, the main use is as a refractory aggregate, which accounts for two-thirds of global production (excluding production for metallurgy)[1]. In the application as a refractory aggregate, bauxites are used in high-alumina refractories and can be part of the composition of shaped and monolithic refractories[2].

With refractory bauxite production controlled only by producers located in China and the Guianas [1], there is a need for new providers to achieve greater diversification and availability of the product globally. In recent years, due to several factors, production in the main producing country has been significantly reduced, which directly impacts the entire production chain. Therefore, the present study introduces a new source of material produced from the gibbsite ore in the region of Barro Alto, Goiás state, Brazil [3].

Bauxite can have two mineralogical sources, diaspore, predominant in China, and gibbsite, predominant in tropical regions such as the Guianas, India, and Brazil, and also, the contaminants that directly influence the properties of the final product, it is necessary to conduct a comprehensive analysis from the characterization of raw materials, the appropriate mineral processing, which greatly impact the quality of the final product [4], to the formation of the industrial sintered aggregate.

Refractory bauxites on the other hand, are specified to have low levels of contaminants, including iron oxides, titanium, alkali and alkaline earth minerals. This is due to the lower refractoriness found in bauxites with few impurities compared to the pure $Al_2O_3$-$SiO_2$ system [5], where even small contamination of titanium and iron significantly reduces the refractoriness of the material.

Typically, refractory bauxites have high refractoriness (~1840°C), but their refractoriness is reduced under load (1450-1550°C) due to impurities such as $TiO_2$ and $Fe_2O_3$, responsible for forming a liquid phase at these temperatures.

Secondary thermal expansion is another phenomenon that decreases the mechanical properties of refractories made from bauxites. Bauxites from specific regions in China have low secondary thermal expansion due to their low impurity content and unique phase change behavior in diaspore bauxites. In contrast, South American raw materials, mostly gibbsitic, exhibit a more significant occurrence of this phenomenon, making it harder to be used in high-alumina refractories applications, particularly when combined with refractory clays.[6]–[8]

Previous work on literature evaluated the impact of aggregate particle size in a refractory with 70% alumina composition. Fine bauxite fractions and coarse fractions, as well as fine and coarse alpha alumina, were analyzed. The study found that the use of fine fractions reduces the initial temperature of secondary volume increase. This is attributed to the easier dissolution of smaller bauxite particles, which accelerates the mullite formation process and volumetric expansion compared to coarser fractions of the same bauxite. The study also examined the influence of impurities present in bauxite compared to a refractory made with alpha alumina. It was observed that the behavior of the refractory resembled that of the bauxite in terms of secondary expansion only when contaminants like $Fe_2O_3$ and $TiO_2$ were included. [7], [9]

Caballero et al. [4] conducted a study to examine the influence of processing on the mechanical properties of bauxites, comparing South American and Chinese bauxites. Three processing methods were considered: direct sintering, grinding followed by pressing and sintering, and calcination followed by grinding, pressing, and sintering. Figure 1 shows the results that samples subjected to more complex processing had better mechanical properties, when compared to no processing ones. The maximum strength of South American bauxites, with no previous calcinantion (RBS and BSP) was significantly affected by the higher hydroxyl content compared to Chinese bauxites (RBC and BCP). The samples with the complete processing (BSPP and BCPP) were the ones with the better performance.

*Figure 1: Stress-strain curves at 1550°C for a constant load rate of 8,3 x 10 $^{-7}$ m/s. a) China samples b) South America Samples[4]*

The stress-strain curves revealed different behaviors for Chinese and South American bauxites. South American bauxites exhibited a toughening mechanism due to the presence of a needle-like mullite skeleton, which deflected cracks and increased toughness. Chinese bauxites, on the other hand, showed a brittle behavior due to the presence of alpha alumina. The tougher behavior of South American bauxites resulted from the more pronounced precipitation of secondary mullite, facilitated by the greater dissolution of unstable alpha alumina grains during sintering. In contrast, Chinese bauxites had more stable alpha alumina grains, therefore not been able to form as much secondary mullite.

Given the restrictions on high impurity levels and the available chemistry in the Barro Alto – GO bauxite deposit, a better understanding of the influence of iron oxide in refractory bauxite compositions is necessary. It has been observed that mullite and corundum have some susceptibility to enter solid solution with $Fe_2O_3$ by substituting $Al^{3+}$ cations with $Fe^{3+}$. Herein, Caballero and Aza [10] studied the influence of increasing iron content on the high-temperature mechanical properties of refractory bauxites. Analyzing the mineralogical composition of the samples, was observed that the addition of iron results in a considerable reduction in mullite content. It can be concluded that the addition of iron leads to the deterioration of refractory properties due to lower mullite formation and increased liquid phase formation.

The solubility of $TiO_2$ and $Fe_2O_3$ oxides, studied by Caballero and De Aza [11], [12], was analyzed in refractory bauxite compositions containing approximately 80% $Al_2O_3$ at different temperatures (1450 to 1700°C). The results of the solid solution concentrations of each mineralogical phase were analyzed using EDS. The solubility limit of each compound was determined for the main mineralogies present in refractory bauxite: corundum, mullite, and tialite. It can be observed that $Fe_2O_3$ exhibits solubility in all three major phases present in refractory bauxites. However, as the temperature increases, $Fe_2O_3$ tends to reduce its solubility in all compounds, reaching almost no solubility for tialite and mullite phases at 1700°C and 2% in weight for corundum.[7]

Considering the influence of alkalis on the composition and behavior of refractory bauxites, the study by Zhong et al. [13] analyzed that for every 1% of $K_2O$ present, there was a 7% increase in the glassy phase, a reduction of 15-20% in mullite content, and an increase of 8-13% of the corundum content. Therefore, with the addition of $K_2O$, the crack deflection mechanism generated by the presence of intragranular mullite around alumina grains is reduced. Based on the analysis of the quaternary phase diagram $Al_2O_3$-$SiO_2$-$Fe_2O_3$-$TiO_2$, it has been determined that while alkali and alkaline-earth oxides do not affect the phase relationship and crystallization sequence, their presence significantly influences the liquid formation temperature and its concentration at various temperatures.

In conclusion, two studies analyzed the production of refractory-grade bauxite using a blend of Brazilian gibbsite sources with low TiO2 content, similar to the ore present in this study. The South American bauxite exhibited thermomechanical properties similar to the standard product from Guyana and superior to the standard Chinese product. Considering the chemistry of the produced Brazilian bauxite, it had a high Fe2O3 content (+4.5%) and a relatively low TiO2 content (-1.5%). As a result, it predominantly generated Gibbsite and Mullite phases, with a lower formation of Hematite.[14], [15]

The present study will focus on the processing, characterization, and thermomechanical analysis of refractory-grade bauxite, exclusively using the Barro Alto - GO bauxite source. The production method will encompass the entire ideal ceramic processing, including initial thermal treatment, grinding, briquetting, and sintering. Additionally, after the thermal treatment of the gibbsitic ore, a magnetic separation process will be applied to achieve a higher-grade product with Al2O3 content above 90%, controlled Fe2O3 below 3.0%, and TiO2 content below 0.5%. These unique characteristics are specific to the RGB developed in this study.

## MATERIALS AND METHODS

For the preparation of bauxite samples from Barro Alto, Goiás, their initial step involved calcination at 1200°C in a rotary furnace. This process followed the recommended procedure [5], which includes a necessary thermal treatment prior to sintering. After calcination, the samples were subjected to magnetic separation to reduce the $Fe_2O_3$ content. The magnetically separated product was then ground to sizes of 0.150 mm and 0.075 mm and pressed at pressures of 40, and 80 MPa using a uniaxial press. The pressed bodies were fired in a static electric furnace at 1600°C, with a dwell time of 3 hours and a heating rate of 5°C/min. The sintered bodies were subsequently measured for apparent density and porosity in accordance with the ABNT NBR 8592 standard. X-ray diffraction analysis were conducted on the sintered gibbsitic bauxite samples from Barro Alto (BAUTEK R-90), along with the market bauxite samples (from Guiana and China). This analysis was performed using an Empyrean X-ray diffractometer equipped with a position-sensitive detector. The identification of crystalline phases was carried out by comparing the sample diffractogram with the PDF2 and ICSD databases from the International Centre for Diffraction Data. Quantification of the phases was carried out using the Rietveld method, employing crystal structures from the ICSD.

Benchmark refractory grade bauxite samples were obtained from two global suppliers, one from the Guianas (South America) and the other from China, both with reported $Al_2O_3$ contents above 88%. XRF analysis was performed on fused pellets using Panalytical equipment to confirm the composition of the market samples and the product made from the Barro Alto ore. Thermodynamic simulation was conducted using the FactSage software to evaluate the microstructural composition at different temperatures based on the oxide contents of each sample.

## RESULTS AND DISCUSSION

Table 1 depicts the results of the XRF analysis of the three samples, the bauxite from Barro Alto mine is described as BAUTEK R-90, the guianese bauxite is the BX GUIANA and the chinese one is the BX CHINA.

*Table 1: XRF Analysis of the three analyzed samples.*

| Sample | $Al_2O_3$ [%] | $Fe_2O_3$ [%] | $SiO_2$ [%] | $TiO_2$ [%] | $K_2O$ [%] |
|---|---|---|---|---|---|
| BAUTEK R-90 | 93.00 | 2,54 | 3,04 | 0,39 | 0,01 |
| BX GUIANA | 89,70 | 1,57 | 4,84 | 3,47 | 0,10 |
| BX CHINA | 86,70 | 2,01 | 4,62 | 3,48 | 0,26 |

Based on the XRF data provided in the table above, thermodynamic analyses were conducted to evaluate the possible phases present and the presence of a liquid phase at the proposed sintering temperature in this study.

Analyzing the data presented in Table 2 and Figure 2, it was observed that among the three bauxite samples, BAUTEK R-90 showed a lower formation of liquid at 1600°C and higher viscosity compared to BX CHINA and BX GUIANA, despite having a higher Fe2O3 content.

Additionally, from the analysis of

19

Figure 2, only corundum and mullite phases are detected in the BAUTEK R-90 sample. As observed, there is no presence of phases containing $Fe_2O_3$, as it tends to form solid solutions with the presented phases and high temperature [11], [12]. On the other hand, the benchmark samples showed the presence of the same two phases as well as some phases containing $TiO_2$, predominantly tialite.

Figure 2:FactSage analysis of the three analyzed samples

*Table 2: Liquid phase analysis of the three samples at 1600°C*

| Sample | Temperature [°C] | Liquid Phase [wt%] | Viscosity [mPa.s] |
|---|---|---|---|
| BAUTEK R-90 | 1600 | 2,1 | 449 |
| BX GUIANA | 1600 | 2,7 | 175 |
| BX CHINA | 1600 | 13,4 | 249 |

The presence of only corundum and mullite phases in BAUTEK R-90 indicates a lower formation of liquid phase at 1600°C, as seen in Table 2, compared to the other two samples, and a higher refractoriness for its composition compared to the others. To confirm the data obtained from thermodynamic simulation, X-ray diffraction analysis was performed, and the quantification of phases was carried out using the Rietveld refinment method and comparing to them crystal structures from the ICSD.

The phase composition of the analyzed bauxites, as shown in Table 3 and **Erro! Fonte de referência não encontrada.** , confirms the thermodynamic simulation previously conducted based on the XRF measurements. The BAUTEK R-90 sample exhibited only corundum and mullite phases. On the other hand, the Chinese and Guiana bauxites, due to their higher content of $TiO_2$, showed a lower concentration of these phases and the formation of tialite.

*Figure 3: XRD Analysis of the three samples. a) BAUTEK R-90; b) BX GUIANA; c) BX CHINA*
*Table 3: XRD Analysis of the three samples*

| Sample | BAUTEK R-90 | BX GUIANA | BX CHINA |
|---|---|---|---|
| Corundum ICDD 01-071-1123 | 86,00 | 72,00 | 83,00 |
| Mullite ICDD 98-002-8304 | 14,00 | 12,00 | 8,00 |
| Tialite ICDD 98-008-5054 | - | 16,00 | 8,00 |
| Hematite ICDD 98-007-0038 | - | - | 1,00 |
| Rutile ICDD 01-076-0319 | - | - | pp |

Figure 4 presents the apparent densities in relation to the established process variables (particle size and pressing pressure). It is observed that the variation in particle size did not result in a significant change in the density of the fired body. For a pressing pressure of 80 MPa, there was a density variation from 3.32 g/cm³ for particle size of 0.150 mm to 3.36 g/cm³ for particle size of 0.075 mm. On the other hand, it can be observed that the variation in pressing force had a significant influence on the sintering of the BAUTEK R-90 refractory bauxite, with the density varying from 3.07 g/cm³ to 3.36 g/cm³ for the product ground below 0.075 mm.

*Figure 4: Processing variables analysis for the sintering of the BAUTEK R-90*

## CONCLUSIONS AND NEXT STEPS

The results demonstrate that the refractory bauxite produced from Barro Alto ore exhibits a unique characteristic of not containing $TiO_2$ in its composition, unlike the Chinese and Guianese bauxites. It was also observed that for proper sintering, where the physical properties of the sintered product meet market standards, a processing route consisted of calcination, grinding, and pressing of the body is necessary before sintering with best results being attained under 0.150 mm of grinding size and 80 MPa of compaction pressure, exhibiting a promising rout for processing of this class of bauxites.

# ALMATIS MISSION NEUTRAL REPRESENTS OUR SUSTAINABLE COMMITMENT TO THE REFRACTORY RAW MATERIALS INDUSTRY

Charles Compson
Almatis, Inc, Leetsdale, PA, USA

Andreas Buhr, Hans-Leo Groβ, Admir Skula
Almatis GmbH, Ludwigshafen, DE

**ABSTRACT**

There is increasing focus on carbon accounting and product carbon footprint throughout the value chain from mined materials to consumer goods. Pressure comes from legislators, financiers, end-users, customers and filters down through all supply chain partners. If the European steel & refractory market is to succeed in carbon reduction transformation, a key component will be transparency and understanding within that value chain. As a crucial alumina raw material supplier within that value chain, Almatis will provide a breakdown of the key components that impact our product carbon footprint and the role of Scopes 1,2 & 3 in determining a roadmap for the future. We will further outline our sustainability ambition, target commitments, strategic initiatives and areas of concern over the coming decade.

**SUSTAINABILITY INITIATIVE**

In September 2015, As part of the "*2030 Agenda for Sustainable Development*," the United Nations *17 Sustainable Development Goals* and their combined *169 associated targets* were announced. [1,2] This was stated as "a decision of great historic significance" and a "charter for people and plant in the twenty-first century", and a "...call-for-action for global governments, Parliaments, international institutions, local authorities, civil society, business & the private sector, the scientific and academic community - and all people."

*Figure 1: 17 UN Sustainable Development Goals (SDGs)*

At COP 21 in Paris, On December 12, 2015, the *Paris Agreement* on climate change was signed by 196 participants. [3] More than 70% of the world economies have now pledged their commitment to this binding international treaty. The treaty, as written "...aims to strengthen the global response to the threat of climate change, in the context of sustainable development and efforts to eradicate poverty, including by:

- Holding the increase in global average temperature to well below 2°C above pre-industrial levels and pursue efforts to limit the temperature increase to 1.5°C. This level is now commonly referred to as the *Science Based Targets Initiative (SBTi)*
- Increasing the ability to adapt to the adverse impacts of climate change and foster climate resilience and low greenhouse gas emissions in a manner that does not threaten food production
- Making finance flows consistent with a pathway towards low greenhouse gas emissions and climate-resilient development."

Out of this Treaty, many new goals & targets, government regulations and initiatives have been born. At COP25 in 2019, the *Climate Ambition Alliance* was announced. [4] This was another UN initiative, in an effort to "accelerate the necessary transformation to reach the goals of the Paris Agreement and stabilize the global temperature rise to 1.5°C." All members of the alliance committed to the same goal," achieving *carbon neutrality by 2050*.

**ALMATIS MISSION NEUTR*AL***

Almatis' commitment towards sustainability is our Mission Neutr*AL*. The mission is to provide the lowest delivered carbon footprint in the alumina industry to our core markets and is our long-term ambition towards a sustainable raw material industry. We further envision to lead the development & launch of lower carbon footprint products the advance a lower carbon economy.

Throughout Mission Neutr*AL*, we must impress short-term urgency within the context of a long-term outlook. It is essential that we align with all business & industry partners to ensure progressive targets and transparent reporting. Sustainability must not be just a corporate exercise, it is personal. Everyone must do their part to ensure that daily progress leads to lasting success. Our future generations depend on it.

Mission Neutr*AL* has three key areas:
- Neutr*AL* Ambition – Our vision and roadmap towards a carbon neutral business that delivers products with the lowest carbon footprint in the industry
- Neutr*AL* Commitment – Our strategic targets and initiatives to ensure that our business makes clear and determined progress in the Material Topic areas that are critical to our stakeholders
- NeutrAL Transparency – Our assurance that all critical data will be independently certified and our promise to report progress annually to stakeholders.

*Figure 2: Almatis Key Pillars of Mission Neutral Sustainability Strategy*

**SUSTAINABILITY STRATEGY**

Since the end of 2021, Almatis has been steadily progressing towards a clearly articulated NeutrAL Ambition. Together With our carbon accounting partner Ökotec and independent auditor GütCert, Almatis is certifying our corporate carbon footprint (CCF) and product carbon footprint (PCF). With our sustainability strategy partner, DNV Business Assurance, Almatis is building a sustainability strategy and will publish its first sustainability report.

Almatis program has been developed in alignment with global standards such as GRI (Global Reporting Initiative), SASB (Sustainable Accounting Standards Board), and the GHG (Green House Gas) Protocol and establishing Corporate Carbon Footprint (CCF) and Product Carbon Footprint (PCF) reporting. Together with our external partners, over the course of one year, Almatis developed a strategy and roadmap for carbon reduction, established its first corporate and product carbon footprint calculations and successfully passed audit verifications of our carbon accounting methodology and the carbon footprint of our European products.

From the 17 UN Sustainable Development Goals (SDG), seven were selected as being relevant for Almatis: #3 Good health and well-being, #7 Affordable and green energy, #8 Decent work and economic growth, #9 Industry, innovation and infrastructure, #10 Reduced inequalities, #12 Responsible consumption and production, #13 Climate action. After a base line study including the readiness analysis for Almatis, the "materiality" analysis was done. Materiality means here the "material" so relevant topics for the company for establishing the sustainability strategy and definition of targets and action plans. The global standards provide guidance for potential material topics, however, from these big lists of potential topics, it must be narrowed down and focused on about 6 key material topics, which are now being addressed appropriately in the strategy.

The result from internal and external evaluation is the materiality matrix, which enables the selection of those five resp. in our case six material topics for Almatis: Occupational Health & Safety, Employer Attractiveness, Sustainable Supply Chain Management, Energy and GHG Emissions, Environmental Performance, Innovation and R&D.

*Figure 3: Material topics in relation to selected UN sustainable development goals*

The proposed targets for each material area then are aligned with UNGC principles and specific SDGs and sub-SDG targets. Further, these have to be linked directly to a corporate strategy, so that metrics and actions plans are not in conflict. At Almatis, sustainability strategy is a part of our corporate strategy, embedded in all areas of the business. Examples of how this is outlined is given in figure 4.

23

**Respecting our People**

| Material Topic | UNGC Principle | UN SDG's |
|---|---|---|
| Occupational Health & Safety | | |
| • Total recordable injury rate per 200,000hrs<br>• Lost work days per year | **Principle 1** | |
| Employer Attractiveness | | |
| • Turnover rate<br>• Training hours completed | **Principle 6** | |

**Respecting our Planet**

| Material Topic | UNGC Principle | UN SDG's |
|---|---|---|
| Energy & GHG Emissions | | |
| • Implementation of renewable energy<br>• Reduction in Scope 1&2 emissions | **Principle 9** | |
| Environmental Performance | | |
| • Product life cycle assessments complete<br>• | **Principle 8** | |

**Respecting our business**

| Material Topic | UNGC Principle | UN SDG's |
|---|---|---|
| Sustainable Supply Chain | | |
| • Scope 3 emission reductions<br>• Supplier LCA assessments completed | **Principle 4** | |
| Innovation and R&D | | |
| • New products with a sustainable advantage<br>• Alternative & Bio-based fuel implementation | **Principle 9** | |

*Figure 4: Examples of sustainability metrics as part of Almatis corporate strategic directions.*

**CARBON ACCOUNTING**

Once the accounting methodology is established, all data must be compiled and evaluated for reporting specific material & packaging related product carbon footprints. The data collection is quite complex and requires cooperation and establishing data that is either coming from suppliers or else a reliable basis remains a huge challenge for determining an accurate and verifiable footprint calculation. GutCert audited and validated the method first, and then audited and verified the product carbon footprint reports and results. Fig. 5 gives an example of verified PCFs for Almatis sintered aggregate products and cement products. The carbon footprint of Almatis products is lower when compared to public available figures for competitive white aggregates, which is a significant benefit to the general EU refractory industry that has, up to now, been using significantly higher figures.

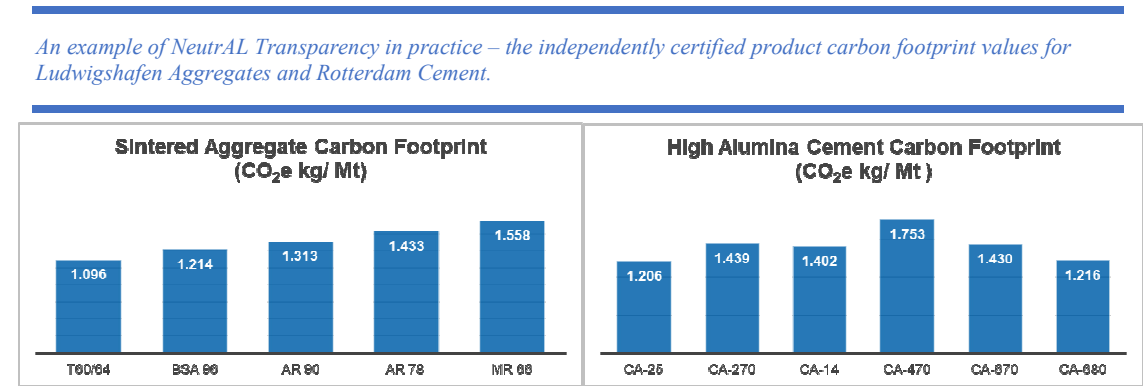
*An example of NeutrAL Transparency in practice – the independently certified product carbon footprint values for Ludwigshafen Aggregates and Rotterdam Cement.*


*Figure 5: EU Product Carbon Footprint (PCF) examples*

The carbon accounting methodology can be extrapolated and shared with other operations around the world and utilized for faster calculation and therefore also audit and verification. This process is underway, with the target to have 95% of products verified by 2024.

**PRODUCT INNOVATION WITH SUSTAINABLE ADVANTAGE**

Future product & process developments must focus on having a sustainable advantage. Almatis is committed to future products having a sustainable advantage in 1 of our 6 material topic areas outlined in figure 3. In recent years, the reduction of thermal losses in the steel making process is continuously gaining momentum, and cyclical used vessels such as the steel ladle are of special interest. The heat which is lost from the hot face during the empty stage in ladle cycling depends on the thermal properties of the ladle lining, which are the heat capacity, related to the density, and the thermal conductivity. For alumina-spinel-based, carbon-free linings, the heat losses are 10-15K lower when compared to magnesia-carbon bricks, which can save specific cost per tonne of steel in the magnitude of the refractories lining costs of the ladle! Almatis is developing a lower density aggregate than tabular alumina which will further reduce such heat losses and also reduces the weight of the refractory lining.

CA-SYNC cement was developed to overcome challenges in the production of pre-cast shapes with an inner core such as well blocks, seating blocks, EAF delta sections, and others. Due to the inherent setting shrinkage taking place when the cement phases are hydrating, the time window for removing the inner core is rather short, e.g. 20 min for regular 70% alumina cement whereas it is more than an hour for CA-SYNC. If the core is removed too late, microcracks are induced which lead to macrocracks during drying and yield losses in production. CA-SYNC helps to improve production efficiency and saving energy.

In China, the use of chromium oxide in purging plugs still is very common, though the synthetic chromium oxide is expensive and the disposal of chromium containing refractories waste can become an issue as it is in many cases already in the rest of the world. Extended investigations including thermal shock and slag resistance testing have proved that E-SY 88 reactive alumina can replace chromium oxide in such formulations without compromising hot properties and slag resistance, and the thermal shock resistance is even improved.

Another example from outside the refractories industry is Almatis TR 150, a crystalline silica free polishing alumina as alternative to natural based Tripoli for industrial polishing of aluminum and brass. Tripoli has been classified carcinogenic due to its crystalline silica content. TR 150 provides a safe alternative with equivalent or better performance than the crystalline silica counterpart and is a safe, sustainable solution for the future.

**CONCLUSION**

Almatis' mission is the be the chosen partner in alumina-based products and solutions. Almatis Mission NeutrAL means a long-term ambition and commitment towards a sustainable future. Our target is to supply alumina products with the lowest delivered carbon footprint in order to help advance our industry and the global community. We have achieved verified product carbon footprints for our European sintered aggregate products and cements, and for most European calcined and reactive aluminas. These are just stepping stones in a path toward understanding our carbon impact, stablishing the baseline of our product carbon footprint and the foundational structure behind our sustainability strategy.

# MANAGING PERFORMANCE OF CALCINED ALUMINAS THROUGH MANUFACTURING PROCESS MODIFICATIONS

Carl Zetterström, Jerome Contat, Paul Soler, Johnson Lee
Alteo, Gardanne, France

**ABSTRACT**

The characteristics of calcined alumina impact greatly on the behaviour of refractory castables and the final refractory properties in application. Calcined aluminas are typically described by a chemical analysis, the specific surface (BET) and the particle size distribution (PSD), and these in turn depend on the manufacturing process.

Over the last century, Gardanne plant has been a major actor in the world of alumina manufacturing using the Bayer process, which consists in dissolving bauxite and precipitating an alumina hydrate. In 2022, the Bayer process in Gardanne was partially closed, and instead alumina hydrates are sourced on the market and used for the manufacturing of Calcined Aluminas.

Following the modifications to the manufacturing process, extensive work was done in order to ensure the quality and stability of the products, independently of variations in the properties of the alumina hydrates. Work was carried out to achieve the same quality of calcined alumina in terms of chemistry, BET and PSD of the alumina powder, while using alumina hydrates having varying characteristics, and furthermore also evaluating the impact from the calcined alumina on the behaviour of refractory castables.

## INTRODUCTION

Alteo, located in Gardanne, France, is a prominent alumina manufacturer with a rich history in the industry. For over a century, the company has been at the forefront of producing high-quality alumina and related products. With its roots dating back to 1894, Alteo has consistently demonstrated its expertise and commitment to excellence.

The company's journey began with the creation of the worlds first industrial Bayer process, and a few years later was integrated with the Pechiney industrial group.

Over time, the company expanded its operations, optimizing its production processes and diversifying its product portfolio. Today, Alteo is recognized as a leading global supplier of specialty aluminas for the refractory market as well as a wide range of industries such as technical ceramics, lithium-ion batteries and abrasives.

The Gardanne plant has consistently invested in research and development to enhance its product offerings and stay at the cutting edge of alumina technology. The company has developed innovative solutions and tailored products to meet the specific needs and requirements of its diverse customer base. With a strong emphasis on sustainability, Alteo has also made significant strides in reducing its environmental impact and promoting responsible practices throughout its operations.

Through its dedication to quality, innovation, and sustainability, Alteo has earned a reputation for reliability and excellence in the alumina industry. The company continues to evolve and adapt to the changing market dynamics, driving forward the development of new applications for alumina and supporting its customers' success worldwide.

In 2022, as a logic step in Alteo's continuous focus on specialty aluminas, the Bayer process was replaced by external sources of alumina hydrates. The purpose of this paper is to give some insight into the vast program of testing and validation that was issued in order to guarantee that our products would maintain the high standards our customers have come to expect, and that defines our brand.

## MANUFACTURING OF ALUMINA

*The Bayer Process*

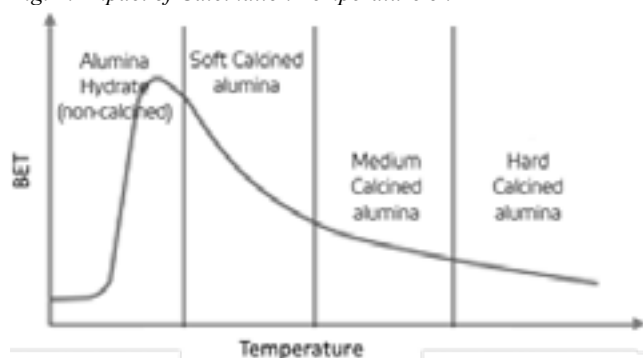
The initial step in manufacturing alumina for the purpose of refractory materials always starts with the Bayer process. Alumina hydrate is extracted from the mineral ore Bauxite in the Bayer Process which involves a dissolution of bauxite in soda and precipitation and drying of hydrates as a white crystalline powder.

One of the significant factors driving the global alumina hydrate market is the ever-increasing demand for aluminium metal. The construction sector also contributes to the demand for alumina hydrate due to its use in fire-retardant materials, ceramics, and glass manufacturing.

*Calcination of alumina hydrate*

The hydrate is calcined in a rotary furnace. In the first step of calcination, de-hydration occurs transforming the hydrate into a highly disorganized structure of pure alumina, during this step the specific surface (BET) increases drastically to numbers above 300 $m^2/g$. A schematic of the influence on BET during calcination is represented in *Fig 1*. While temperature increases during the calcination, and depending on the initial structure of the hydrate, its particle size and the rate of decomposition, the alumina will morph through different types of transition alumina before reaching the most stable state which is the alpha-alumina crystal structure [1]. Starting from the alumina hydrate gibbsite, $Al(OH)_3$, this usually follows two routes: (a) gibbsite-boehmite-$\delta$-$\gamma$-$\theta$-$\alpha$-$Al_2O_3$ or (b) gibbsite-$\chi$-$\kappa$-$\alpha$-$Al_2O_3$ [1] [2]. The former is supposedly more common, but both can happen simultaneously, and some different parameters can be beneficial for one route or the other. While this transformation goes on, the BET gradually decreases down to below 1 $m^2/g$. The temperature required to transform the transition alumina into alpha-alumina takes place above 1200°C, even if route (b) is at a slightly lower temperature than (a). Nevertheless, it's possible to decrease this temperature significantly independently of route, by use of additives, such as nucleation seeds ($\alpha$-$Al_2O_3$, $\alpha$-$Fe_2O_3$) [3] [4] and mineralizers [5] [6]. Furthermore, after it is formed, the alpha-alumina crystal will grow and typically reaches a size of between 2 to 3 µm in highly calcined products. This is important because the crystal size will be a natural limit for the particle size during milling. It can be mentioned here that for transition alumina, the BET is mostly a measure of calcination degree, while for hard calcined products the BET becomes a measure mainly related to particle size.

*Fig. 1: Impact of Calcination Temperature on BET*



In commercial products, aluminas are referred to as "calcined" and "reactive". The distinction between these two words will be found in the degree of calcination. Typically, products that are "hard"

calcined, where the transformation to alpha-alumina is almost complete, specific surface is very low and the crystal size is large are what we call "calcined". Reactive aluminas are made from a combination of slightly higher BET, and particularly a smaller crystal size which allows for smaller particle size. It's the combination of BET and particle size that make the product more reactive.

*Milling stage*

The final stage in manufacturing of alumina for refractories consists in the milling. Various processes exist including continuous and batch processes, ball milling, air jet and wet grinding. As mentioned, the alpha-alumina crystal size plays an important role in the milling. In fact, the milling process consists in breaking apart agglomerations of individual crystals, but its virtually impossible to break the actual crystal. In highly calcined products, the crystal size is typically in the range of 2 to 3 μm, and most ground high calcined products will have a particle size between 3 and 6 μm.

**MATERIALS AND METHODS**

In the framework of finding a new raw material source, multiple different sources of alumina hydrate, were obtained and evaluated. Part of this work is presented in this paper. The hydrates are evaluated as such for their chemical properties, granulometry and morphology. The calcined products are characterized according to their BET, crystal size (sd50R), particle size distribution (PSD) and chemical composition. The applicative performance is evaluated by the flow properties in concrete (standard recipe in Tab. 4) and mechanical properties after firing. All externally sourced hydrates (EH-1 to EH-10) are compared to the historical hydrate from the internal Bayer process of Gardanne (AH). The chosen refractory formula is a relatively pure recipe with minimal impurities added from the aggregates. This way the maximum impact from chemical impurities, particularly soda, from the calcined alumina is expected to be observed.

**RESULTS AND DISCUSSION**

**Characterisation of Hydrates**

Tab. 1: Chemical Analysis of Alumina Hydrates

| Hydrate | $H_2O$ | ld50 | $Na_2O$ tot | CaO | $SiO_2$ | $Fe_2O_3$ |
|---|---|---|---|---|---|---|
| | [%] | [μm] | [ppm] | [ppm] | [ppm] | [ppm] |
| AH | 3,1 | 111 | 1000 | 105 | 35 | 95 |
| EH-1 | 4 | 130 | 2800 | 40 | 90 | 75 |
| EH-2 | 1,2 | 140 | 2300 | 130 | 60 | 105 |
| EH-3 | 5 | 115 | 2100 | 20 | 60 | 80 |
| EH-4 | 4,2 | 106 | 2300 | 130 | 50 | 100 |
| EH-5 | 5,5 | 125 | 2350 | 240 | 35 | 40 |
| EH-6 | 3,9 | 116 | 2300 | 115 | 75 | 185 |
| EH-7 | 4,9 | 77 | 2100 | 105 | 165 | 125 |
| EH-8 | 9,3 | 129 | 500 | 60 | 25 | 55 |
| EH-9 | 1,3 | 80 | 1450 | 295 | 100 | 55 |
| EH-10 | 5,8 | 122 | 2950 | 225 | 60 | 45 |

The main impurity of alumina hydrates is soda from the Bayer process, and the measured content in most externally sourced hydrates are higher than the historical Gardanne hydrate. This has an impact on the calcination which is discussed later.

Fig. 2: Color variation of hydrates and Fe2O3 content in [ppm]

| EH-8 (55) | AH (95) | EH-6 (185) |
Second important impurity to consider in Tab. 1 is the iron content. Several applications of aluminas are sensitive to iron and it also has an impact on the color/whiteness of the hydrate, turning it slightly reddish. An example is given in *Fig 2*.

A third important factor is related to the PSD. Increased amounts of small particles, (small ld10), will impact the flow of the particles in the furnace and it is believed to improve the alphanisation of the alumina by promoting the route (b) of alphanisation.

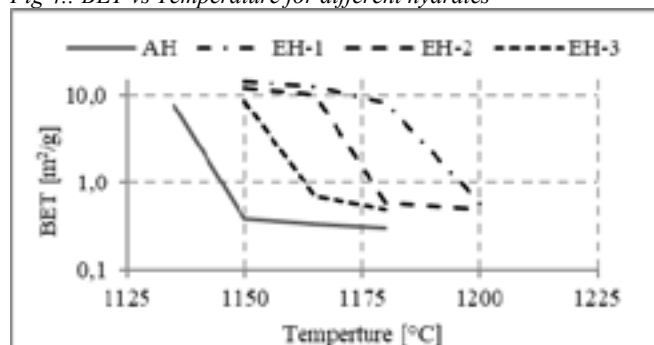
Finally, the morphology of the hydrates was also investigated, and they can be classified according to two typical cases: large crystals in a blocky shape or agglomerates of small crystals in a mosaic type of geometry. Only two hydrates are of the blocky type: AH and EH-4, all other hydrates are mosaic type. This property was studied in some depth. It will be shown later that the impact from the morphology of hydrates on properties of "high" calcined aluminas is low to insignificant. It can have a small influence on lower calcined products, ie. reactive aluminas. To give an example, SEM pictures of these differences are shown in *Fig 3*. However, for the case of reactive aluminas in Gardanne, all hydrates independently of origin, are dissolved and reprecipitated in the Bayer installations. The resulting hydrate is identical to the historical product. This is done primarily for the sake of chemical properties but simultaneously eliminates any difference in morphology, whether it has an influence or not.

Fig. 3: Hydrate Morphology, SEM x1000, bottom scale = 10μm

| AH | EH-3 |
**Characterisation of Calcined Alumina**

The target set in order to compare the different hydrates is to reach the same BET compared to the historical hydrate AH.

Fig 4.: BET vs Temperature for different hydrates



It is observed in *Fig 4*, that during the calcination of different hydrates, the alphanisation takes place at higher temperature when the soda content is higher. The variation is roughly up to 50°C difference. The reason for this is thought to be that the soda ion is relatively large and takes up a lot of space in the alumina crystal structure, thereby physically obstructing movement of atoms into other configurations, notably the alpha structure. Furthermore, this variation in transformation temperature is mentioned in literature [7] and can be observed via thermogravimetric analysis thanks to an exothermic peak related to the alpha transformation. The calcined alumina (C) properties are shown in Tab. 2 here below

Tab 2: Hard Calcined Alumina properties from respective hydrate

| Calcined Hydrate | d10 | d50 | d90 | BET | sd50R | Na$_2$O | CaO | SiO$_2$ | Fe$_2$O$_3$ |
|---|---|---|---|---|---|---|---|---|---|
| | [µm] | [µm] | [µm] | [m$^2$/g] | [µm] | [ppm] | [ppm] | [ppm] | [ppm] |
| CAH | 14 | 81 | 142 | 0,48 | 2.60 | 1950 | 165 | 60 | 150 |
| CEH-1 | 16 | 102 | 185 | 0,46 | 3.30 | 4150 | 105 | 175 | 130 |
| CEH-2 | 17 | 100 | 181 | 0.49 | 2.80 | 3450 | 270 | 185 | 160 |
| CEH-3 | 20 | 85 | 148 | 0,49 | 2.65 | 3000 | 70 | 125 | 115 |

There is an additional impact from the soda, and/or from the higher required calcination temperature, which is an increased crystal size (sd50R). The variation is not insignificant but is still within a normal range in comparison to historical production data over longer periods. As a property of the calcined alumina, a larger alpha crystal size is probably a positive attribute, however, it has a negative impact on the milling time, as can be seen in Tab. 3.

*Morphology of medium calcined alumina*
*Fig 5: SEM pictures of medium calcined hydrates at x1000 and x20.000, bottom scales = 10µm and 1µm respectively*

AH — EH-1

EH-2 — EH-3
After calcination to a BET of 12m$^2$/g, one can still distinguish the morphology of the initial hydrate. It is most probably not of importance and is definitely not visible in milled products.

*Morphology of hard calcined alumina*
*Fig 6.: SEM pictures of hard calcined alumina at x500 and x5.000, bottom scale = 50µm and 5µm respectively*

AH — EH-1

EH-2 — EH-3
After "hard" calcination down to a BET of below 1m$^2$/g, the initial morphology of the hydrate is unrecognizable. Only the chemical composition of the hydrate is of real importance.

**Characterisation in Application**
The calcined alumina obtained from each respective hydrate were milled to 5µm (Tab. 3) and used in the standard refractory self-flow formula (Tab. 1) for evaluation of application performance.

Tab 3: Hard Calcined Milled Alumina properties

| Calcined and Milled Hydrate | d10 | d50 | d90 | Milling time |
|---|---|---|---|---|
| | [µm] | [µm] | [µm] | [min] |
| CMAH | 1,9 | 5 | 12,9 | 53 |
| CMEH-1 | 2,2 | 5 | 11,5 | 150 |
| CMEH-2 | 2 | 5 | 14,6 | 75 |
| CMEH-3 | 2,12 | 5,1 | 13,2 | 55 |

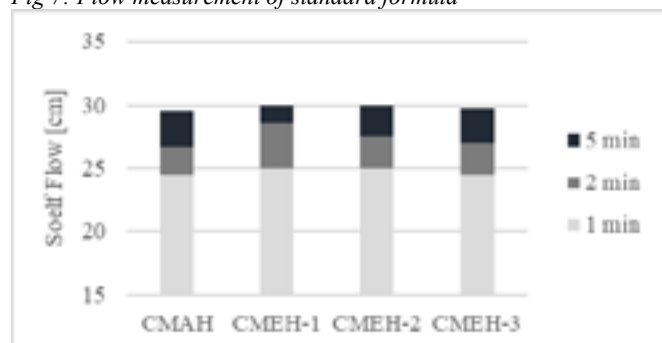
28

Tab. 4: Standard Refractory Formula for Application Tests

| Raw Material | Specification | [%] |
|---|---|---|
| Tab Alumina | 0-6 mm | 80 |
| CAC | 70% Alumina | 5 |
| Calcined Alumina | Various tested | 6 |
| Reactive Alumina | PFR20 | 4 |
| Reactive Alumina | PFR | 5 |
| Dispersant | PCE | 0,2 |
| Water | | 4,5 |

*Fig 7* shows the flow properies of the concrete using the different hard calcined and milled aluminas.

*Fig 7: Flow measurement of standard formula*



There is no visible impact on flow between any of the aluminas. The one property that is generally associated with flow behaviour is the particle size distribution. In this case all aluminas have been ground down to 5μm and the flow is near identical. In other words, we don't see any influence from for example the soda content on flow properties of castable.

*Fig 8: Porosity and Density of standard formula*

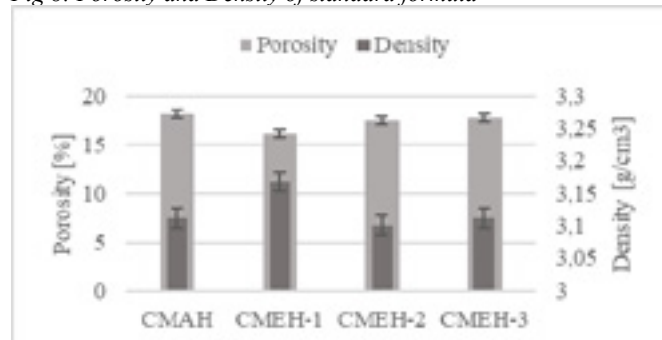


*Fig 9: CCS and MOR of standard formula after firing at 1600°C*

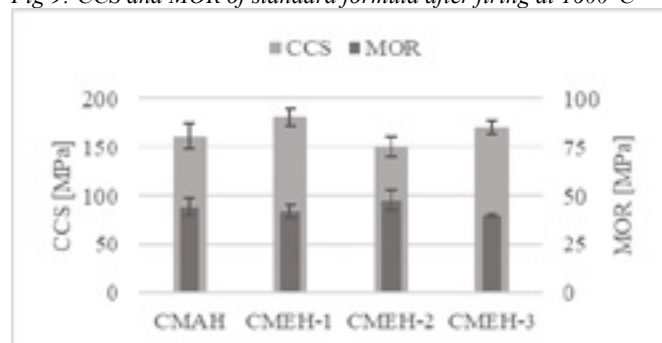

While we see some variations on porosity and density of the obtained concrete slabs after casting. This variation is within what we normally see in concretes. The one alumina that is somewhat different is CMEH-1 where a lower porosity is obtained. We don't believe this is significant.

Lastly, cold crushing strength (CCS) and modulus of rupture (MOR) was measured. All samples are very good and comparable to each other. No significant difference can be attributed to the calcined alumina. A slightly higher value for CMEH-1 is most probably related to the higher density that was obtained with this alumina in this specific series of test.

**CONCLUSION**

Various tests were carried out calcining and milling alumina starting from several different sources of alumina hydrates. It was observed that variations exist in both morphology and chemistry of the hydrates.

The morphology of hydrates could be described as falling into two different types, large crystals in blocky shape or small agglomerated crystals. This morphology remains observable after calcination to $12 m^2/g$ but becomes indistinguishable after "hard" calcination to $1 m^2/g$.

The behaviour of the hydrate during calcination varies depending on the chemistry, specifically the soda content. With higher soda content, the calcination temperature needs to be increased by up to 50°C depending on the % in order to obtain an equivalent specific surface of the calcined alumina. Following the variations in calcination temperature, and/or due to the chemical composition, a varying alpha alumina crystal size is observed which impacts the milling time in order to obtain iso D50 for aluminas calcined from different hydrates.

Results were shown from three different hydrates that had been calcined and milled to close to identical powder properties. The in-application performance was equivalent for all products and in comparison to historical calcined alumina from hydrates of the Gardanne Bayer process.

Managing the performance of the final calcined alumina product finally relies on the capacity and expertise to adapt the calcination and milling processes according to the varying chemical properties of the hydrates.

Any hydrate can be dissolved and reprecipitated, which allows for making of a hydrate identical to historical Gardanne products in terms of both chemistry and morphology, this is the case for all current reactive aluminas in the portfolio for refractory products.

# INFLUENCE OF MINERAL COMPOSITION ON THE PROCESSING OF IRON−RICH BAUXITE RAW MATERIALS BY USING HYDROCHLORIC ACID LEACHING

Alena Stein, Almuth Sax and Peter Quirmbach

Institute for Integrated Natural Sciences, Technical Chemistry and Corrosion Sciences, University of Koblenz, Koblenz, Germany

## ABSTRACT

Bauxite is an essential raw material for the refractory industry, but it can only be used with sufficient raw material quality. For the classification of bauxite as refractory grade, first of all the chemical composition is crucial and especially the $Fe_2O_3$ content should be < 2 wt%. The global availability of suitable qualities will, however, become increasingly problematic in the future, which is made clear by the European Commission's classification of bauxite as a critical raw material in 2020. Therefore, it is already of great importance to develop strategies that make different bauxite raw materials, for example those rich in iron, accessible for the refractory industry. In this study, it is demonstrated that a beneficiation of iron-rich bauxite raw materials can be carried out by an acid leaching process. For this purpose, raw material grades of different chemical and mineralogical composition are leached in hydrochloric acid and their $Fe_2O_3$ and $Al_2O_3$ contents are compared before and after leaching. In addition, the findings of powder X-ray diffraction measurements (PXRD) to determine mineralogical composition before and after leaching are used to draw conclusions about the leachability of various iron and aluminum minerals in bauxite. These findings, in conjunction with methodologies for determining optimal leaching conditions, complete the understanding of the effectiveness of bauxite processing using hydrochloric acid leaching.

## INTRODUCTION

Bauxite is a residual or sedimentary rock in which the content of aluminum, iron or titanium oxides and/or hydroxides is higher than 50 % by weight and the aluminum minerals dominate over the iron and titanium minerals [1]. Because of its natural formation, bauxite is not a clearly defined mineral of a particular composition. Different bauxites exhibit large differences in both chemical and mineralogical composition. Generally, a chemical composition of 50–80 wt-% $Al_2O_3$, 0–10 wt-% $SiO_2$, and 0–30 wt-% $Fe_2O_3$ is assumed [2], but this is not binding. Especially the iron oxide content varies greatly and influences various properties of the material. In terms of mineralogical composition, the aluminum minerals commonly identified in bauxite are gibbsite, boehmite, and diaspore [2–5]. These form the major phase. The iron-bearing minerals hematite, goethite, maghemite, magnetite, ilmenite, or chamosite are often present as minor phases. Other minerals are for example kaolinite, as well as a variety of other iron- and aluminum-substituted silicates, quartz, anatase, and rutile [4, 6, 7].

Depending on its composition, bauxite can be used for different applications [3]. In the EU, for example, applications include aluminum production at about 90 %, chemical production at about 2 %, use as an abrasive at about 2 %, use in the cement industry at about 3 %, and use as a refractory at about 3 % [8].

The use of iron-rich bauxites is particularly problematic for the refractory industry. Since too high iron contents in the raw material have a strong negative influence on the refractoriness as well as the CO resistance, only raw materials with low $Fe_2O_3$ (< 2 wt-%) can be used. At the same time, the $Al_2O_3$ content in the raw material should be as high as possible (about 80–85 wt-%) [9–13]. For this reason, it is useful to process previously unusable raw materials by reducing the $Fe_2O_3$ content [12, 13].

In the past, there have been several studies on the processing of bauxites and other raw materials by using hydrometallurgical processes [12, 13]. In particular, acid leaching with hydrochloric acid has been shown to be a method with great potential [14–16]. In this context, studies on the kinetics of the dissolution process of different (pure) iron minerals or different iron minerals in bauxite have also

been carried out repeatedly [14–22]. However, the findings obtained vary widely depending on the study and usually relate only to the single mineral studied or to specific leaching conditions such as a particular acid concentration or leaching temperature. In order to specifically investigate the leachability of minerals present in bauxites, different bauxite minerals were leached in this study and their chemical and mineralogical compositions were compared before and after leaching. The focus was on the iron and aluminum minerals present as well as the $Fe_2O_3$ and $Al_2O_3$ contents before and after leaching.

## MATERIALS AND METHODS

### Bauxite raw material

In this study, three different bauxites, Na1, IMF2 and IMC2 were investigated. All three bauxites have different optical appearances (especially color) and differed in their origin. Na1 and IMF2 are European bauxites, while IMC2 is a Chinese one.

### Bauxite leaching

The leaching of the bauxites was carried out on a laboratory scale in a three-neck round bottom flask with reflux condenser. The temperature was set with a tempered oil bath and controlled with an additional thermometer in the flask [23]. First, V = 50 mL or V = 400 mL of hydrochloric acid (HCl) of the desired concentration c(HCl) were added to the flask and heated to the leaching temperature T with stirring. Once the temperature T was reached, m = 10–20 g of bauxite corresponding to the desired solid-acid ratio s/a of grain size GF was added and the leaching time t was started. After completion of the leaching time t, the solid was separated from the acid by a sieve and a centrifuge and was washed with demineralized water to pH neutrality. Drying of the solid took place at T = 40 °C in a drying oven.

The factor settings used for leaching for each bauxite are shown in Tab. 1. Selection of the factor settings was based on computerized statistical design of experiments (DOE) after individual model development and fitting for each bauxite. The detailed procedure is explained in [23] and [24]. The settings used are the conditions at which the lowest $Fe_2O_3$ content was obtained for the respective bauxite by leaching.

Tab. 1: Factor settings of leaching experiments.

| Bauxite | c(HCl) in mol/L | s/a in g/L | T in °C | t in min | Grain fraction GF |
|---------|-----------------|------------|---------|----------|-------------------|
| Na1 | 11,69 | 100 | 90 | 300 | 2.36–3.35 mm |
| IMF2 | 12,00 | 100 | 90 | 180 | < 1.25 mm |
| IMC2 | 6,50 | 100 | 60 | 300 | < 1.25 mm |

### Chemical characterization

For the chemical characterization of the bauxites used, X-ray fluorescence analyses were performed before and after leaching. The X-ray fluorescence (XRF) analyses were performed quantitatively on lithium tetraborate melt tablets in accordance with DIN EN ISO 12677. A Bruker wavelength dispersive spectrometer was used for this purpose. For sample preparation, all samples were ground with the Pulverisette 0 from the company Fritsch (mortar and ball made of hardened stainless steel).

**Mineralogical characterization**

Mineralogical characterization of the samples before and after acid leaching was performed by X-ray powder diffraction (PXRD). PXRD measurements were performed on a Bruker D8 ADVANCE with Cu-Kα radiation and subsequently analyzed using DIFFRAC.EVA V6.0 software, the Crystallography Open Database [25], and the ICDD PDF-4+ 2022 database. Semi-quantitative analysis was performed by Rietveld refinement using TOPAS V6 software. For preparation, the samples were also ground with the Pulverisette 0.

**RESULTS**

**Chemical characterization**

The results of the chemical analyses of the three bauxite raw materials used as well as the leached samples can be seen in Tab. 2, Tab. 3 and Tab. 4. All percentages refer to the ignited substances. The $Al_2O_3$ contents of all samples have increased due to acid leaching, while the $Fe_2O_3$ contents have decreased significantly. In the case of bauxite Na1, it is also noticeable that both the $SiO_2$ and $TiO_2$ contents are significantly higher after leaching (?). In the case of IMC2, the $SiO_2$ content has also risen strongly as a result of the leaching.

Tab. 2: Contents of the main components present in Na1 in wt.-% (based on the ignited substance).

| component | $Al_2O_3$ | $SiO_2$ | $Fe_2O_3$ | $TiO_2$ | LOI (1,025 °C) |
|---|---|---|---|---|---|
| Na1 [24] | 61.17 | 3.01 | 31.27 | 3.83 | 24.56 |
| Na1-HCl | 81.87 | 6.39 | 1.41 | 9.52 | 28.30 |

Tab. 3: Contents of the main components present in IMF2 in wt.-% (based on the ignited substance).

| component | $Al_2O_3$ | $SiO_2$ | $Fe_2O_3$ | $TiO_2$ | LOI (1,025 °C) |
|---|---|---|---|---|---|
| IMF2 [24] | 64.30 | 5.02 | 23.99 | 2.96 | 13.45 |
| IMF2-HCl | 87.23 | 5.97 | 2.66 | 3.50 | 14.21 |

Tab. 4: Contents of the main components present in IMC2 in wt.-% (based on the ignited substance).

| component | $Al_2O_3$ | $SiO_2$ | $Fe_2O_3$ | $TiO_2$ | LOI (1,025 °C) |
|---|---|---|---|---|---|
| IMC2 [24] | 61.90 | 5.54 | 25.52 | 3.30 | 15.71 |
| IMC2-HCl | 82.05 | 9.17 | 2.52 | 4.57 | 13.60 |

**Mineralogical characterization**

Fig. 1, Fig. 2 and Fig. 3 show the measured X-ray diffractograms of the bauxites before and after leaching. The characteristic peaks of the associated phases are marked respectively.

The X-ray diffraction pattern of Na1 shows that goethite and hematite are present as iron phases prior to leaching. The main Al phase is gibbsite ($\gamma$-Al(OH)$_3$). This high proportion of gibbsite causes the comparatively high loss on ignition (see Tab. 2). After leaching, especially the peaks characteristic for hematite ($\alpha$-Fe$_2$O$_3$) are no longer visible and also the peaks assigned to goethite ($\gamma$-FeO(OH)) have lost considerably in intensity. This becomes especially clear in the enlarged section in Fig. 1.

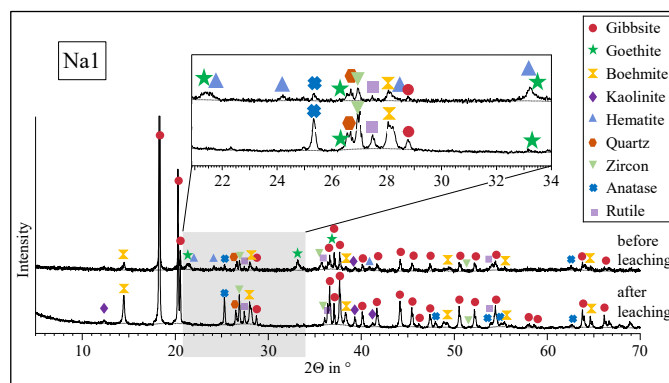

*Fig. 1: PXRD diffractogram of Na1 before and after leaching. According to [24].*

From the X-ray diffractogram of IMF2 in Fig. 2, it is clear that this bauxite contains diaspore ($\alpha$-AlO(OH)) as the main mineral. Furthermore, boehmite ($\gamma$-AlO(OH)) is clearly identified as an aluminum mineral present. The iron minerals are hematite, goethite and ilmenite. After leaching, the intensity of the peaks characteristic of hematite, goethite and ilmenite (FeTiO$_3$) is much lower, so that they can hardly be identified. Boehmite and anatase (TiO$_2$) associated peaks show a significantly higher intensity at the same time. It is also noticeable that calcite (CaCO$_3$) present in the raw material seems to be completely removed after leaching.

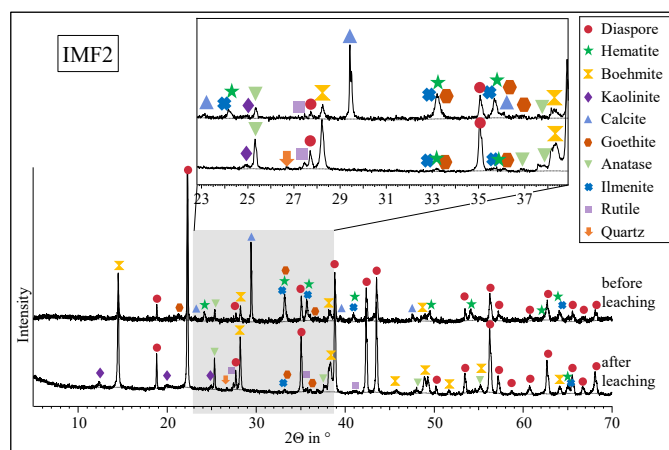

*Fig. 2: PXRD diffractogram of IMF2 before and after leaching. According to [24].*

The X-ray diffraction pattern in Fig. 3 shows a very complex mineral composition of the bauxite IMC2. The main Al mineral is diaspore. As iron minerals goethite, hematite and magnetite (Fe$_3$O$_4$) can be identified in small amounts. Furthermore, iron occurs as a substituent in small amounts in the numerous different silicates present, such as epidote ((Ca$_2$Al$_{2,16}$Fe$_{0,84}$)(SiO$_4$)$_3$(OH)), yoderite ((Al$_{2,84}$Fe$_{0,16}$Mg)O$_2$(SiO$_4$)$_2$), clinozoisite (Ca$_2$Al$_{0,79}$Fe$_{0,21}$Al$_2$[O$_2$(SiO$_4$)(Si$_2$O$_7$)]), chamosite ((Mg$_{5,036}$Fe$_{4,964}$)Al$_{2,724}$(Si$_{5,70}$Al$_{2,30}$O$_{20}$)(OH)$_{16}$) and lizardite (Mg$_{2,79}$Fe$_{0,15}$Al$_{0,06}$)(Si$_{1,84}$Al$_{0,16}$)O$_5$(OH)$_4$). After leaching, only minor changes can be seen in the X-ray diffractogram. The intensity of the peak characteristic of the pure iron minerals goethite and magnetite only decreased. Hematite can no longer be identified after leaching. At the same time, the intensity of the peaks characteristic of diaspore has increased significantly.

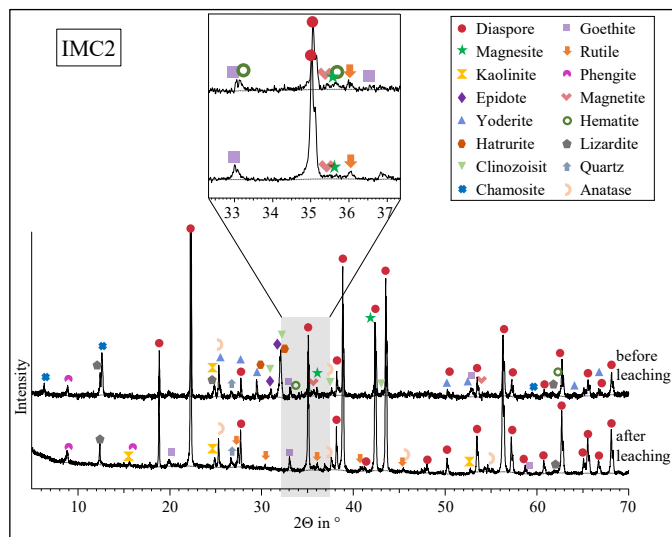
31


*Fig. 3: PXRD diffractogram of IMC2 before and after leaching. According to [24].*

## DISCUSSION

The results of the chemical and mineralogical analyses of the three bauxites investigated show overall that hardly any aluminum minerals are dissolved during the leaching process. This is evident from the higher intensities of the corresponding peaks in the X-ray diffractograms and from the increased $Al_2O_3$ contents after leaching in all three bauxites. Likewise, the results show that hematite in particular is dissolved during the leaching process. Hematite was identified in all of the bauxites examined prior to leaching, while it was not detectable, or only in very small amounts, after leaching. The goethite contents also appear to have decreased in all three bauxites. However, larger proportions are still present here after leaching compared to hematite.

It is remarkable that after leaching the lowest $Fe_2O_3$ content was obtained at Na1 although the $Fe_2O_3$ content was highest there in the raw material. The results of the X-ray powder diffraction indicate in this context that this is due to the apparently good solubility of hematite in hydrochloric acid. In the case of the bauxites IMF2 and IMC2, in addition to hematite and goethite, ilmenite and magnetite could be identified, respectively, which were also partially dissolved by the hydrochloric acid but can still be detected after leaching. On the other hand, especially IMC2 contains many Fe-substituted silicates, whereby iron is incorporated firmly into foreign crystal lattices. This iron can hardly be reached despite the optimal leaching conditions and therefore remains in the bauxite even after leaching. As a result, the $Fe_2O_3$ content is comparatively high even after leaching, although hardly any characteristic peaks of the iron minerals can be seen in the X-ray diffraction pattern.

The strongly increased $SiO_2$ and $TiO_2$ contents in Na1 after leaching additionally indicate that significant portions of gibbsite were dissolved by the acid leaching. This could additionally indicate that gibbsite bauxites are overall more attacked than diasporic bauxites during the leaching process. As a result, iron components trapped in the bauxite or present as a substituent would also be better removed, resulting in a lower $Fe_2O_3$ content after leaching.

## CONCLUSIONS

Chemical and mineralogical analyses of different bauxites before and after acid leaching were used to investigate the influence of the bauxite composition on the leaching result.

It was observed that hematite in particular can be well dissolved from the bauxite by the acid. Iron constituents that are incorporated as substituents in the crystal lattice of other minerals, in contrast, can hardly be dissolved by the acid. The results have further shown that gibbsite bauxites can be leached better than diasporic bauxites due to

the lower resistance of gibbsite to hydrochloric acid. This means that lower $Fe_2O_3$ contents can be obtained by leaching at optimum parameters. At the same time, however, the $SiO_2$ and $TiO_2$ content in the raw material increases due to the dissolution process of gibbsite.

# FROM LAB TO PLANT – FROM MINE TO REFRACTORY BRICKS: MAKING USE OF A NEW DOLOMITE RAW MATERIAL SOURCE IN EUROPE

C. Ebner, M.-A. Müller, M. Marout, J.-F. Stenger
RHI Magnesita GmbH, Technology Center Leoben, Leoben, Austria

T. Müller
Veitsch-Radex GmbH&Co OG, Dolomite Resource Center Hochfilzen, Hochfilzen, Austria

## ABSTRACT

A previously not commercially used dolomite mine in Hochfilzen, Austria has recently been developed to produce high-quality dead burnt dolomite for basic refractory bricks and mixes. The extremely high purity of dolomite from this mining site normally demands a 2-step process and profound raw material research has been undertaken to provide a simplified process. Main target was to produce high-purity high-density dead burnt dolomite in a single-step rotary kiln process. In extensive laboratory and industrial trials, the kiln parameters and sintering additives were optimised and the suitability for brick and mixes production was confirmed and yielded products which at a minimum display similar physical properties and superior chemical composition when compared to the current standard raw material from shaft kiln processes. This paper summarizes the journey of raw material development and gives some insights about the implementation in refractory production. In addition, some performance related details of the resulting refractory products will be provided.

## INTRODUCTION

Doloma-based refractory bricks for high-quality stainless-steel production have been used with great success for many decades now [1,2]. The main base raw material for such products, the mineral dolomite ($CaMg(CO_3)_2$) which is converted to doloma (or sintered dolomite/doloma sinter/dead burned dolomite = $CaO+MgO$) during raw material production has mainly been formed from calcite deposits by diagenetic processes in the upper earth's strati [3,4]. It is abundantly available in large quantities, refractory application, however, has special requirements strongly narrowing down the useful part for high-temperature applications. The scarcity of appropriate carbonatic rock deposits and the developments in production technology of doloma-based raw materials as well as recent spikes in energy prices have influenced the search for new raw material sources in terms of ecological and economical aspects. Deposits which formerly had not been utilizable are now gaining importance and their exploitation has been made possible only by new developments in the field of raw mineral mining and refractory aggregate production. In this proceeding the economic utilization of a formerly unused dolomite mine in central Europe is summarised covering all steps from raw material development and production to refractory goods manufacturing and field application.

## RAW MATERIAL DEVELOPMENT

### From lab to plant

Dolomite raw material from a mine situated in the west of Austria was subjected to extensive investigations in terms of sinterability, densification and the potential use of appropriate additives supporting an economically viable firing process. The mine formerly had not been commercially exploited for refractory raw material production as the extremely high purity of its carbonate rocks prevented sufficiently high densification without using excessive amounts of energy. By explorative drillings on site the high quality of the dolomite stone was re-confirmed along with a predicted lifetime for the mine exceeding 50 years.

First attempts to make use of this mine dating back to the 80ies of last century led to the conclusion that an expensive 2-step process of dolomite calcining in a low-temperature shaft kiln followed by briquetting and re-firing in a high temperature shaft kiln would have been needed to provide dense and well sintered dead burned doloma (DBD).

30 years later, however, the approach was revived, and a multinational team of research and production experts started to design experiments investigating into a cost-efficient one-step approach by making use of new insights gained from other raw material research areas. Target of these lab trials was to provide sintered dolomite with a density of at least 3.15 to 3.20 g/cm³ and an overall flux level between 1.7 and 2.2% in the final raw material which is an excellent starting point for high-quality refractory products. Direct comparison with the former standard doloma raw material coming from a shaft kiln process was done to benchmark the resulting refractory material [5].

The tests clearly showed potential of designing a single-step process in a modern rotary kiln by using additives which can promote sintering of dolomite-based minerals [6,7]. These successful trials subsequently paved the way for first scale up tests in already existing rotary kilns to confirm the findings. Raw stone from the mine was sized to a grain size dimensionally corresponding to the needs of final dead burned dolomite. By doing so, the efforts for crushing grains down to the size needed for refractory formulations can be minimised. Results from the laboratory trials could be validated and the resulting doloma raw material showed higher density than the former raw material from shaft kilns while the impurity level could be kept below other commercially used raw materials (table 1).

*Table 1: Density and impurity levels of doloma raw materials from old shaft kiln process and new rotary kiln process. Taken from [5].*

|  |  | New source | Old source |
|---|---|---|---|
| $Al_2O_3$ | % | 0.4 | 0.4 |
| $SiO_2$ | % | 0.2 | 0.8 |
| $Fe_2O_3$ | % | 0.9 | 0.7 |
| Bulk density | g/cm³ | 3.20-3.25 | 3.18 |

Notably, the $SiO_2$ content of the resulting sinter dolomite was exceptionally low and, considering the low alumina level, a very low share of low melting phases was expected for the final product. Iron oxide was mainly found inside the periclase crystals and only small amounts of well-dispersed interstitial phases were found in mineralogical investigations. Periclase crystals had an average size of 10-15 μm which is in the range of other doloma raw materials [Fig. 1].

*Fig. 1: Microstructure of sinter dolomite showing well distributed interstitial phases (red square) and small amounts of iron-containing phases (red arrow). Reprinted from [5] with permission.*

Due to the switch from shaft kiln to the rotary kiln process another benefit could be realised: The dense outer layer of doloma grains beholds a clear advantage for hydration resistance, one of the major drawbacks of lime-containing refractory materials [Fig. 2].

*Fig. 2: Polished section of a doloma grain from the new rotary kiln process showing a dense outer layer and low porosity on the inside. Black spots represent pores. Reprinted with permission [5].*

The higher iron content as compared to the former shaft kiln material had another effect on the final material by giving it a much darker colour as depicted in figure 3 where macrographs of both materials are shown next to each other.

*Fig. 3: Doloma grains from the new rotary kiln process [left] and the former shaft kiln process [right] showing darker colour due to higher iron oxide levels. Reprinted from [5] with permission.*

Comparative hydration tests which were done on both, the new and the former doloma raw material, showed significant improvement of hydration resistance for the rotary kiln material due to the higher density and the lower surface porosity providing a protective layer against water attack (table 2 and [8]).

*Table 2: Hydration susceptibility of rotary and shaft kiln doloma tested under autoclave conditions of 120 °C with 100% RH and a pressure of 1.6 bar. Taken from [5].*

| | | Shaft kiln doloma crushed and sieved 1-5 mm | Rotary kiln doloma | |
|---|---|---|---|---|
| | | | uncrushed and sieved 1-5 mm | crushed and sieved 1-5 mm |
| Weight gain | % | 2.5 | 0.9 | 1.2 |
| Hydration susceptibility | % | 16.7 | 2.1 | 5.1 |

Based on the very successful and promising outcome of the lab and plant trial sets, a significant investment into a new raw material centre including mining, automatic transportation from the mine to the sinter plant and a new state-of-the-art rotary kiln was approved. The construction works for the rotary kiln were completed in 2021 and raw material production was started right away. Raw material transportation from sinter plant to brick production plants was switched from predominant truck delivery to train transfer resulting in improved energy and $CO_2$ efficiency.

## IMPLEMENTATION OF NEW DOLOMA RAW MATERIAL IN BRICK PRODUCTION

### From mine to refractory bricks-Testing of the new raw material in production environment

Preceded by successful large scale raw material production trials and thorough lab testing of the resulting doloma raw material, brick production trials were initiated to learn more about the material's behaviour in a brick production environment. The higher iron content of the new rotary kiln material was identified as a potential risk of higher shrinkage during the firing step. This was supported by former trials done with another doloma-based raw material with a similar $Fe_2O_3$ content in which severe deformation and tilting of the brick columns on the tunnel kiln car were observed [Fig. 4].

*Fig. 4: Severely deformed bricks on kiln car due to high iron levels in raw material. Reprinted from [5] with permission.*

Precautions to prevent kiln blockage by falling bricks were taken by a pyramid-like setting of the bricks produced with the new doloma raw material [Fig. 5].

*Fig. 5: Pyramid-like setting pattern to prevent bricks from falling and blockage of tunnel kiln. Reprinted from [5] with permission.*

However, the bricks did not show excessive shrinkage or deformation after firing and the switch from one material to the other could be done in a rather uncomplicated and straight-forward manner. Before full implementation, extended production testing for fired as well as unfired (tempered) refractory bricks was done.

### Property evaluation of fired refractory bricks

Thorough investigation of mineralogical features and physical hot properties showed at least similar, in many cases even superior properties for density, porosity and cold crushing strength when the new rotary kiln material-based bricks were compared to the ones produced with the former shaft kiln doloma raw material. All relevant data are shown in tables 3 and 4.

*Table 3: Typical chemical composition of fired doloma bricks produced with former shaft kiln sinter doloma and with newly developed rotary kiln material. Taken from [5].*

| Product type (shaped) | Fired doloma | Fired doloma | Fired magdol | Fired magdol |
|---|---|---|---|---|
| Type of raw material | Rotary kiln doloma | Shaft kiln doloma | Rotary kiln doloma | Shaft kiln doloma |
| Chemical analyses | Wt.% | Wt.% | Wt.% | Wt.% |
| MgO | 40.1 | 40.2 | 56.5 | 57.7 |
| $Al_2O_3$ | 0.37 | 0.56 | 0.28 | 0.41 |
| $SiO_2$ | 0.22 | 0.91 | 0.32 | 0.79 |
| CaO | 58.3 | 57.7 | 42.0 | 40.4 |
| MnO | 0.11 | 0.09 | 0.10 | 0.09 |
| $Fe_2O_3$ | 0.86 | 0.54 | 0.75 | 0.57 |

*Table 4: Typical physical properties of fired doloma bricks produced with former shaft kiln sinter doloma and with newly developed rotary kiln material. Taken from [5].*

| Physical test results | | | | | |
|---|---|---|---|---|---|
| Test method | Unit | | | | |
| Bulk density | g/cm³ | 3.01 | 3.00 | 3.02 | 3.00 |
| Apparent porosity | Vol% | 11.5 | 12.0 | 11.7 | 12.2 |
| Cold crushing strength | MPa | 80 | 70 | 70 | 60 |
| HMOR @ 1400 °C | MPa | 2.3 | 2.3 | 1.9 | 1.7 |
| HMOR @ 1500 °C | MPa | 1.6 | 1.8 | 1.6 | 1.7 |
| CMOR @ RT | MPa | 19.3 | 14.5 | 17.0 | 9.5 |

Special emphasis was put on to the thermomechanical behaviour which was determined by means of creep-in-compression tests carried out at 1500 °C with an applied load of 0.2 MPa. Figure 6 clearly illustrates the advantage of the new raw material showing significant reduction in load-related deformation at high temperatures.

*Fig. 6: Creep-in-compression tests of refractory brick samples produced with rotary kiln material (green) and shaft kiln material (blue).*

Low silica levels in doloma-based refractory bricks are generally seen as a benefit, especially when it comes to resistance against silica-based slags which are predominantly used in AOD converter processes. To provide evidence for this assumption, finger shaped brick samples produced with the newly developed and samples with the former shaft kiln-based doloma raw material were subjected to slag corrosion tests in an induction furnace employing an aggressive synthetic silica-rich AOD slag with a low C/S ratio of ~1.2. Testing temperature was kept at 1650 °C for a test duration of 3 h. Results showed superior slag resistance of the rotary kiln-based brick samples, mainly due to the raw material's lower silica content but also due to higher bulk density and lower porosity [Fig. 7 and table 3]. The samples on the right-hand side had a significantly higher remaining thickness. Quantitative measurement of thickness was prevented due to complete disintegration by phase change of dicalcium silicate during sample cooling.

*Fig. 7: Finger-shaped slag testing samples after slag corrosion tests. Brick samples prepared with shaft kiln doloma material (left) and rotary kiln doloma having higher bulk density and lower silica levels (right).*

**Property evaluation of tempered refractory bricks**

Benefits coming from higher density, lower porosity and improved hydration resistance showed even more benefit of the newly developed rotary kiln doloma material. It is assumed that higher hydration resistance of raw material has significant influence on the overall properties. Comparative properties of resin bonded straight doloma bricks are summarised in tables 5 and 6.

*Table 5: Typical chemical composition of tempered doloma bricks produced with former shaft kiln sinter doloma and with newly developed rotary kiln material. Taken from [5].*

| Type of product (brick) | Tempered resin bonded | Tempered resin bonded |
|---|---|---|
| Type of raw material | Rotary kiln doloma | Shaft kiln doloma |
| Chemical analyses | Wt.% | Wt.% |
| MgO | 42.0 | 41.8 |
| $Al_2O_3$ | 0.4 | 0.5 |
| $SiO_2$ | 0.3 | 0.7 |
| CaO | 56.4 | 56.4 |
| MnO | 0.1 | 0.1 |
| $Fe_2O_3$ | 0.8 | 0.4 |
| Total carbon content | 4.8 | 5.5 |
| Residual carbon content | 3.1 | 3.2 |

Table 6: *Typical properties of tempered resin bonded doloma bricks produced with former shaft kiln sinter doloma and with newly developed rotary kiln material. Taken from [5].*

| Physical test results | | | |
|---|---|---|---|
| Test method | Unit | | |
| Bulk density | g/cm³ | 2.95 | 2.86 |
| Apparent porosity | Vol% | 3.9 | 5.6 |
| Cold crushing strength | MPa | 100 | 87 |
| Bulk density after coking@1000 °C | g/cm³ | 2.87 | 2.79 |
| Apparent porosity after coking @1000°C | Vol% | 12.8 | 14.8 |
| Cold crushing strength after coking @1000 °C | MPa | 40 | 38 |
| HMOR @ 1400 °C | MPa | 2.8 | 3.9 |
| HMOR @ 1500 °C | MPa | 3.1 | 2.7 |
| CMOR @ RT | MPa | 21.0 | 17.4 |

**LARGE SCALE RAW MATERIAL PRODUCTION, ENERGY & ADDITIVE OPTIMIZATION**

Production of doloma with the new rotary kiln in Austria made a good development in 2022 and sustainably stabilised in 2023. The quality of DBD could be kept on high levels regarding all relevant parameters. Like many other fields, the energy crisis also hit the refractory industry in 2022/2023, especially in highly energy-intensive processes like raw material production requiring temperatures above 2000 °C. With all this in mind, considerations were made to look for more cost-effective sintering additives than the ones used so far. Obviously, the target was to keep the high quality of the product at the same levels. A screening of possible alternatives provided among others a recycling material from refractory products. The selected materials were evaluated for sintering simulation tests in a lab rotary kiln.

The results with recycling material addition looked promising enough to initiate a large-scale trial in the sinter plant. One of the additive silos was filled with the new recycling material and a smooth overlapping switch from the standard material to the new one was made using the dosing conveyor belts. Regular analysis of the dolomite sinter chemistry and bulk density safeguarded the quality of the product.

This first large-scale trial lasted only for a few days and the influence of dust recycling back into the kiln feed with possible aggregation of certain compounds could not be evaluated. Density levels, however, were well above the target [Fig.8] and chemical composition was still very good.

Fig. 8: *Grain bulk density of doloma before, during (red square) and after trial.*

Therefore, a longer trial was scheduled lasting for around one month. This trial confirmed the good results from the first one and, most importantly, did not show any negative effects coming from kiln dust recycling. Since then, the production has been switched to the new recycling material-based additive providing benefits for the cost of sinter dolomite.

**CONCLUSIONS**

A high-quality supply of sintered dolomite has recently been set up in Western Austria by making use of a high-quality dolomite mine through implementing a newly designed one-step rotary kiln process using sintering additives. Raw material and process development were started with extensive lab trials followed by scale-up trials and thorough testing of raw materials in lab and production plant environment. Since the start of the sinter plant, several optimization steps have led to improved energy efficiency and cost structure by introduction of new additives, recycled materials, and side-products. Main benefits of the rotary kiln process and the resulting doloma raw material over the former shaft kiln process and material are:

1. Cost-efficient and highly flexible single-step process allowing for changes in fuel as well as dosing of different additives and recycled materials.
2. Higher density of dolomite sinter and very low surface porosity significantly improving hydration resistance.
3. Extremely low silica content and overall low flux level in final doloma.
4. Improved density and porosity of bricks produced with rotary kiln doloma.
5. Improved slag resistance of bricks produced with the new raw material as compared to bricks produced with the former shaft kiln raw material.

By implementing this new process, the future supply of high-quality doloma and doloma-based refractory products from Europe has been secured for the next decades to come. Continuous improvements of feeding raw materials and fuel usage will lead to higher energy and mining efficiency at the same time keeping the good performance level of the final products.

# DESIGNING ECO-FRIENDLY ALTERNATIVE TO THE MAGNESIA-CHROMITE AGGREGATES

O. H. Borges, F.G. Coury, D.N.F. Muche, V.C. Pandolfelli

Federal University of Sao Carlos, Graduate Program in Materials Science and Engineering, Sao Carlos-SP, Brazil.

## ABSTRACT

Due to its outstanding thermomechanical and corrosive performance, electrofused magnesia-chromite aggregates (EMCA) have been consistently applied to refractory compositions since the beginning of the 20th century. Notwithstanding the performance of refractories containing this raw material, the rising environmental and safety concerns have been driving the replacement of chrome-containing compositions by greener alternatives as this type of refractory can generate a highly toxic by-product ($Cr^{6+}$), suppressing landfilling and recycling. However, finding eco-friendly and affordable alternatives to EMCA remains a challenge. Firstly, there is a lack of understanding of the mechanisms that give rise to its good performance and, secondly, conventional formulation criteria can hardly account for the microstructure complexity of this raw material. In this work, multiple electron-microscope-based techniques, such as EBSD and EDS, were used to assess EMCA microstructural features and a mechanism to explain their generation was proposed. Based on the latter and with the aid of thermodynamic calculations, the concepts of designing compositionally complex ceramics were applied to find eco-friendly alternatives to EMCA. From the 154 simulated systems, the 4 most promising compositions were experimentally produced and characterized at a laboratory scale. Although kinetics aspects still must be addressed, Cr-free EMCA mimetized microstructures were obtained, highlighting that this design approach can be used to support the development of novel raw-material that can better merge performance, cost and eco-friendliness.

## INTRODUCTION

The search for refractory systems capable of withstanding the complex solicitations (*e.g.* thermal shock, corrosion, erosion) is a constant demand in high-temperature industries[1]. To address such a scenario, refractories containing electrofused magnesia-chromium aggregates (EMCA) have been broadly applied since the 1960s[1]. In these systems, which fit into the compositionally complex ceramic classification[1], the predominant phases are periclase and a solid solution based on a complex spinel obtained by combining different types of spinel structures ($AB_2O_4$-type phases, in which A represents a divalent cation and B a trivalent one)[2]. This complex structure results in excellent resistance to corrosion and slag penetration[2]. Additionally, although the literature does not report in detail the driving force for this phenomenon, the high number of preferentially oriented microcracks formed on the EMCA microstructure gives rise to a material with good flexibility and thermal shock damage resistance.

Besides its outstanding corrosion and thermal shock damage resistance, EMCA has received little attention from the scientific community in recent decades, which can be attributed to its toxicity (mainly due to the formation of hexavalent chromium). Thus, greater efforts have been made to study safer systems, especially based on $MgAl_2O_4$, as alternatives to replace EMCA, but equivalent performance in applications such as in RH degassers has not yet been achieved[3]. Consequently, there is a lack of understanding of the mechanisms that lead to EMCA properties, especially related to its high thermal shock damage resistance.

Aiming at understanding the mechanism that leads to their features, multiple techniques were used in this work to assess the microstructure of commercially-available EMCA. Based on that and using thermodynamic calculations (CALPHAD), the concepts of designing compositionally complex ceramics[4] were applied to find eco-friendly alternatives to this chromium-containing raw material. Some of the most promising compositions were then processed by electrofusion in lab-scale arc furnace equipment and their resulting microstructures were analysed.

## EXPERIMENTAL PROCEDURE

Microstructural characterization was firstly conducted for commercially-available electrofused magnesia-chromium aggregates (FMCR 18-20, $d_{50}$ = 3 mm, Chenglong, Liaoyang, China). The as-received samples were embedded in a polymeric resin, cut to expose their sectioned surface, ground using SiC-based sandpaper, and polished in AutoMet (model Phoenix Beta, Buehler, USA) using polycrystalline diamond paste with particle sizes ranging from 15 μm to 0.25 μm (MetaDi Medium Concentration, Buehler, USA). The diamond-polished samples had their microstructure assessed by backscattered electrons imaging (BSE) coupled with energy-dispersive X-ray spectroscopy (EDS) on a scanning electron microscope device (Inspect S50, Thermo Fisher Scientific, USA). To avoid charging artefacts, the latter analysis was conducted on golden-coated surfaces (Balzers SCD 004, Bal-Tec, Switzerland). The crystallographic orientation of the EMCA phases was assessed by electron backscattered diffraction technique (30 kV, Inspect S50, FEI, USA). Thermodynamic calculations were carried out in Equilib module of FactSage software (FToxid and FactPS databases, version 6.4, CRCT, Canada) using the EMCA chemical composition (X-ray fluorescence, MagiX PRO, Malvern Panalytical, UK) to assess its solidification path.

Aiming at finding eco-friendly alternatives to the chromium-containing material, the same thermodynamic approach was used to assess the solidification path of binary, ternary or quaternary spinel systems (available in the aforementioned database) together with 66.4 wt% of MgO, giving rise to 154 distinct systems. This MgO content was selected because it is the same as that presented by the reference material (EMCA). To allow a better comparison among the simulated systems, they were ranked considering 5 key indicators, which will be presented later in this work. This ranking showed four systems with similar features to those presented by EMCA, thus, they were selected as the most promising and experimentally processed in a lab-scale arc melter (MAM-1, Edmund Buehler, Germany). To enable their electrofusion in this equipment, the raw materials presented in Tab. 1 were dispersed in a ball-milling with alumina balls for 2h and moulded into small (~ 1 cm³) uniaxially-pressed (~ 60 MPa) pieces, avoiding powder aspersion during electric arc opening.

Tab. 1: Composition of the four selected electrofused systems in a lab-scale arc melter.

| Composition | MgO | FeO | Fe₂O₃ | Al₂O₃ | NiO | Ni₂O₃ |
|---|---|---|---|---|---|---|
| | | | wt% | | | |
| 1 | 69.54 | 5.59 | 24.87 | - | - | - |
| 2 | 66.40 | 11.27 | 8.35 | 5.33 | - | 8.65 |
| 3 | 71.12 | 4.21 | 18.70 | 5.97 | - | - |
| 4 | 70.01 | 3.22 | 14.30 | 9.13 | 3.34 | - |

These pressed pieces were placed inside the electric arc melter and the melting process took place for ~ 90 seconds. Compared with the industrial electrofusion process, the lab-scale equipment imposes distinct processing conditions, such as much higher cooling rates (the samples cool down within seconds). Therefore, to bring them closer to the thermodynamic equilibrium, the as-fused samples were annealed for 5h at 1500 ºC in a conventional electric heated furnace (Lindberg/Blue M, Thermo Fisher Scientific, USA). After that, the microstructure of the annealed samples was assessed by BSE/EDS and XRD (D8 Focus, Bruker, Germany).

## EXPERIMENTAL PROCEDURE

Firstly, the microstructure of the commercially-available EMCA was analysed by BSE coupled with EDS (see Fig.1), highlighting that the aggregate is formed by a magnesium-oxide matrix

containing nodular precipitates with oxygen, magnesium, chromium, aluminium and iron as its main elements. Using the CALPHAD-based FactSage software, the mean composition of the two distinct regions was used as input for the thermodynamic calculation. The result indicated that the EMCA should be comprised of a complex spinel solid solution (spinel[SS]) with the chemical formula $(Mg_{0.865}Fe_{0.135})(Al_{0.099}Cr_{0.877}Fe_{0.024})_2O_4$, surrounded by a periclase solid solution $[(Mg_{0.991}Cr_{0.006}Fe_{0.003})O]$ matrix. XRD analysis (not presented here) attested the formation of both phases, in line with previously reported works. Additionally, image analysis software was used to measure the mean diameter of the spinel precipitates, which was $15 \pm 2$ μm.

Although the mineralogical composition and the microstructure of EMCA have already been reported in the literature, the mechanism that leads to the cracking behaviour seen in the microscopy (Fig.1) remains unclear. Thus, microcrack generation due to thermal expansion mismatch between distinct ceramic phases during the cooling process was considered. By using the approach proposed by Luchini *et al.*[5] and considering the properties of the spinel[SS] and periclase extracted from the literature (further information on these calculi is described in[6]), the minimum precipitate diameter ($d_c$) to generate microcracking in this system was calculated as 2.3 μm. As the average spinel size measured in the EMCA ($15 \pm 2$ μm) is considerably bigger than this value, microcracking due to thermal expansion mismatch is, indeed, expected. However, although the thermal expansion mismatch accounted for the highly cracked microstructure of the EMCA, it does not explain their crack orientation pattern, which plays a key role in the outstanding flexibility of this raw material. To assess the mechanism that leads to this oriented microcracking, EBSD analyses were conducted.

Fig. 1: Morphology and elementary mapping of the EMCA microstructure assessed by scanning electron microscopy coupled to energy dispersive spectroscopy. Extracted from [6] with Elsevier permission (nº 5573751435544).

Due to the unevenness of the surface, generated by the distinct hardness between the spinel and periclase ($H_{Vickers's}$ typically varying from 5.3 GPa to 8.6 GPa and 12 GPa to 16 GPa, respectively), no Kikuchi lines were detected for the former, however, the analysis could be conducted for the MgO matrix. Evaluating the obtained results (displayed in Fig. 2), the formation

of distinct MgO grains inside the aggregates was attested, giving rise to intergranular flaws, likely generated by solidification defects, at their interfaces (marked as F). Besides them, oriented cracks were observed within the MgO grains (marked as C). The post-processing software was used to determine their relative orientation, revealing a good fit with the {110} family of crystallographic planes, which are the MgO slip planes, whereas {100} are the cleavage ones. Additionally, the intersection among the oriented microcracks formed triangular slits (marked as S). These two features – cracks on slip planes instead of cleavage planes and the formation of triangular cracks – are in agreement with the cracking mechanism proposed by Zener and further described by Stroh[7]. According to these authors, crack nuclei are induced by a pile-up of edge dislocations that are halted at an obstacle, such as precipitates. In the case of MgO, non-homogeneous deformations (as those generated by thermal expansion mismatch) induce the pile-up of edge dislocations, resulting in crack nucleation at the {110} family of planes and triangular slits at the crack intersection, similar to what was observed for the EMCA[8].

Fig. 2: Microstructure of EMCA assessed by EBSD. The colours indicate the MgO orientation. Intergranular flaws, oriented cracks and triangular slits are highlighted as F, C and S, respectively. Extracted from [6] with Elsevier permission (nº 5573751435544).

Therefore, the microcrack orientation pattern established in the EMCA – and that gives rise to their flexibility – is attributed to the Zener-Stroh crack mechanism triggered by the stress generated due to the thermal expansion mismatch between the MgO and the complex spinel. Thus, the properties and geometry of the spinel precipitates play a key role in promoting such a structure as it will affect, (a) the thermal-induced stress level and, (b), act as dislocation barriers. At first sight, all these features seem to be feasible to obtain in a nontoxic and simpler system, such as a magnesia-rich MgO-Al$_2$O$_3$ composition. However, previous works showed that instead of spinel precipitates in a MgO matrix, this system presents the formation of periclase and spinel grains separately, which halts attaining preferentially oriented microcracks. Thus, to understand the role played by the chromite mineral on the formation of its microstructure, the solidification path of the EMCA and MgO-Al$_2$O$_3$ system were assessed by thermodynamics calculations carried out in the FactSage software. The solidification seen in Fig. 3 explains the distribution of phases in the EMCA (Fig.1), pointing out that the chromium addition plays a key role by enabling the formation of a MgO[SS] at high temperatures, which exsolves a spinel[SS] as the material cools down.

The results discussed so far pointed out the mechanism and key features responsible for the formation of the EMCA microstructure and, consequently, good thermomechanical properties. To do this, a system capable of forming a broad solid solution with MgO at high temperature, but exsolving a second phase presenting a lower thermal expansion coefficient, as internal precipitates with mean size higher than the critical value to induce fracture by thermal expansion mismatch is required to trigger the Zener-Stroh cracking mechanism, leading to highly oriented microcrack formation. This

intricate set of features explains why finding other compositions to replace the EMCA is so difficult, especially using the traditional selection paradigm. Therefore, the compositionally complex ceramic (CCC) selection approach was used to assess promising alternatives that could mimetize the EMCA but without containing chromium addition. The validated systems of FactSage 6.4 gave rise to a total of 154 compositions, which were ranked by taking 5 key indicators into account: (i) the periclase decay step; (ii) whether any gas was predicted to be generated up to 2800 ºC; (iii) the solidification interval; (iv) the $\Delta\alpha$ between the periclase and the spinel formed; and (v) the temperature of the first liquid formation.

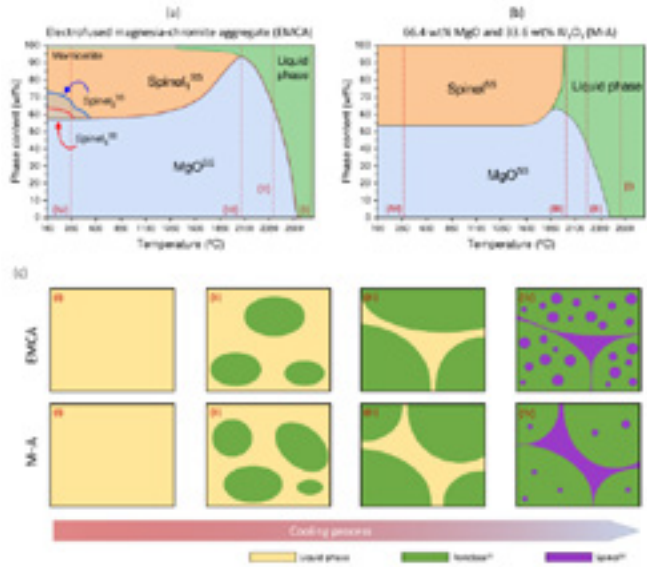

Fig. 3: EMCA (a) and M-A (b) solidification path assessed by FactSage. The drawings (c) presented a schematic representation of the microstructure at different temperatures. Extracted from [6] with Elsevier permission (nº 5573751435544).

According to these indicators and considering the reference values, 4 systems stood out as promising compositions to mimetize EMCA, as depicted in Tab. 2 (the values for all the 154 evaluated systems can be checked in[6]). At first, it is worth noticing that no Zn-containing system was selected, which is attributed to the high partial pressure of this element, resulting in gas formation at temperatures close to 2400 ºC. Secondly, all selected compositions presented Fe additions, which was observed to display a similar role of Cr, also presenting a high solubility in periclase at high temperatures and able to exsolve a spinel structure during cooling.

Tab. 2: Indicator values for the EMCA and the four most promising compositions to mimetize it.

| Composition | MgO decay (wt%) | Gas formation | Solidification interval (ºC) | $\Delta\alpha$ (%) | First liquid formation (ºC) |
|---|---|---|---|---|---|
| EMCA | 40.4 | No | 450 | 42.9 | 2200 |
| 1 | 38.6 | No | 525 | 67.3 | 2200 |
| 2 | 34.0 | No | 550 | 37.8 | 2125 |
| 3 | 36.4 | No | 575 | 38.2 | 2100 |
| 4 | 34.5 | No | 550 | 38.2 | 2100 |

Although this computer-based selection method is valuable to guide the search for alternative eco-friendly compositions to replace the EMCA without performance losses, it must be experimentally validated to check its accuracy. Therefore, compositions 1 to 4 were processed in a laboratory-scale arc melter, which allows the production of small electrofused pieces (~ 1 cm³). Due to the processing conditions imposed by this equipment (especially high cooling rates), which are distinct from the industrial ones, the as-fused samples were annealed for 5 h at 1500 ºC to bring them closer to the thermodynamic equilibrium. Aiming at assessing the mineralogical phases for each system, annealed samples were

grounded and the resulting powder was analyzed by XRD. Fig. 4 shows the X-ray diffractogram, highlighting the regions of 2θ next to 35.5 º and 43 º, where the most intense spinel and periclase peaks are located, respectively. By indexing the profiles, one can notice that just these two phases were identified, as the content of contaminants was lower. The highlighted peaks show significant changes for the spinel phase, remaining quite constant for periclase. This trend was expected as the systems were designed to present distinct spinel[SS] compositions, whereas the periclase matrix is very similar, and is almost fully comprised by MgO. Moreover, quantitative mineralogical content indicated that all samples presented spinel content ranging from 34 wt% to 36 wt%, which is quite close to the values estimated using EDS data collected in the internal region of the grains of compositions 1 to 4 (see Fig. 5), especially considering the inherent uncertainty related to these experimental techniques.

Fig. 4: X-ray profile of the EMCA and compositions 1 to 4 after the annealing treatment. Extracted from [6] with Elsevier permission (nº 5573751435544).

However, the XRD analyses does not provide information regarding phase distribution and the presence of minor contaminating phases, thus the compositions were further analyzed by SEM in the BSE coupled with energy dispersive X-ray spectrometry (EDS), depicted in Fig. 5. Comparing the general morphological aspects similar trends could be observed for the four compositions:

(i) Solidification defects were detected in the samples, which are assigned to the high solidification interval (> 500 ºC) present by all compositions and the high cooling rates imposed by the lab-scale arc melter. In the industrial process, the compositions are produced in a block geometry that is subsequently broken and milled to give rise to the aggregates, which usually withdraws such solidification defects from the final microstructure.

(ii) The microstructures presented some contamination mainly located at the periclase grain boundaries. The lighter color in the image indicates the presence of heavier elements in these regions, which were identified as calcium and tungsten that originated from the MgO raw material and the W-based electrode used in the melting process, respectively.

(iii) All compositions underwent the formation of a periclase matrix with spinel precipitates. The EDS data coupled with thermodynamic calculations were used to assess the phase content of some selected regions showing that the grains are formed by ~ 40 wt% of spinel and ~ 60 wt% of periclase.
Fig. 5: Backscattered electron images of compositions 1, 2, 3 and 4. Extracted from [6] with Elsevier permission (nº 5573751435544).

However, obtaining a microstructure with MgO grains with spinel precipitates is a required but not sufficient condition to achieve a highly flexible material mimetizing the EMCA. Taking a closer look at the microstructure of compositions 1 to 4, the distinct morphology of the second phase stood out. For composition 1, a needle-like spinel structure was observed, whereas, for the other, nodular-like geometries were detected. Their sizes were assessed using image processing software (ImageJ, version 1.53t), which pointed out 0.9 μm, 1.4 μm and 2.5 μm as the mean equivalent diameter of the precipitates in compositions 2, 3 and 4, respectively. Not coincidentally, composition 4 presented the highest number of cracks, as bigger precipitates lead to higher stresses on the periclase matrix. Nevertheless, even for composition 4, the mean spinel size was considerably below the 15 μm presented by commercially produced EMCA, resulting in less crack generation than expected. In this sense, it is worth highlighting that the thermodynamic approach used in this analysis does not take kinetics into account. Thus, the larger spinel size observed in the EMCA (see Fig. 1) could be attributed to the much lower cooling rates applied in the industrial manufacturing of this raw material (electrofused blocks usually take close to 7 days to completely cool down) compared to that imposed by the laboratory-scale arc melter. To address such issues and understand whether the selection method should also consider the temperature of spinel formation or if this variable could be neglected for industrially produced aggregates, electrofusing these compositions in larger scales would be needed and its on course.

## CONCLUSIONS

In this work, multiple electron-microscope-based techniques were used to assess EMCA microstructural features. BSE coupled with EDS highlighted that the aggregate comprises a magnesium-oxide matrix containing nodular-like precipitates. The mean size of the precipitated spinel was measured as $15 \pm 2$ μm, which is above the critical diameter to induce microcracking due to thermal expansion mismatch in this system. However, such cracking is not randomly distributed and EBSD was used to assess its pattern, unveiling a good fit with the {110} family of crystallographic planes. Therefore, the microcrack orientation pattern in the EMCA could be attributed to the Zener-Stroh crack mechanism triggered by the stress generated due to the thermal expansion mismatch between the MgO and the complex spinel. Based on this mechanism and with the aid of thermodynamic calculations, the concepts of designing compositionally complex ceramics were applied to find eco-friendly EMCA alternatives. From the 154 simulated systems, the four most promising compositions were experimentally produced using a laboratory-scale arc melter and characterized by XRD and BSE/EDS. Although kinetics aspects still must be addressed, Cr-free EMCA-inspired microstructures were obtained, highlighting that this design approach can be used to support the development of novel raw-material that can better merge performance, cost and eco-friendliness.

# DEVELOPMENT OF NOVEL DBM PORTFOLIO FOR STEEL, CEMENT AND GLASS REFRACTORIES

Matheus, Moraes, Gustavo, Nogueira, Graziella, Pacheco, Pedro, Almeida, José Alvaro, Sardelli
RHI Magnesita, Contagem, Brazil

Jacob, Kerr
RHI Magnesita, York, United States of America

**ABSTRACT**
The verticalization of refractory producers, with sustainable exploitation of mineral reserves, and the development of alternatives for Chinese raw materials are important topics for the industry. RHI Magnesita is investing in a new rotary kiln on its Brazilian plant, located in Brumado, and more than a cost-reduction target, the optimization of its magnesite reserves and the production of value-added products were prioritized. Therefore, novel high-quality DBMs were developed with characteristics to supply steel, cement, and glass refractories. The research focused on an innovative production process, strengthening RHI Magnesita vertical integration and delivering to the market sustainable products. This article explores the DBMs development process, including lab, pilot and industrial trials, as the refractory trials for the selected product lines. Finally, the reference DBMs are compared to the new portfolio according to product properties and sustainability impact.

**INTRODUCTION**
The dead burned magnesia (DBM) is one of the most important raw materials for refractory production. Bricks and monolithics based on this refractory aggregate are produced for steel, cement, glass, non-ferrous metals, and other key industries [1].
Nevertheless, each application has a different wear mechanism and the DBM characteristics directly influence the performance of the final product.
For steel applications, the DBM needs different features according to the application. Some examples are relative high grain bulk density (GBD) and low thermal conductivity for the safety lining of different vessels, high purity, GBD and periclase crystal size in ladle and electric arc furnace (EAF) bricks, right amount of fluxes for a good sinterability and low corrosion in EAF mixes, low cost, chemical compatibility and correct particle size distribution (PSD) for repair mixes and, finally, low-cost, compatible chemistry, necessary porosity and PSD for tundish mixes [2,3,4].
For cement, especially in the burning zone, high GBD, controlled lime to silica ratio (C/S) and high purity are desired, avoiding chrome oxide addition to the DBM aiming to increase GBD [5,6].
Finally, in glass application, low iron content, high GBD, low C/S (<1), particularly due to a low CaO content, and high purity are desired for high performance [7,8].
RHI Magnesita, out of its plant in Brumado (Brazil), produces two DBM grades. The M30B is a high-purity and high-GBD DBM for brick applications, produced in double step firing being sintered in a pressurized shaft kiln in temperatures surpassing 2200°C. The M10, in turn, is a medium grade and intermediate density DBM mainly used for mixes but with brick applications, produced in single step firing using a conventional shaft kiln at 1850°C. This paper describes the development process of new qualities especially linked to a new rotary kiln being installed in this Brazilian plant [9].

**NEW GRADES DESIGN**
The development of the new DBMs for Brumado plant was motivated by the investment on a state-of-the-art rotary kiln, with a process specifically designed to take advantage on the two magnesite mines (figure 1) being operated at this site and other deposits on the vicinity with mining rights granted to RHI Magnesita.

The new DBMs were designed to reduce the stripping ratio, increase the process yield and use ores that couldn't be used due to operational restrictions from the shaft kilns and technical constrains from the current specs. These features lead to a more sustainable process, increasing the life of mine (LOM), reducing landfilling, and improving the cost-competitiveness of the complete site operation.
The development process was divided in three steps. First the differences in kiln technology and how the exploit the upsides of the new rotary kiln are explored. Secondly, the characteristics expected of new DBMs for each application is described. Finally, the process design features, and properties of the new raw materials are detailed.

*Fig. 1: Pedra Preta (left) and Pomba (right) mines from RHI Magnesita in Brumado-BR.*

**DIFFERENCES ON KILN TECHNOLOGY**
The conventional shaft kiln technology (as the one used to sinter M10 in Brumado, figure 2) in comparison to a rotary kiln (new kiln being installed in the same plant) has the advantage of a low specific energy consumption and a more flexible control on the residence time, normally capable of operating with longer retention period. Nevertheless, it has strong limitation on the particle size to be fed and for ores prone to decrepitation (breaking down inside of the kiln), since the gas permeability is utterly important for a proper operation in this case which the kiln is almost fully filled with material [9].

*Fig. 2: Vertical shaft kilns from RHI Magnesita in Brumado-BR.*

The rotary kiln (figure 3 presents the rotary kiln operated by RHI Magnesita in Turkey to produce DBM), in turn, operates with a low filling rate and the gas is transported above the material. This characteristic gives more flexibility for the feedstock, allowing finer particles to be fed and the ore breakage inside of the kiln does not have a strong impact on the operation parameters.
The downside of the rotary kiln is the less efficient heat transfer and higher thermal dissipation, increasing the specific energy consumption compared to the shaft kiln. However, the total cost is reduced, as the productivity is higher, workforce is reduced and

alternative fuels can be applied (gas, liquid and solid). Another point of attention for the rotary kiln is the dedusting system capacity and dust return to the process. With finer material being fed and the breakage of original feedstock due to decrepitation and the tumbling effect of rotary kiln, the dust load can be as high as 30% of the feed rate (even higher in some cases). Hence, a robust dedusting system to handle this load combined to a proper system and strategy for recirculation is necessary to increase productive and improve energy efficiency.

*Fig. 3: Rotary kiln from RHI Magnesita in Eskişehir-TR.*

Therefore, the new rotary kiln in Brumado open new possibilities for feedstocks never explored due to technology restrictions and alternative DBMs started to be explored to be supplied to different market applications.

## NEW DBMs AND TARGETED APPLICATIONS

The new DBMs were developed to improve the deposit utilization and increase the value generation. The first DBM described is an intermediate grade and density, targeting to combine high decrepitation ores and accommodate higher silica and iron oxide for steel application. Secondly, a higher grade DBM was developed for EAF hearth construction mixes, with increased density and controlled silica content. Finally, a high grade DBM with low iron content and low C/S for glass and cement applications is detailed.

## DBM M9

The DBM M9 was designed to combine different ore sources to maximize the mine utilization and increase the life of mine, without loosing performance on target applications. The main modification compared to the M10 is a slightly higher $SiO_2$ and $Fe_2O_3$ content, keeping the same density and particle size for refractory application. With this modification, combined to others debottlenecking provided by the rotary kiln technology, the estimated LOM for Pedra Preta was increased from 47 years to more than 120 years, considering the current geology dataset. Figure 4 illustrates the increase on ore recovery due to the modifications (consequence of DBM M9 and the other DBMs, combined to the kiln characteristics.)

*Fig. 4: Increase in ore recovery due to technology and product design.*

This intermediate grade was designed to be supplied to repair mixes, tundish mixes and EAF mixes, for ramp construction and hearth repair. For these markets a cost-competitive alternative is necessary, but the right chemistry must be achieved, not too pure

that would hinder a quick sintering on the application and controlled fluxes to prevent early wear. Additionally, the process must be able to generate both coarse fractions (>2mm) for the EAF products and fines (<1mm) for repair and tundish mixes without excessive chemistry segregation.

Finally, the density should not be high for these applications since a certain reactivity is still desired for the quick sintering and, especially for tundish and EAF hearth repair, lower thermal conductivity is desired. Nevertheless, if the GBD is too low and the material is still not stable, high shrinkage might be observed, leading to cracks formation reducing the thermomechanical stability and increasing infiltration. Therefore, the right balance on properties must be achieved. Figure 5 show trials successfully carried out with this new DBM concept, with similar application behaviour, specific consumption, and operational time.

*Fig. 5: DBM M9 applied to EAF wall hot repair mix (left) and tundish work lining (right) on RHI Magnesita products.*

## DBM M25F

The DBM M25F was developed to be used in EAF hearth construction, replacing the top-grade DBM (M30B) that is normally combined to high-lime and iron-rich DBMs to improve sinterability. The two key aspects for this application are keeping the $SiO_2$ content low (combined a high MgO grade), to prevent corrosion by slag in the EAF cycles, and provide a proper sintering of the hearth, more intense in the upper portion to generate mechanical strength but gradually decreasing for the lower portions to accommodate the impact of the kiln feeding material and reduce the temperature on the anode (due to the lower thermal conductivity of the mix). Figure 6 exemplify the lab trials carried out to evaluate the application of this DBM on EAF heart mixes, checking for linear change (PLC) and crushing strength (CCS) upon different firing temperatures. The results were very similar to the reference and field trials will be carried out as soon as the volume necessary is available for industrial utilization.

*Fig. 6: Tested properties of M25F applied to EAF hearth mix.*

## DBM M25S

For glass application, the low iron content is necessary to avoid inclusions on the desired product, while the forsterite present as a secondary phase is important for sulphate attack resistance. Additionally, a good creep behaviour is key for a long-lasting product. Finally, complex shapes are necessary for the kilns and a controlled expansion upon firing, still in the refractory production,

is necessary to reduce the scrap generation, keep production costs and quality under control.

The M25S was designed to cope with these demands, the silica content balanced to generate the necessary forsterite and reduce the thermal expansion that would be observed for a top-grade DBM being applied in the same product. Figure 7 exhibits glass bricks successfully produced with M25S and shipped to customers and its microstructural analysis with the M25S grain highlighted.

Fig. 7: Glass checker brick produced with M25S and its microstructure.

Another application being studied for M25S is cement bricks for the intermediate zone, exposed to a lower temperature as an opportunity to replace top-grade DBM without loss on performance. With the same objective, this DBM is being tested for magnesia-chrome bricks for non-ferrous metals applications and for tundish furniture in steel production.

## DBM PRODUCTION PROCESS DEVELOPMENT

In order to achieve the targeted properties on the DBM and produce a cost competitive high-grade DBM from a macro-crystalline magnesite in a rotary kiln, an innovative process was developed.

This process was designed combining different stages of pre-processing, binders, and sintering additives. For each DBM, different pre-processing set-ups were tested combined to sintering trials at different temperature levels, assess the feasibility to be produced in a rotary kiln. The sintering trials were carried out first in a batch furnace and, for selected conditions, using a pilot rotary kiln, both present at RHI Magnesita R&D Centre in Brazil. Figure 9 shows the batch and pilot rotary kilns used for the trials.

Fig. 8: Batch (left) and pilot rotary (right) kilns at RHI Magnesita R&D Centre Brazil.

The main challenges faced in the process development were to achieve the grain bulk density necessary for brick application and preserving the coarse fraction after the tumbling effect promoted in the rotary kiln.

Initially, the sintering process was explored, evaluating alternative process parameters combined to firing temperature to achieve the grain bulk density goal. Figure 9 illustrate the development steps for the M9, M25S and M25F according to the adjustments.

To evaluate the particle size after the rotary kiln, trials were carried out in the pilot device and the product of was compared to the M30B, the reference for coarse grain generation. In this analysis, two assessments were carried out after the binders and sintering additives were optimized.

First, the particle of the kiln product (run of kiln – ROK) without processing compared to the reference, also without processing. In the second step, both samples were crushed and their PSD were compared after processing. Figure 10 presents the results for the M25 DBM class compared to M30B for ROK and after crushing.
Fig. 9: Grain bulk density evolution according to parameter set-up on batch sintering trials.

Fig. 10: Particle size distribution of new DBM class compared to reference.

Despite having a finer particle size distribution after the kiln processing, the M25 class DBM has a very similar PSD after a single crushing stage, within the coarse size fraction generation range for brick application.

Considering the firing results and process alternatives evaluated, an innovative plant design could be stablished combining the desired specs for each DBM to a cost-effective processing route.

## PORTFOLIO CHARACTERISTICS

Table 1 is elaborated to compare the different DBMs developed with the regular products, giving an overview of the new portfolio to be produced out of Brumado.

Tab. 1: New DBM portfolio and properties

| DBM | M9 | M10 | M25F | M25S | M30 |
|-----|-----|-----|------|------|-----|
| GBD | + | + | ++ | ++ | +++ |
| MgO | + | + | ++ | ++ | +++ |
| SiO2 | ++ | + | + | ++ | - |
| Fe2O3 | ++ | ++ | + | - | - |
| CaO | - | - | - | + | + |
| C/S | - | - | - | - | ++ |

Considering this new portfolio, and the state-of-start technology rotary kiln being implemented, the Brumado DBM production in Brazil is prepared to supply competitive amd high-performance refractory raw materials for a wide varity of applications, reafirming the importance of this plant for the global supply and improving its sustainability for the long-term.

## CONCLUSIONS

Taking advantage on the RHI Magnesita knowledge on the full production chain of refractories, new dead burned magnesia grades

were developed to increase the value and sustainability of its Brumado plant in Brazil.

The new DBMs were designed to have the desired characteristics of each targeted market, in steel, glass and cement industries. To achieve the properties, trials were carried out in lab, pilot and industrial scale, evaluating the process design and impact on downstream processes.

For all new DBMs, M9, M25F and M25S, the desired chemical and physical properties could be achieved. Combined to this results, refractory trials were successfully carried out, in some cases even considering customer application.

With this new portfolio, RHI Magnesita strengthen its backward integration and Brumado plant improve its cost-competitiveness and sustainability, expanding the pool of applications and potential customers for the high-quality DBMs produced at this site.

## ABSTRACT

High-grade magnesite raw ore for DBM97 production became rare in China after a frenzy of mining for over 30 years. But the demand for high-purity sintered magnesia grows in high temperature industries that accompanies volatile components. Some attempts have been made for the purification and densification from the flotation of low-grade natural magnesite, flash calcination in suspension calciner, and sintering in extraordinarily high temperature shaft kiln. In this work, a novel eco-friendly approach is developed, based on a pilot plant with the capacity of 40 t/d, to calcine natural magnesite grading as low as 40% MgO, to carry out three levels of watering treatments removing Si-, Fe- and Ca- components and hydrating MgO (gaining >90% $Mg(OH)_2$), to calcine magnesium hydroxide for active MgO in suspension calciner, and finally to burn high purity magnesia to high densification. MgO hydration process is highlighted with the pivotal parameters of hydrating duration and temperature. The calcined caustic magnesia obtained has high activity of < 20 s with citric acid. Dead burnt magnesia reaches the purity of > 97.5% MgO and the bulk density of > 3.4 $g/cm^3$, from low grade natural magnesite, in industrial potential.

## 1. INTRODUCTION

A plentiful resource of natural magnesite deposits lies in the northeast of China, with 3,115 million tonnes and 26% of global reserves [1,2], where various grades of refractory magnesia have been dominantly supplying the global demand of high temperature industries [3]. After high grades of magnesite are merely mined and traditional manufacturing processes of magnesia are performed for over 30 years, critical technologies of magnesite calcination and purification are being developed, as well as sintering approaches to the magnesia densification [4,5].

In order to remove more than 50% $CO_2$ from magnesite, light calcination must be firstly made in the magnesia manufacturing process, which produces caustic calcined magnesia (CCM). As the most widely used technology (China), about 1500 reverberatory furnaces are being run in Liaoning province with the production capacity of over 10 million tonnes CCM per year. This is a typical fixed bed calcination reactor, in which the calcination occurs at a temperature in the range from 1,000 °C to 1,300 °C. Only large size magnesite lumps in 30–80 mm are adopted to allow gas flow from bottom to top in reverberatory furnace and to ensure the combustion space for fuel gas and the transportation channels for emitted gases, which makes the calcinating time elongated up to 3–5 h and a low production capacity of maximumly 30 tonnes per day. A mass of small-size magnesite generated during mining are abandoned. On the other hand, over-burning on lump surface and insufficient-burning in the inner core occur, resulting in unstable quality and low activity of CCM. In general, the drawbacks of reverberatory furnace are high energy consumption, bad feedstock adaptability, long reaction time, unsteady CCM quality, low CCM activity and severe environmental pollution [6,7]. Due to the reducing availability of high-grade magnesite, dozens of flotation magnesite lines have been built in last 10 years to upgrade low-grade magnesite fines. A flash calcining technology is developed as suspension calciner for calcining floated magnesite powders.

As a traditional manufacturing route, lumps of magnesite are calcined in a reverberatory furnace to produce caustic calcined magnesia, and CCM briquettes are sintered in a shaft kiln to produce dead burnt magnesia (DBM97). Mainly due to low activity of CCM from

reverberatory furnace, the bulk density of DBM97 is in the range between 3.24 and 3.30 $g/cm^3$. The purified magnesite powders after floating can be calcined in multiple hearth furnace for CCM production and the DBM98 briquettes have the optimal bulk density of 3.36 $g/cm^3$. While floated magnesite is calcined in a suspension calciner, the bulk density of DBM98 can reach 3.42 $g/cm^3$ [8]. In these cases, all high purity magnesia briquettes have to be sintered at ultra-high temperature of 1,950–2,100 °C in shaft kiln. Additionally, impurity of iron-component is hardly removed in the flotation process if iron ions enter MgO lattice.

The most common beneficiations are carried out by dense-media separation, magnetic route and flotation process. The potential pollution exists during flotation process of magnesite purification because a lot of chemicals are used. There are no appropriate solutions to deal with 20–30% tailings of magnesite floatation. In some deposits of magnesite ore, the impurities are strongly bound to the crystalline structure, for instance, Fe ions in MgO crystals. An eco-friendly approach has been developed for purification and densification, firstly to calcine low grade magnesite, then to hydrate CCM for separating the suspension of magnesium hydroxide from $Ca^{2+}$ and precipitating Al-, Fe- and Si-components. After de-watering of magnesium hydroxide suspension, the paste of magnesium hydroxide is dried and calcined in the system of suspension calciner to have secondary CCM, which is sintered at various temperatures for densification.

## 2. EXPERIMENTAL PROCEDURE

Low grades of magnesite ore are used as raw material for purification. Their chemical analyses are listed in Table 1.

*Tab. 1: Chemical analyses of magnesite ore used for purification*

| Magnesite sample | MgO wt% | $Al_2O_3$ wt% | $Fe_2O_3$ wt% | CaO wt% | $SiO_2$ wt% | LOI wt% |
|---|---|---|---|---|---|---|
| No. 1 | 81.43 | 0.67 | 2.17 | 9.15 | 6.57 | 49.50 |
| No. 2 | 86.74 | 0.57 | 1.80 | 4.82 | 6.07 | 48.96 |
| No. 3 | 83.28 | 0.69 | 1.78 | 8.26 | 6.07 | 47.05 |
| No. 4 | 89.10 | 0.50 | 1.30 | 3.47 | 5.08 | 48.55 |
| No. 5 | 88.97 | 0.55 | 1.30 | 3.50 | 4.68 | 48.02 |

The flow chart from raw magnesite ore, calcining, hydrating and purifying, secondary calcining to sintering is shown in Figure 1. Raw magnesite ore is crushed and ground to 90% below 200 mesh.

1) Magnesite calcination: Magnesite powders are fed to the suspension calciner by 1.6 t/h, to have 0.7 t/h primary CCM.
2) First stage hydration: primary CCM is put into a water tank with agitating vane. After 1 hour, suspension solution of MgO and magnesium hydroxide is generated. Undecomposed magnesite, grains and contamination are removed from suspension solution by precipitation.
3) Second stage hydration: Suspension solution overflows from first tank to second tank with heating instrument and stirrers. The temperature of suspension solution is adjusted according to increasing solution quantity. Entire hydration is completed in this stage, which takes 2 hours at the temperature of 90–100 °C. The impurities of $SiO_2$ and $Fe_2O_3$ are precipitated to reduce their contents on the levels of $SiO_2$ < 0.15% and $Fe_2O_3$ < 0.25%.

4) Chlorination stage: magnesium hydration solution flows to third tank and remains certain temperature of 90–100 °C. By adding hydrochloric acid and/or $MgCl_2$, CaO is solved in the solution for separation. Finally, at least 90% Mg $(OH)_2$ is acquired in the solution.

5) Calcining magnesium hydroxide powders: After de-watering, magnesium hydroxide powders are calcined in a suspension calciner, to produce secondary CCM.

6) Briquetting and sintering: Secondary CCM briquettes are sintered at the temperatures of 1,400°C, 1,500°C and 1,600°C for 5 hours in maffle furnace, 1,650°C, 1,700°C and 1,750°C for 5 hours in tunnel kiln.

*Fig. 1: Flow chart of magnesia purification and densification*

## 3. RESULTS AND DISCUSSION

### 3.1 Flash decomposition in suspension calciner

The flow chart of magnesite calcination is shown in Figure 2. Magnesite powders with the size of < 200 mesh are fed into dryer to mix with hot exhausted gas for removal of free water. The material is reversely flowed with hot gas to heat up itself and finally separated by multiple stage cyclones. The airstream and solid materials are in reverse flow. After calcinating, CCM powders are cooled and separated also by multiple stage cyclones, from the top of which the exhausted gas is expelled. CCM falls down to storage tank.

The concentrates paste is dried at 450 °C by reversely flowing hot gas coming from the calciner. The dried concentrates (the moisture <1%) are separated in three stages cyclones, and then fed into the lower portion of the suspension calciner. The magnesite concentrates are calcined at the temperature of 680–850 °C in the flowing movement from the bottom to the top, with hot gas, which takes about 3 seconds. Again, caustic calcined magnesia is separated by three-stage cyclones and then stored in silos with eco-friendly production. Natural gas is consumed in 1,950–2,100 m³/h, combusted with air of 40,000 m³/h and later cooled with air of 50,000 m³/h. It is a new generation of the magnesite calciner with some preferred characteristics. 1) Instantaneously calcining magnesite with the homogeneous mixture of solid and gas, as well as the large specific surface for dissociation; 2) Continuous operation, ensuring stable activity of CCM; 3) Entirely closed system under negative pressure and multiple stages separation, being eco-friendly, high productivity.

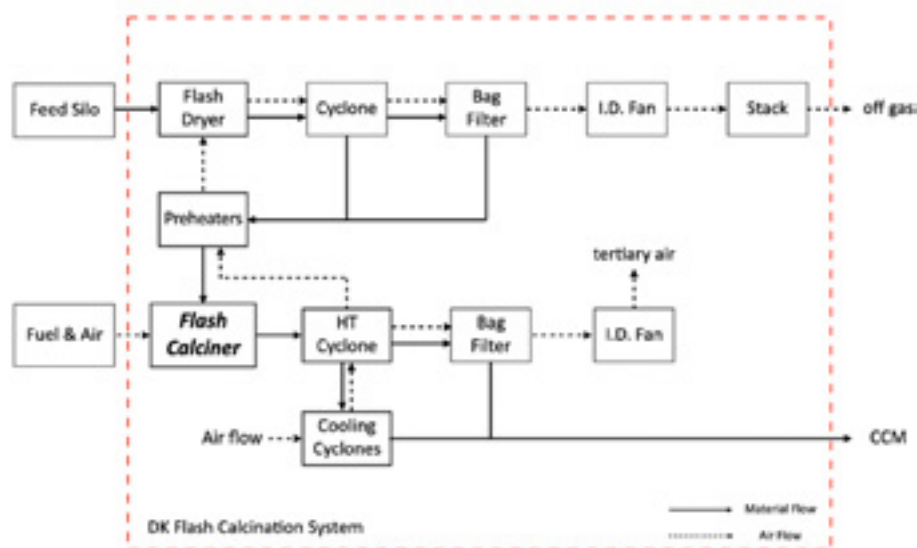

*Fig. 2: Flow chart of suspension calcination process*

The illustration and principle of suspension calciner are displayed in Figure 3, where the temperature and pressure are graphed. Fuel is completely combusted to yield high temperature gas (up to 1,400 °C), which is drawn into cyclone accelerator to mix with preheated magnesite powder. The particle size is smaller than 200 mesh. The large particles mostly receive radiation transfer heat because of high centrifugal force in spiral motion, while the small particles have more convection transfer heat. Therefore, due to high specific surface area, the particles in swirl movement are exposed to radiate heat and transfer heat within calciner. Flowed with hot gas in conjugate movement of 7–12 seconds, and moved in a route of 80–130 m, magnesite particles complete overall decomposition in the following equation, by absorbing radiate energy.

$$MgCO_3 \rightarrow MgO + CO_2$$
*Fig. 3: Illustration and principle of suspension calciner*

The calciner is operated under the negative pressure between –90 Pa and –150 Pa. The loss on ignition is controlled with the limit of 2% for primary CCM.

After hydration and purification, most of primary CCM have been transformed to magnesium hydroxide, which needs to be calcined in suspension calciner again. Eventually, secondary CCM is obtained, according to the following equation.

$$Mg(OH)_2 \ \rightarrow \ MgO + H_2O$$
The physical and chemical properties of secondary caustic calcining magnesia are listed in Table 2. Compared to the chemical composition in Table 1, secondary CCM have been significantly purified, which upgrades low grades of natural magnesite for manufacturing high grade of sintered refractory magnesia.

*Tab. 2: Physical and chemical properties of secondary CCM*

| No. | MgO wt% | Al$_2$O$_3$ wt% | Fe$_2$O$_3$ wt% | CaO wt% | SiO$_2$ wt% | Size* μm | Ac** s |

| 2Se | 96.57 | 0.15 | 0.19 | 1.46 | 0.55 | 29.55 | 17 |

*Particle size, D$_{90}$; **Activity: Reaction time with citric acid.

### 3.2 Purification in hydration process

After grinding and calcining raw ore of magnesite, primary CCM is purified in three stages, as shown in Figure 4.

*Fig. 4: Hydration and chlorination of primary CCM for purification*

In the first tank, primary CCM is in hydrating process to form a suspension of magnesium hydroxide and to precipitate undecomposed magnesite and contamination at room temperature. While the suspension is moved to the second tank, most of CCM would complete hydration at 90–100 °C.

$$MgO + H_2O \rightarrow Mg(OH)_2$$
Most of Si- and Fe- components are precipitated on the bottom of the second tank. When the suspension is drawn to the third tank, hydrochloric acid and/or MgCl$_2$ are fed to react with Ca(OH)$_2$ to form CaCl$_2$ in the solution. The following reactions take place in the third tank. In this way, CaO content is reduced in the suspension of magnesium hydroxide.

$$Mg(OH)_2 + HCl \ \rightarrow \ MgCl_2 + H_2O$$

$$MgCl_2 + Ca(OH)_2 \ \rightarrow \ Mg(OH)_2 + CaCl_2$$

$$Ca(OH)_2 + HCl \ \rightarrow \ CaCl_2 + H_2O$$
The chemical compositions of magnesium hydroxide from the second tank and from the third tank are listed in Table 3, which proves the approaches of purification are really functional.

The suspension of magnesium hydroxide, out of the third tank, is de-watered to have the paste, which is dried and calcined in the suspension calciner for secondary caustic calcined magnesia.

*Tab. 3: Chemical analyses of magnesium hydroxide powder*

| Treatment | MgO wt% | Al$_2$O$_3$ wt% | Fe$_2$O$_3$ wt% | CaO wt% | SiO$_2$ wt% | LOI wt% |
|---|---|---|---|---|---|---|
| Hydrating | 67.00 | 0.08 | 0.04 | 4.00 | 0.20 | 28.30 |
| Chlorinating | 68.88 | 0.06 | 0.12 | 0.86 | 0.33 | 29.55 |

### 3.3 Sintering of CCM

Low-grade magnesite is firstly calcined in a suspension calciner and the acquired caustic magnesia is hydrated to precipitate the impurities of $Al_2O_3$ and $Fe_2O_3$ from magnesium hydroxide suspension solution. The chlorination is then carried out to dissolve $Ca(OH)_2$ to $CaCl_2$ to reduce CaO content. After de-watering, magnesium hydroxide is calcined in the suspension calciner to produce secondary caustic magnesia.

A commercial CCM is collected for sintering comparison, which is made by magnesite flotation and calcination process. Its compositions are 97.75% MgO, 1.44% CaO, 0.48% $Fe_2O_3$, 0.33% $SiO_2$. Both CCM powders are compacted and sintered in a muffle furnace (1,400 °C, 1,500 °C, 1,600 °C) and a tunnel kiln (1,650 °C, 1,700 °C, 1,750 °C). Apparent porosity and bulk density of magnesia are displayed in Figures 5 and 6, as a function of sintering temperature. The process of calcination, hydration and chlorination, secondary calcination and sintering is called as 3-step firing. The flotation, calcination and sintering route is named as 2-step firing. It can be seen in Figure 5 that the apparent porosity is near linear reduction and down to < 2% by 3-step firing, and decreased at lower temperature and on the same level (near 10%) at higher temperature by 2-step firing.

*Fig. 5: Apparent porosity of magnesia as a function of sintering temperature*

As shown in Figure 6, the influence of sintering temperature on densification is more significate by three-step firing than 2-step firing. By hydrating and 3-step firing process, the magnesia density reaches 3.43 $g/cm^3$ after sintering at 1,750 °C, but the bulk density of magnesia directly from magnesite maximally attains the density of around 3 $g/cm^3$. It is the similar results to previous lab experiment [4].

It is hard to densify magnesia directly from natural magnesite. Only possibility is to sinter magnesia at the temperature range of 1,950–2,100 °C in a shaft kiln. Through hydration beneficiation process, it is possible to sinter and to densify magnesia at ordinarily high temperature of 1,750 °C.

*Fig. 6: Bulk density of magnesia as a function of sintering temperature*

### 4. CONCLUSION

An eco-friendly approach is developed to purify low-grade magnesite by hydrating primary calcined magnesia and precipitating impurities of Ca-, Fe- and Al-components. The resulted magnesium hydroxide powders are calcined again to acquire secondary calcined magnesia, which is compacted and sintered at various temperatures (1,400 °C–1,750 °C). By hydrating caustic calcined magnesia for precipitating impurities and firing in three steps, high purity and density of DBM97.5 have been produced at the ordinarily high temperature.

# ENHANCED PERFORMANCE OF FREE CAO IMPURITY CONTAINING MAGNESIA WITH AL$_2$O$_3$–TIO$_2$ COMPOSITE POWDER

Yibiao Xu*, Yawei Li, Zhenzhen Li

The State Key Laboratory of Refractories and Metallurgy, Wuhan University of Science and Technology, Wuhan, PR China

## ABSTRACT

Free CaO impurity containing magnesia has intrinsic shortcomings of poor resistance to hydration and thermal shock. Here, a novel approach, the introduction of $Al_2O_3$-$TiO_2$ composite powder, is proposed to enhance the performances of such magnesia in this work. The results showed that with increasing the composite powder, $CaTiO_3$ and $Mg_{1+x}Al_{2(1-x)}Ti_xO_4$ phases were sequentially formed at MgO grain boundaries, which affected the microstructure and properties of the specimens. the addition of $Al_2O_3$-$TiO_2$ enhanced the MgO grains growth and conversion of free CaO to $CaTiO_3$, and therefore weight gain rate of the specimens after hydration test reduced from 0.212 % to 0.097 % with increasing $Al_2O_3$-$TiO_2$ from 0 wt% to 7 wt%. The formed intergranular $CaTiO_3$ and $Mg_{1+x}Al_{2(1-x)}Ti_xO_4$ phases reduced the thermal expansion coefficient and induced the crack deflection, which thus siginifically improved the thermal shock resistance the specimens.

## INTRODUCTION

Magnesia is a refractory raw material widely used in industrial metallurgical furnaces owing to its high refractoriness and excellent corrosion resistance to basic slag [1]. In China, magnesia produced by cryptocrystalline magnesite usually exhibits high chemical stability and excellent thermo-mechanical properties due to the infinitesimal $SiO_2$ and $Fe_2O_3$ impurities. However, this kind of magnesia shows low hydration resistance due to the presence of free CaO [2]. Besides, magnesia raw material has intrinsic shortcoming of poor thermal shock resistance (TSR),which would shorten service life of the magnesia based refractories [3]. To improve TSR of the magnesia, several researches have been carried out in recent years. Zou et al. [4] prepared magnesia aggregates with the introduction of nanosized $Al_2O_3$. They found that the formation of $MgAl_2O_4$ phase reduced the pore size and enhanced the ceramic bonding, thus improving TSR of the magnesia aggregates. Our previous work introduced $ZrO_2$ to high purity magnesia and found that $ZrO_2$ grains would distribute at the MgO grain boundaries and perform pinning effect, which caused the crack deflection and therefore enhanced the TSR [5]. More recently, Zhao et al [6] reported that the introduction of $Al_2TiO_5$ as second phase in the magnesia matrix could effectively reduce the thermal expansion coefficient and thus improved the residual bending strength of the magnesia after three thermal cycles.

Based on the above work, it was expected that for the free CaO containing magnesia, the performance could be enhanced by the combination of $Al_2O_3$ and $TiO_2$. For one hand, the thermodynamic calculations presented in **Fig. 1** demonstrated that free CaO would preferentially react with $TiO_2$ forming high melting point phase $CaTiO_3$ (2000°C), which could eliminate the free CaO and effectively improve the hydration resistance [7]. On the other hand, $MgAl_2O_4$ and $Al_2TiO_5$ may be generated in the magnesia at elevated temperature, contributing to the superior TSR of such material [4, 6]. Therefore, in order to fully utilize the advantages of $Al_2O_3$ and $TiO_2$, micro-sized $Al_2O_3$-$TiO_2$ composite powder was added into free CaO containing magnesia in the present work and its effects on sintering behavior, phase compositions, microstructure, hydration resistance, and TSR of such refractory raw material were studied in detail.

*Fig. 1 Gibbs free energies for reactions of MgO-CaO-Al$_2$O$_3$-TiO$_2$*

## EXPERIMENTAL

The raw materials are light burned magnesia powder ($D_{50}$= 15.1 μm, MgO ≥ 96.06 wt%; 0.97wt% CaO, 0.05 wt% $SiO_2$, 0.07 wt% $Fe_2O_3$) and reagent grade $Al_2O_3$-$TiO_2$ composite powder consisting of 50 mol% $Al_2O_3$ and 50 mol% $TiO_2$. The specimens with various amounts of composite powder (0, 1, 3, 5, 7 wt%) were ball-milled for 6 h and named as MAT0, MAT1, MAT3, MAT5 and MAT7, respectively. Subsequently, the mixtures were dried, screened, and pressed into specimens with dimensions of Φ50mm×20mm under 100 MPa. Finally, all these specimens were sintered at 1600 °C for 3 h in an electric furnace in air.

The bulk density and apparent porosity were measured by Archimedes's Principle. The phase composition and microstructure were determined by X-ray diffraction (XRD, X'Pert Pro, Philips, Netherlands) and scanning electron microscope (SEM, Nova 400 NanoSEM, FEI Company, USA), respectively. The thermal expansion of the specimens was tested in Ar atmosphere by a thermal dilatometer (Anter Corp., Pittsburgh, PA). The flexural strength (3 mm×4 mm ×34 mm) before and after thermal shock tests (ΔT=1100°C, oil quenching) was evaluated by three-point bending method [5]. During hydration resistance, specimens with size of Φ20 mm×10mm were put in an autoclave and heated till the pressure reached 0.14 MPa at 134 °C. After maintaining for 3 h, the specimens were dried in an oven at 110 °C. The percentage weight gains were used to characterize the hydration resistance [8].

## RESULTS AND DISCUSSION

Fig.2 exhibits the phase compositions of the specimens after treated at 1600 °C. Only periclase phase could be found in specimen MAT0 due to its low impurity content. In specimen MAT1, apart from periclase, $CaTiO_3$ compound could be detected. With further increasing the amount of $Al_2O_3$-$TiO_2$, a composite spinel phase identified as $Mg_{1+x}Al_{2(1-x)}Ti_xO_4$ was generated, which was a solid solution formed by interdiffusion between $Mg_2TiO_4$ and $MgAl_2O_4$ [9]. Besides, as shown in Fig. 2b, the diffraction peaks of the composite spinel shifted toward lower angles as the composite powder amount increased, demonstrating that more $Mg_2TiO_4$ with a larger cell volume diffused into $MgAl_2O_4$ [10].

*Fig. 2 XRD patterns of the specimens after firing at 1600°C*

SEM images of the specimens are shown in Fig. 3. For specimen MAT0, the MgO grain size was small and some pores with a size of 2-6μm could be found. Free CaO and tiny $Ca_2Fe_2O_5$ could also be observed in the matrix, although they were not detected in the XRD patterns. As for specimen MAT1, the amounts of free CaO and $Ca_2Fe_2O_5$ reduced dramatically, whereas $CaTiO_3$ together with trace $CaAl_2O_4$ was generated at the boundaries. In the specimens MAT3, MAT5 and MAT7, apart from periclase and $CaTiO_3$, $Mg_{1+x}Al_{2(1-x)}Ti_xO_4$ solid solution could be observed, whose amount increased continuously with the $Al_2O_3$-$TiO_2$ content. Furthermore, as shown in Table 1, with increasing composite powder content, the size of both MgO grains and pores in the specimens showed an increase tendency. The mean MgO grain size of specimens MAT0 to MAT7 was 20.3, 34.1, 38.8, 49.6 and 43.8 μm, respectively. Correspondingly, the mean pore size increased from 1.2 μm in specimen MAT0 to 6.4 μm in specimen MAT7.

It can be proposed that when 1 wt% $Al_2O_3$-$TiO_2$ was added to magnesia, the CaO impurity firstly reacted with $TiO_2$ to form $CaTiO_3$ and part of the residual CaO would then combine $Al_2O_3$ to generate $CaAl_2O_4$. As the composite powder was 3 wt% or higher, all free CaO transformed into $CaTiO_3$ phase, while the $Al_2O_3$ together with residual $TiO_2$ would react with MgO to produce $MgAl_2O_4$ and $Mg_2TiO_4$ respectively, which in turn formed the $Mg_{1+x}Al_{2(1-x)}Ti_xO_4$ solid solution. The above reactions promoted mass transfer andMgO grain growth, whereas the pores were not eliminated further due to their agglomeration and growth at the MgO boundaries. Therefore, as shown in Table 1, the addition of $Al_2O_3$-$TiO_2$ had no obvious effect on the relative density.

Fig. 4a shows the flexural strength of the specimens and their residual strength after thermal shock tests. As the $Al_2O_3$-$TiO_2$ increased from 0 wt% to 7 wt%, the flexural strength decreased constantly from 161.4 MPa to 106.8MPa. Since all specimens had similar density, the reduction in flexural strength was probably attributed to the coarsening of MgO grains and pore size [11]. However, after the thermal shock tests, compared with specimen MAT0, specimens with composite powder possessed both higher residual flexural strength and residual flexural strength ratio (Fig. 4b), indicating the effective enhancement in TSR. Based on the thermoelastic theory, TSR of the composites is closely related to the thermal expansion coefficient. Fig. 5 revealed that specimens with more composite powder obtained lower thermal expansion coefficient. This was mainly because MgO ($13.8 \times 10^{-6}$/K) had higher thermal expansion coefficient than that of $CaTiO_3$ ($12.2 \times 10^{-6}$/K), $MgAl_2O_4$ ($7.8 \times 10^{-6}$/K) and $Mg_2TiO_4$ ($10.1 \times 10^{-6}$/K). As a result, less surface thermal stress would be produced in the specimens with higher composite powder, which contributed to improving the TSR. Again, the crack propagation behavior is another key factor affecting TSR [12]. As shown in Fig. 6, transgranular fracture occurred when the specimen MAT0 was subjected to thermal stress. However, for the specimens with composite powder, the $CaTiO_3$ and $Mg_{1+x}Al_{2(1-x)}Ti_xO_4$ phases induced the crack deflection and intergranular fracture gradually became the main fracture mode. The crack deflection could increase the crack path and absorb more fracture energy, leading to the enhancement of the TSR [13].

Table 1: Mean grain size, mean pore size and relative density

| Index | Grain size (μm) | Pore size (μm) | Apparent porosity (%) | Relative density (%) |
|---|---|---|---|---|
| MAT0 | 20.3 | 1.2 | 0.7 | 95.8 |
| MAT1 | 34.1 | 3.2 | 0.6 | 94.9 |
| MAT3 | 38.8 | 3.9 | 0.6 | 95.1 |
| MAT5 | 49.6 | 6.5 | 0.5 | 95.3 |
| MAT7 | 43.8 | 6.4 | 0.5 | 95.6 |
*Fig. 6 Crack propagation in the specimens after thermal shock tests*

After the hydration test, the weight gain rate of the specimens is shown in Fig. 7. It can be found that the weight gain rate decreased from 0.212 % to 0.156 % when 1 wt% $Al_2O_3$-$TiO_2$ was introduced, and further reduced to 0.107 % as the composite powder increased to 3 wt%. With further increasing the composite powder content, the weight gain rate of the specimens showed a negligible change. Specimens MAT3, MAT5 and MAT7 exhibited an obvious improvement in hydration resistance, whose weight gain rate was approximate half that of the pure MgO specimen. XRD patterns of the specimens after the hydration test are shown in Fig. 8. In specimen MAT0, the characteristic diffraction peaks of newly formed $Ca(OH)_2$ hydrated products could be detected. As for the specimens with composite powder, the diffraction peaks of the $Ca(OH)_2$ phase disappeared completely. Besides, the diffraction peak intensity of $Mg(OH)_2$ hydrated product decreased sharply when the composite powder increased from 0 wt% to 3 wt% but had a negligible change with further increasing the content of composite powder. Fig. 9 presented the SEM image of the specimens after the hydration test. For specimen without composite powder, plenty of granular $Ca(OH)_2$ and lamellar $Mg(OH)_2$ hydrated products were formed on the outer surface, demonstrating the occurrence of serious hydration reactions. The hydration processes preferentially occurred in the CaO grains, which resulted in formation of cracks on the surface and sustained hydration of CaO and MgO in the inner part of the specimen [7]. As 1 wt% composite powder was added into the magnesia, obvious decrease in the amount of both $Ca(OH)_2$ and $Mg(OH)_2$ could be found. As for specimens MAT3, MAT5 and MAT7, only a trace of $Mg(OH)_2$ hydrated product could be observed on their outer surface, indicating the effective suppression of the hydration processes. These XRD and SEM observations were entirely consistent with the results of weight gain rate shown in Fig. 9.

Combining the hydration test results with the phase and microstructure evolutions, the significant improvement in hydration resistance by adding $Al_2O_3$-$TiO_2$ could be proposed. i) Due to the increased MgO grain size and decreased grain boundaries, diffusion channels for water vapor into the inner part of the specimens declined, which retarded the hydration processes [14]. ii) The free CaO transformed into high hydration resistant phase $CaTiO_3$, eliminating the CaO hydration and effectively improving the hydration resistance of the raw material [7].

*Fig. 7 Mass gain rate of the specimens after the hydration test*

*Fig. 8 XRD patterns of the specimens after the hydration test*

*Fig. 9 SEM images of the specimens after the hydration test*

## CONCLUSIONS

The effects of $Al_2O_3$-$TiO_2$ composite powder on the sintering behavior, phase composition, microstructure, hydration resistance, and TSR of free CaO containing magnesia were investigated in the present study. The main conclusions can be drawn as follows:

(1) With increasing the composite powder, $CaTiO_3$ and $Mg_{1+x}Al_{2(1-x)}Ti_xO_4$ phases were sequentially formed at MgO grain boundaries, which promoted MgO grain growth but had little effects on the density owing to the agglomeration of pores. Due to the conversion of free CaO to $CaTiO_3$ and MgO grains growth, hydration resistance of the specimens was improved effectively by introducing the composite powder.

(2) The addition of $Al_2O_3$-$TiO_2$ composite powder reduced the flexural strength of the magnesia due to the coarsening of MgO grains and increase of pore size. However, TSR of the specimens improved gradually with the composite powder content attributing to the reduction in thermal expansion coefficient and occurrence of crack deflection.

# THE PREPARATION OF ELECTRICAL−GRADE MAGNESIA FROM MICROCRYSTALLINE MAGNESITE

Zhixun Li*, Xiaoli Tian, Runtang Feng,Tianqing Li
Puyang Refractories Group Co.,Ltd, Puyang, Henan 457100, PR China

**ABSTRACT**
The preparation of electrical grade magnesia from microcrystalline magnesite in the Sichuan Tibet area is made by melting at 2800 ℃ in an electric arc furnace. Then broken and sorted according to content from MgO. High-temperature electrical grade magnesia powder was prepared by crushing, screening, iron removal, modification, and other processes.After studying its properties. The results show that the flow rate of the prepared high-temperature electrical grade magnesia powder is 150 ± 20s/100g, compaction density is 2.34 ± 0.05g/cm$^3$. In this process, the higher the MgO content, the better the corresponding electrical performance.

The electrical grade magnesium oxide prepared based on 98.5% MgO grade fused magnesia has a tube meter load of 12w/cm$^2$, the current is less than 0.30 mA, and the insulation withstand voltage strength is greater than 2500v. The durability test show that the leakage current of each electrical grade magnesium oxide decreases slightly and tends to be stable with the extension of the test time.

The high-temperature electrical grade magnesia powder prepared from Sichuan Tibet microcrystalline magnesite by electric melting has excellent electrical properties and is attributed to the unique ultra-low Fe$_2$O$_3$ content characteristics of the microcrystalline magnesite.

**KEY WORDS:** Microcrystalline magnesite, electrical-grade magnesia,leakage current

**INTRODUCTION**
Magnesite is a main natural mineral raw material in the refractory industry[1-2]. According to the different crystalline states, it is generally divided into crystalline magnesite with complete cleavage and amorphous magnesite with dense structure, high hardness and colloidal form[3]. Magnesite in the Sichuan-Tibet area is called microcrystalline magnesite because it has dense, fine, smooth, hard and brittle texture, uniform ceramic-like macrostructure, typical lattice constant and complete crystal morphology[4]. It has the characteristics of high purity and low iron content. Electrical grade magnesium oxide is an electrically fused magnesium oxide produced by melting Magnesite at high temperature in an electric arc furnace. It is crushed and matched with different particle sizes (mesh size) according to a certain proportion. It is directly or modified and used in tubular electric heating elements as an insulating medium for heat conduction at high temperatures. It has excellent insulation performance and thermal conductivity[5]. The application of electrical grade magnesium oxide is very wide. For civil use, it is mainly applicable to high-grade stainless steel tubes such as microwave oven tubes, Bread machine tubes, oven heating tubes, and Ingley tubes. High-end products can also be used to produce insulation materials in fields such as aviation, aerospace, and nuclear power[6]. Relying on the high purity and low iron properties of Sichuan-Tibet microcrystalline Magnesite, electrical grade magnesia is prepared, and expect to obtain products with superior electrical performance and high-cost performance.

**1. EXPERIMENT**
**1.1 Experimental materials**
The microcrystalline magnesite in the Sichuan-Tibet is fused in an electric arc furnace at 2800~3000℃, and the resulting magnesium oxide was FM985, FM98, FM975, FM97 and FM965 after breaking and sorting. The chemical composition is shown in Table 1. It can be seen that the microcrystalline magnesite has a high purity and extremely low iron content.

Tab. 1: Chemical composition of the fused magnesium oxide and magnesite

| | Chemical composition/% | | | | | |
| --- | --- | --- | --- | --- | --- | --- |
| | SiO$_2$ | Al$_2$O$_3$ | Fe$_2$O$_3$ | CaO | MgO | Loss |
| Magnesite | 0.25 | 0.02 | 0.03 | 0.70 | 47.25 | 51.72 |
| FM 985 | 0.35 | 0.01 | 0.03 | 1.04 | 98.52 | 0.02 |
| FM 98 | 0.39 | 0.03 | 0.05 | 1.35 | 98.14 | 0.03 |
| FM 975 | 0.43 | 0.03 | 0.06 | 2.05 | 97.39 | 0.03 |
| FM 97 | 0.69 | 0.04 | 0.07 | 2.71 | 96.42 | 0.05 |
| FM 965 | 1.01 | 0.05 | 0.08 | 2.76 | 96.06 | 0.03 |

**1.2 Experimental method**
High temperature electrical grade magnesium oxide powder were obtained by crushing, screening, removing iron, and adding organic silicon and silicate additives to FM985, FM98, FM975, FM97, and FM965, respectively. Their physical and electrical properties were detected.

**1.3 Test method**
Chemical composition analysis: This experiment uses the PANalytical fluorescence spectrum analyzer produced by Panaco to analyze the chemical composition of microcrystalline Magnesite and fused magnesia in the Sichuan Tibet area.

Flow rate(F.R) and tap density (T.D): F.R and T.D refer to the density measured with AP901122 tap densimeter made in the USA. The method is to put 100g of magnesium oxide into a density meter 3 # Ford cup and measure the flow time and density.

Electrical performance: Electrician-grade magnesium oxide samples are filled into electric heating tubes and made into standard components. After heat treatment at 1050 ℃, they are lowered to room temperature. Electrical properties such as thermal insulation that withstand voltage strength and leakage current are tested under the corresponding tube meter load.

**2. RESULTS AND DISCUSSION**
**2.1 Effect of raw materials on physical and electrical properties**
High-temperature electrical grade magnesium oxide powder was prepared from raw materials with different magnesium contents and standard components were prepared. After heat treatment at 1050 ℃, the leakage current was tested at a tube meter load of 11w/cm$^2$ (with a detection time of 20 minutes). The physical properties and leakage current of electrical-grade magnesium oxide powder are shown in Fig. 1.

(a)

(b)

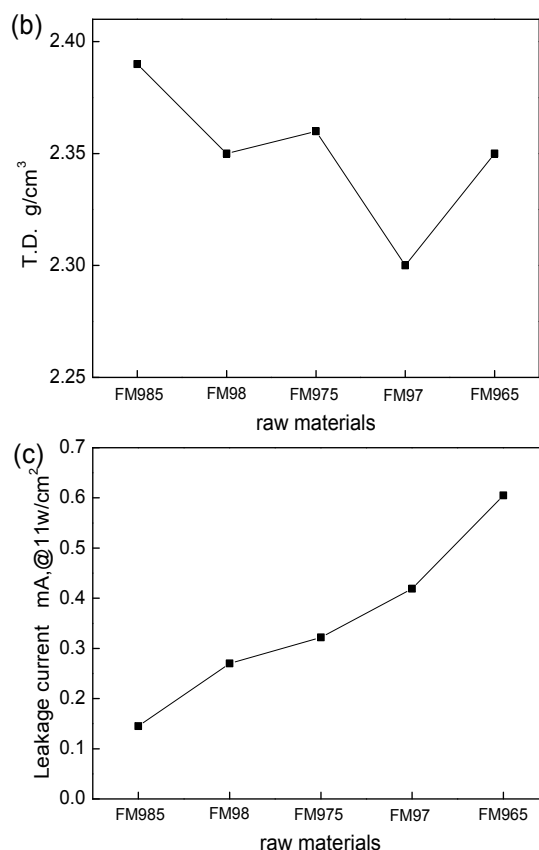
(c)


*Fig.1 Effect of raw material type on physical indexes:(a)Flow rate;(b) Tab density;(c)Leakage current*

From Fig.1 a and b, it can be seen that the high-temperature electrical grade magnesium oxide prepared from raw materials with different magnesium contents has a flow rate of $150\pm20s/100g$ and a tap density of $2.34\pm0.05$ g/cm$^3$. Fig. 1 c shows that at a tube meter load of 11w/cm$^2$, the leakage current increases with the decrease of magnesium content in the raw material, indicating that the higher the magnesium content, the better its electrical performance.

**2.2 Impact of tube meter load on electrical performance**
The high-temperature electrical grade magnesium oxide powder prepared from FM985 was tested for its electrical performance under different tube meter loads (with a detection time of 20 minutes) as shown in Fig .2.

(a)

(b)

*Fig.2 Impact of tube meter load on electrical performance：(a)Leakage current;(b)Insulation withstand voltage strength*

In Fig. 2, the electrical grade magnesium oxide powder prepared with FM985 has an increase in tube meter load from 9w/cm$^2$ to 12w/cm$^2$, the leakage current from 0.049mA to 0.291mA, a gradual decrease in insulation withstand voltage strength from 3250V to 2520V, an increase in tube meter load from 12w/cm$^2$ to 13w/cm$^2$, a sharp increase in leakage current from 0.291mA to 0.558mA, and a rapid decrease in insulation withstand voltage strength from 2520V to 1350V. Therefore, the high-temperature electrical grade magnesium oxide prepared with FM985 has a tube meter load of less than 12w/cm$^2$, a leakage current of no more than 0.3mA, and an insulation withstand voltage strength of more than 2500V. Higher tube meter load has potential safety risks.

**2.3 Durability test**
The standard component is made of electrical grade magnesium oxide using FM985 as the raw material. As the tube meter load of 12w/cm$^2$ ,it is continuously tested for 10080 minutes, and the leakage current value is recorded as shown in Fig. 3. a. The 0-60 minute portion is enlarged, as shown in Fig. 3. b.

(a)

(b)

*Fig.3 FM985 Durability test:(a)for 10080min; (b)for 60min*

In Fig. 3. a, with the increases of testing time, the leakage current of the standard components prepared with electrical grade magnesium oxide gradually decreases and tends to stabilize. Fig.3.b shows that the leakage current rapidly increased 2 minutes before the test, reaching a maximum of 0.292mA in about 12 minutes, and then stabilized.

The high temperature electric grade magnesia powder prepared by electric melting of Sichuan-Tibet microcrystalline Magnesite has excellent electrical properties, thanks to its microcrystalline Magnesite with unique ultra-low $Fe_2O_3$ content. The characteristics of low iron effectively reduce the leakage current during the use of electric heating components and increase their withstand voltage performance.

## 3. CONCLUSIONS

The flow rate of high-temperature electrical grade magnesia powder prepared from Sichuan Tibet microcrystalline Magnesite is $150 \pm 20s/100g$, and the compaction density is $2.34 \pm 0.05g/cm^3$. The higher the content of magnesium oxide, the better the corresponding electrical performance.

The electrical grade magnesium oxide prepared using FM985 has a tube surface load of $12w/cm^2$, a current of less than 0.30 mA, and an insulation withstand voltage strength greater than 2500v. As the testing time prolongs, the leakage current slightly decreases and tends to stabilize.

High temperature electrical grade magnesia powder prepared by electrofusion of Sichuan-Tibet microcrystalline Magnesite has excellent electrical properties and its attributed to the unique ultra-low $Fe_2O_3$ content characteristics of the microcrystalline magnesite.

# EFFECT OF CALCINATED CONDITIONS ON THE PREPARATION OF HIGH-LY ACTIVE MAGNESIUM OXIDE FROM MICROCRYSTALLINE MAGNESITE

XuePei, Wang[1], Xiaoli TIAN[1]
1.Puyang Refractories Group Co., Ltd (PRCO), Puyang, 457100, PR China

## ABSTRACT

The effect of magnesite, calcination time on the activity of magnesia was studied using microcrystalline magnesite from Tibet as raw material. The activity of magnesium oxide was determined by iodine absorption value method. The chemical compositions, phase compositions and microstructure of the magnesium oxide with different iodine absorption value were analyzed by XRF, XRD and SEM. The results indicated that the magnesium oxide obtained the lower activity prepared at lower or higher calcinated temperature. When the particle size of the ore was 3-1 mm and the calcinated temperature was 600 °C for 4 hours, the highly active magnesium oxide with iodine absorption value up to 160 mg/g was prepared successfully. The relationship between the crystal morphology and the iodine absorption value of the magnesium oxide prepared under different conditions was established.

**KEY WORDS**：High active; magnesium oxide; calcination time; iodine absorption value

## INTRODUCTION

In recent years, with the development of technology, the demand for refractory materials in the steel and metallurgical industries has been increasing [1-2].Microcrystalline magnesite is one of the raw materials for refractory production and the main source of magnesium. It has the advantages of high purity and less impurities. Magnesium oxide (MgO) is an ionic compound belonging to the cubic crystal system, Fm3m space group.The activity of magnesium oxide refers to its ability to participate in chemical or physical processes, which can be expressed by the iodine absorption value (adsorption performance index). The greater the activity of magnesium oxide, the greater the iodine absorption value [3].When the iodine absorption value is 120-180 mg/g, it is called highly active magnesium oxide, when the iodine absorption value is 50 ~ 80 mg/g, it is medium active magnesium oxide, and when the iodine absorption value is 19 ~ 43 mg/g, it is low active magnesium oxide.Highly active magnesium oxide has the characteristics of small grain size and large specific surface area, which is conducive to promoting the solid-state reaction [4].As a new type of adsorption material, it also has great application prospects in wastewater treatment [5].In this work, the effect of calcination time on the activity of magnesia was studied by iodine adsorption method using Xizang microcrystalline magnesite as raw material, in order to provide reference for the preparation of high activity magnesia.

## 1. EXPERIMENTAL PART

### 1.1 Reagents and instruments

Experimental reagents include carbon tetrachloride, (AR, Tianjin Fengchuan Chemical Reagent Technology Co., LTD.);Iodine, anhydrous ethanol (AR, Tianjin Yongda Chemical Reagent Co., LTD.);Potassium iodide (AR, Tianjin Kaitong Chemical Reagent Co., LTD.);Sodium thiosulfate (AR, Tianjin Hengxing Chemical Reagent Manufacturing Co., LTD.);Deionized water (homemade).

The phase composition of the sample was detected by PANalytical X'pert Pro diffractometer.The microstructure of the samples was observed by JEOLJSM-6360 scanning electron microscope.Kang's oscillator (Jintan Xicheng Xinrui Instrument Factory);The iodine adsorption value was detected according to the national standard HG/ T3928-2012 "Industrial Active Light magnesium Oxide".

### 1.2 Experiment

**Preparation of magnesium oxide**

The microcrystalline magnesite with particle size of 1-3 mm was put into a Muff furnace, and the calcination time was set for calcination after the temperature was raised to 600 °C.After cooling to room temperature, the product is sifted 100 mesh after vibration grinding and set aside.

**Activity determination of magnesium oxide**

Determination of iodine adsorption value: accurately weigh about 1 g sample, pour 50 mL iodide carbon tetrachloride (I-CCl₄) solution, shock on the oscillator for 25 min, and then quickly move the solution in the bottle to the stopper colorimetric tube, cover the stopper tightly, and stand in the dark for more than 10 min until the solution is clarified.Remove 10 mL of clear iodine-carbon tetrachloride, place it in 250 mL conical bottle, add 20 mL potassium iodide ethanol solution, and titrate with sodium thiosulfate standard titration solution until colorless solution is the end point.At the same time, a blank experiment was carried out according to the following steps: Remove 10 mL iodide-carbon tetrachloride solution, place it in 250 mL conical bottle, add 20 mL potassium iodide ethanol solution, and titrate with sodium thiosulfate standard titration solution until colorless solution was the end point.

The iodine absorption value is measured by $x_1$, and the value is expressed in milligrams of iodine per gram of magnesium oxide ($mgI_2/gMgO$), calculated according to formula (1) :

$$\chi_1 = \frac{(V_2 - V_1)cM}{m(10/50)} \qquad (1)$$

Formula:
$V_1$: The value of sodium thiosulfate standard titration solution volume consumed by titration test solution, in milliliters (mL);
$V_2$: The value of the volume of sodium thiosulfate standard titration solution consumed by titrating the blank test solution, in milliliters (mL);
c: The exact value of the concentration of sodium thiosulfate standard titration solution, in moles per liter (mol/L) (c=0.1 mol/L);
m: The value of the mass of the sample, in grams (g);
M: The number of moles of iodine in grams per mole (g/mol) (M=126.9)

The arithmetic mean of the parallel determination results was taken as the determination results, and the absolute difference between the two parallel determination results was not more than 0.5 mg/g.

## 2. RESULTS AND DISCUSSION

### 2.1 Chemical composition and phase composition of highly active magnesium oxide

The raw material used in the test is Xizang microcrystalline magnesite, and its chemical composition after heat treatment with different calcination time is shown in Table 1.It can be seen that the main component is MgO, which has high purity and belongs to low-silicon and low-iron magnesite. With the extension of calcination time, the content of MgO gradually increases and the LOSS value gradually decreases.

Tab. 1: Chemical composition of highly active magnesium oxide after different calcination time.

57

| Time | SiO$_2$ | Al$_2$O$_3$ | Fe$_2$O$_3$ | TiO$_2$ | CaO | MgO | Loss |
|------|------|------|------|------|------|------|------|
| 1h | 0.34 | 0.07 | 0.04 | 0.04 | 1.45 | 68.80 | 29.26 |
| 2h | 0.36 | 0.14 | 0.05 | 0.05 | 1.76 | 71.27 | 26.37 |
| 3h | 0.34 | 0.15 | 0.03 | 0.04 | 1.57 | 74.37 | 23.5 |
| 4h | 0.25 | 0.03 | 0.03 | 0.06 | 1.86 | 89.59 | 8.18 |
| 5h | 0.32 | 0.08 | 0.04 | 0.06 | 2.04 | 90.43 | 7.03 |
| 6h | 0.51 | 0.19 | 0.04 | 0.02 | 2.23 | 93.49 | 3.52 |

Figure 1 shows the XRD patterns of active magnesia at different calcination times. Compared with the standard PDF cards (45-0946 and 08-0479), it can be determined that the main crystal phases are cubic crystal system MgO and trigonal rhombohedral system MgCO$_3$, and a small amount of Ca impurities exist in the form of dolomite CaMg(CO$_3$)$_2$, which is consistent with the high purity obtained by chemical analysis.With the extension of calcination time, the diffraction peak intensity of MgO is stronger, the diffraction peak intensity of MgCO$_3$ is lower, and the peak shape of each peak tends to be sharp, indicating that magnesite is more fully transformed into oxide, the crystallinity of magnesium oxide gradually increases, and the structure becomes denser.

*Fig. 1: XRD patterns of MgO at different calcination time.*

## 2.2 Microstructure of highly active magnesium oxide

Figure 2 shows the SEM spectrum of active magnesium oxide for 4 h calcination time. It can be seen from the graph that its morphology is spheroidal, the average particle size of magnesium oxide is about 38 nm, the maximum particle size is 55 nm, and the minimum particle size is 25 nm. The distribution is relatively uniform, the dispersion is good, and the agglomeration is small, which promotes the activation of the lattice.

*Fig. 2: SEM images of active MgO for calcination time 4h.*

## 2.3 Influence of calcination time on LOSS

Figure 3 shows the relationship between different calcination time and LOSS of active magnesium oxide. It can be observed that when calcination time is 1h, the LOSS value reaches 29.26 % at the highest level, and gradually decreases with the extension of calcination time. At 6 h, the LOSS value reaches the lowest level of 3.52 %, with the highest MgO content, indicating that calcination is sufficient.

*Fig. 2: LOSS of active MgO at different calcination times*

## 2.4 Effect of calcination time on iodine adsorption value

The activity of MgO increases with the extension of *calcination* time. As shown in Figure 4, When calcination time reaches 4 h, the activity of MgO product obtained from the calcination of magnesite raw material is the highest, and the adsorption value of iodine is 160 mg/g. When calcination time exceeds 4 h, the activity of MgO decreases with the extension of calcination time.This indicates that the crystallization of the product is getting better and better, the crystal shape tends to be complete, and the activity begins to decrease.The activity of magnesium oxide also has a great relationship with the defects on the crystal surface, the better the crystallinity of the crystal, the more complete the crystal, the smaller the surface defect, the lower the activity of magnesium oxide[6].

*Fig. 4: Effects of calcination time on the Iodine absorption value activity of MgO*

## 3. CONCLUSIONS

Using magnesite as raw material, it was calcined at 600 ℃ and held for different time to prepare highly active magnesium oxide. Taking iodine absorption value as sample activity target, when holding time was 4 h, its distribution was more uniform, its dispersion was better, and the highest iodine absorption value was 160 mg/g, meeting the requirement of highly active magnesium oxide.

# TAILOR–MADE POLYCARBOXYLATE ETHERS TO IMPROVE PROPERTIES OF CASTABLE MIX DESIGNS

Joachim Riedmiller, Alexander Ganss, BASF Construction Additives GmbH, 83308 Trostberg, Germany

## ABSTRACT

For about 30 years polycarboxylate ethers (PCEs) are widely known as a family of tailor-made dispersants for castables containing calcium aluminate cement, reactive alumina, microsilica and aggregates improving their water reduction, wetting, and setting. By using these types of dispersants, the castables benefit from improved properties such as reduced porosity, prolonged lifetime, increased density, and strength combined with a significantly improved workability [1].

We will show how specific PCEs in combination with adequate raw materials interact and can be used to formulate custom tailored castables according to specific requirements.

PCEs are highly valuable, essential ingredients to develop and manufacture new, enhanced refractory materials.

## DISPERSING MECHANISM

The general structure of a PCE could be described as a brush having an anionic backbone containing carboxylic groups and several non-ionic sidechains made of polyethylene glycol. As soon as such molecules come closer to positively charged surfaces, such as cement grains, they will adsorb on them due to the interaction with the anionic part of the molecules and leave the outer particle sphere covered with protruding non-ionic sidechains. This arrangement is the basis for a superior dispersing power compared to purely electrostatic dispersants, such as sodium tripolyphosphate or polyacrylic acid (figure 1). The polymer side chains allow an additional long-range repulsive interaction between the inorganic surfaces according to an electrosteric dispersing mechanism leading to a creamy rheology of well-dispersed particles in high solid suspensions.

Fig. 1: Long-range electrosteric dispersing mechanism of PCE.

## POLYMER SYNTHESIS

Beside the general dispersing mechanism, the advantage of PCEs lies in the wide structural variety achieved by monomer selection, synthetic route, and polymer design leading to optimized water reduction, flowability, strength development, adjustment of set time and wetting for refractory mix designs. Sometimes the combination of several polymers or the addition of further additives provides special features such as retardation or acceleration, slump retention and robustness towards microsilica or hydrophobic particles.

One of the most common ways to synthesize PCE for refractory applications is a copolymerization of performance-relevant mono-mers, carboxylic acids and macromonomers containing the poly-ethylene glycol side chain. Alternatively, it is possible to connect the sidechain in a second step which is called grafting (figure 2). Depending on the synthetic route, the PCEs differ in their polymer structure and there are possibly restrictions for the application of additional monomers.

Fig. 2: PCE synthesis via different routes

Once a composition of monomers and a suitable synthetic route has been selected, the systematic variation of three parameters finetunes the further polymer properties (figure 3). The sidechain length of the macromonomer influences for example retardation, robustness of flow, slump retention and heat of hydration. Charge density affects the affinity towards inorganic surfaces due to the adsorption speed and therefore the wet-out time. The molecular weight is responsible for the overall dispersing power which determines dosage efficiency.

Fig. 3: Parameters providing structural variety of PCE

Modern PCE dispersants can be structurally optimized for applications in the refractory and ceramic industry with monitored purity in terms of their thermo-oxidative degradation.

## BENEFITS OF TAYLORED PCEs FOR CASTABLE MIX DESING

PCEs play a key role in the mix design of modern castables at a water amount between 4-6 %. Only such a low water amount guarantees the best castable performance with high mechanical strength, wear and chemical resistance and optimal hot properties. Thereby the workability of the material remains at a very high level. The

combination of good workability and best performance of a modern castable would not be achievable without a high-performance dispersant.

**SELECTED PCEs**

Three different PCE structures were selected for testing in a castable: a PCE with short sidechains (PCE-S), a PCE with medium sidechains (PCE-M), and a PCE with long sidechains (PCE-L). The design of the three different PCEs is optimized for the raw materials used in the refractory application (molecular weight, charge density, spacer).

Fig. 4: Schematic molecular design of the used PCEs

**TEST CASTABLE**

A low cement vibration castable was selected for the test series. The table below shows its composition:

Tab. 1: Castable composition

| Raw material | Type | Amount |
|---|---|---|
| Tabular Alumina | 0-6 mm | 84 % |
| Alumina | D50 = 3.5μm | 12 % |
| High Alumina cement | 70 % $Al_2O_3$ | 5 % |
| PCE var | PCE-S or PCE-M or PCE-L | 0.1 % |
| Water | | 4.5 % |

Three mixes were tested using the castable with the composition given in Tab. 1. To reduce the water to 4.5% and still have a good workability, each one of the three PCEs was added to the mix in an amount of 0.1% by weight of dry mix.

**TEST RESULTS FOR CASTABLE**

*Vibrational Flow*

The vibrational flow was measured with a vibrational table and a cone (100 mm x 70 mm x 50 mm).

With PCE-S a good flow of 21.9 cm after 5 minutes can be achieved. After 60 minutes the flow is slightly increased (22.8 cm). PCE-M has a moderately higher initial flow with 23.4 cm. After 60 minutes, the flow drops to 21.4 cm. PCE-L has the largest initial flow with 25.2 cm. The drop in flow, is not as prominent as with PCE-M, with less than 1 cm after 60 minutes.

The dosage efficiency of the PCE depends on the sidechain length of the polyethylene glycol. The longer the sidechain the more dosage efficient is the PCE. Shorter sidechains mean less dosage efficient. On the contrary the less dosage efficiency leads to a better slump retention over time.

An additional advantage of PCEs with shorter sidechains is the robustness towards raw material fluctuations and water deviations which is less prominent compared to the PCE with longer sidechains.

Fig. 5: Vibrational flow of test castable with selected PCEs

*Castable Setting and Strength Development*

The setting behaviour was measured by the exothermal method (EXO). Details of the method and the terminology were described by Gierisch et al. [2].

The different PCEs influence the setting of the castable significantly. In figure 6 the EXO1_ Start and EXO_Max times are given in hours and minutes. The PCE with long sidechains is the least retarding PCE. The PCEs with medium and short sidechains show a significantly stronger retardation. By choosing the right PCE, the setting and therefore the workability time can be adjusted. In colder environment, a less retarding PCE can be preferable, whereas in warmer environments a more retarding PCE can be beneficial.

Furthermore, the maximum exothermal heat (EXO_Max) is also strongly influenced by the selected PCE. The PCE with the long sidechain shows the shortest EXO_Max time. According to Kockegey-Lorenz al. [1], the EXO_Max time correlates with the strength, which is necessary for demolding of the castable and sufficient strength to transport pre-cast shapes. A shorter sidechain corresponds with shorter demolding times, which is a big advantage in handling of the hardened castable.

Fig. 6: Exothermal data of hydration

Cold crushing strength (CCS) and cold modulus of rupture (CMoR) were measured after 24h curing at 20°C. This is also commonly referred to as green strength.

The CCS and the CMoR show a direct correlation to the length of the sidechain of the PCE (Fig. 7). The longer the sidechain, the higher the strength. The explanation is, that the PCE with longer sidechains do not cover the surface of the cement as densely as shorter sidechains, hence they hinder each other more and move the PCEs further apart. As a result, the water can reach the surface in shorter time. The hydration of the cement is therefore faster and leads

to a better strength development due to the earlier formation of hydration phases.

Fig. 7: Cold crushing strength and cold modulus of rupture

## PCE FOR HYDROPHOBIC RAW MATERIALS

Dispersing raw materials with a hydrophobic surface can be very challenging. Materials with hydrophobic character are mainly carbon-containing raw materials like silicon carbide or micronized or flaky graphite. Further, metal oxides like for e.g., chromium oxide. show a hydrophobic character of the surface. If some percentages of e.g., carbon is incorporated in a castable, and a standard dispersant is added, the typical spots of non-wetted and non-dispersed particles occur, which are swimming on top of the mix (Fig. 8). The application of a modified PCE dispersant can significantly reduce this effect in carbon-containing mixes. Introducing of long polyether sidechains and hydrophobic groups into the backbone of polycarboxylate ether provide a more hydrophobic character. Incorporating of such a product into a castable mix will minimize mixing times and improve the wettability of hydrophobic components. The component is better dispersed, which leads to better overall performance. The effect of such a special PCE design is shown in a castable with carbon black. No unwetted and no undispersed particles can be observed with the optimized PCE (Fig. 8).

| Unwetted spots with a standard PCE for refractory | Good wetting a with specially designed PCE |
|---|---|

Fig. 8: Left side: insufficient dispersion of carbon black. Right side: homogeneous dispersion of carbon black

## PCE FOR MICROSILICA CONTAINING CASTABLE

A common mix design of castable includes microsilica as a matrix filler in an amount of 3-8%. Castable with these amounts of microsilica cannot be dispersed well or at all with standard PCEs. The reason is the PEG sidechains which interact with the surface of the microsilica. This interaction leads to partial flocculation of the particles and prevents a proper dispersion. Therefore, the flow is reduced or even killed. With the design of a special PCE with very short sidechains and special anchor groups, the problem can be overcome.

In the mix design of the castable from Table 1, 5% of alumina was replaced by microsilica Elkem 971 U. The water amount is kept constant at 4.5%.

If the PCE-S is used in this castable, no vibrational flow is detectable (Fig. 9). 10 cm vibrational flow means the diameter of the used cone. With a specially designed PCE for microsilica (PCE-MS), a good vibrational flow of 20.5 cm can be achieved. The flow at 60 minutes is still at 19.8 cm. The workability and casting of the castable with microsilica is therefore possible and easy.

Fig. 9: Vibrational flow of microsilica containing castable with selected PCEs

An acceptable mixing time of the refractory concrete is guaranteed due to the wet-out time of 170 seconds. This is often critical with microsilica-containing castable and is heavily influenced by the used dispersant.

The dispersant has also a strong influence on the workability time and the setting of the castable. The EXO1_Start corresponds to the end of workability which is 80 min for PCE-MS. The EXO_Max is with 20 hours and 10 minutes in the range that the castable can be demolded after 24 hours.

## CONCLUSIONS

Polycarboxylate ethers specially developed for the refractory application play a key role in the design of a modern castable. Without efficient dispersants it is not possible to reduce the water content in castable to 4-5%. This lowest possible water content leads to a high density, low porosity, high strength, and optimal hot properties. A good workability and setting time are thereby obtained. Without the optimization of the PCE structure, an adequate performance in refractory applications would not be possible.

By choosing the appropriate PCE the desired properties of the castable can be set. Wet-out time, flow retention, workability time at different temperatures and strength development can be adjusted. In addition, the choice of the dispersant depends on the type of raw materials used and is the key to optimize the properties of the castable.

All the various influencing factors must be understood to develop and use the optimal dispersant for refractory applications.

**ABSTRACT**

An overview is provided of consistent use of resource-efficient raw materials for the production of functional components for the secondary steel metallurgy, e.g. ingot casting, pouring nozzles.

In recent years, the incorporation of regionally available raw materials in particular into existing production processes has proven to be promising, both from a technological and an economic point of view. In this context, the product-specific carbon footprint is of particular importance, which is also discussed in association with its complexity in calculative considerations.

## ABSTRACT

The present study is part of the CESAREF (Concerted European action on Sustainable Applications of REFractories) doctoral network started in late 2022. The aim of the consortium is the contribution to scientific breakthroughs inherent to refractories for steel making sector thanks to transversal competences deriving from academic and industrial realities. European green deal and circular economy targets set by EU for 2025 are also related to the massive consumption of refractory materials in the steel industry. Operative lifetimes of refractories range from hours to several months depending on their role. As a result of increasingly tightened policies and disposal costs, and due to recent supply chain shortages, end-of-life refractories recovery and recycling practices are receiving great attention. Some of the core requirements for sustainability and circularity are the reduction of open-loop and down scaling strategies, to maintain refractory materials value as long as possible, of the end-of-life materials. Over the years application of numerical models has proved to be a useful strategy for researchers facing in-use issues related to refractory materials. In this study, different finite element models (FEM) applied to end-use refractories are discussed to understand their suitability for potential recyclability prediction. Thermomechanical characterization of prior- and post-use materials allow to identify the critical issues related to numerical models' development. The comparison between empirical results and the appropriate numerical model allow us to identify suitable pathways to improve refractories sustainability.

## CONTEXT

There has always been an intricate connection between society's evolution and raw materials. In fact, the common partitioning of prehistoric periods occurs through the raw materials that enabled progress: stone, bronze, and iron ages. Although advances in materials and technologies have aided development and welfare distribution, unfettered consumption and overexploitation of resources remains a driver for conflicts, geopolitical tensions, and environmental damage. Thus, we are looking for technological solutions to ensure progress, and at the same time make our way of life more sustainable by decoupling economic growth from resources use.

The recent European Union directive regarding wastes introduced a hierarchic strategy to be adopted for waste reduction and circularity improvement.[1] The preference order established by the directive is set as: prevention, re-use, recycle, recovery, disposal. Furthermore, circular economy growth is one of the strategic targets of EU's Green Deal for ensuring raw materials' solid supply chains.[2]

One of the main sectors involved in the green transition is the iron and steel industry, for which ambitious sustainability targets have been set for 2050. Starting from the iron ore to get the final product an energy intensive process is needed. World average data reports $CO_2$ emissions equal to 2 tons per ton of steel produced.[3] That is why EU is strongly pushing steel producers towards more efficient and lower energetically intensive production processes. Hence, projects such as CESAREF (Concerted European actions on Sustainable applications of REFractories) are put in place receiving great attention from the academic and industrial sectors. CESAREF is a big European consortium of universities and companies acting together with the aim of training different doctorate students on excellent science to create breakthroughs in the field of refractory materials for the steel industry.

## INTRODUCTION

Steel embodies a vast class of iron alloys containing carbon in the range between 0.002 and 2.14 wt.%. Steel making occurs through the casting process and nowadays the most used method is the continuous casting, counting for more than the 96% of total steel produced.[3] A modern continuous casting system is composed by three main parts: the ladle, the tundish, and the cooling zone (figure 1). A ladle is a big reservoir of liquid steel (able to contain from tens to several hundred tons of liquid steel) which is then poured into the tundish. The tonnage of the ladle corresponds to one heat, and the number of heats performed with one tundish corresponds to one sequence. The tundish acts as reservoir of molten steel and distributes the liquid metal into the multiple casting molds where steel solidification starts. The tundish stores a small amount of molten steel while dispensing part of this latter elsewhere with general purpose to regulate flow and achieve a steady output with intermittent inputs.

The tundish has the roles of molten steel distribution, buffering, flow control, purification, and heat loss limitation. To nicely exploit the above-mentioned functions many refractory materials are used in the tundish:

- refractories to control and homogenize the liquid metal flow in the vessel (dams, wires, impact pads, purging plugs);
- refractories to enable the steel to move safely with no oxidation limiting material and energy losses from one reservoir to the following, these products can be submerged entry shrouds (SES), submerged entry nozzles (SEN), stoppers, and slide gates;
- refractories to separate and isolate the external steel shell from the molten steel ensuring safety and energy savings, these materials are called lining refractories.

*Figure 1: elements in the continuous casting process for steel production and some of the refractory parts used for the tundish. Reproduced with the courtesy of Vesuvius plc.*

Commonly the lining refractories can be distinguished depending on their position: the working lining is directly in contact with steel and slag, the permanent lining, in between working and insulating lining, is supposed to compensate stresses and to allow operations safeness in case of working line failure; and insulating lining reduces heat exchange between the previous linings and metallic shell. Some of the above-mentioned refractories are highlighted in figure 1 and various refractory products, grouped by their applications, principal functions, main failure mechanisms, average lifetimes, and some of the possible refractory composition that are commonly used, are provided in table 1.

## STRATEGY AND PERSPECTIVES

The thermo-mechanical behavior of most of the refractory materials during operative conditions is complex and difficult to determine and foreseen. The reasons behind are their nonlinear responses to stimuli derived, in part, from heterogeneous nature and harsh operative conditions. Due to that, reliable investigations to improve refractory products lifetime require the combination of experimental analysis and computational methods, such as finite element analysis (FEA).[4,5]

Additionally, to tackle waste production, the re-use and recycling practices need to be fully exploited. In the former case, re-use, the ageing of key thermomechanical properties of the refractories during usage can be assessed and deployed, in combination with the operative conditions severity, into an adapted Failure Modes, Effects, and Criticality Analysis (FMECA). The purpose is to obtain qualitative and quantitative reliable information on the lifetime of the refractory product for a particular application. Furthermore, end-of-life refractories recycling is another key step related to sustainability. During spent material sorting, compositional evaluation, sieving, and other pivotal steps, great bottlenecks must still be overcome. On top of the technical recycling passages, a proper algorithm able to predict profitability has not been developed yet. Hence, this project will focus on the adaptation of a Multi Criteria Decision Approach (MCDA) for refractories sorting based on their intrinsic characteristics, to define recycling convenience.

### Experimental characterization and numerical modelling

Refractory materials are, for definition, supposed to resist high temperatures, chemically aggressive conditions, and various mechanical stresses. It is possible to discriminate between stress and strain-controlled loads.[6] The first are the function of the structure's geometry and its density. The latter, strain-controlled loads, can derive from thermal expansions, creep, or structural constraints. They are function of the material's properties, as for example the thermal expansion coefficient, Young's modulus, Poisson's ratio, thermal conduction, porosity, and others.[4] Refractories for steel-making industry are primarily exposed to thermal loads and, as a response, most of them undergo in softening enhancing the plastic behavior at high temperatures. This is the reason why a strong focus will be given in this project to the key thermomechanical properties variation and elastoplastic laws governing the materials behavior. In particular, attention will be paid on the evolution of thermomechanical properties from prior to after usage state. Identification of the pivotal properties and simulation, through the proper yielding function, of the material behavior, are crucial priorities to enhance the performance of the products, hence tackling the prevention step of circularity.

Refractory materials for tundish linings will be at the center of the research. For example, insulating boards composed mostly of vermiculite will be investigated. Previous works, on the carbon pick-up of similar material utilized in the ladle, identified the thermal properties degradation triggering factors. Densification, impurities diffusion, secondary phases formation, and permanent shrinkage are expected phenomena that will be experimentally assessed during this research's post-mortem experimental characterization.[7] These key properties are also related to the operative conditions such as thermal enhanced diffusion, compressive and shear stresses due to lining system's architecture, but also to the cyclical thermal gradients related to continuous charge-discharge steps. Hence, it is possible to consider periodic fatigue cycles and the proper finite element model is needed not only to identify the magnitude and location of the critical loads (thermal and mechanical), but also to further extrapolate their impact on properties degradation.

Over the years, many yield functions have been developed to explain the plastic behavior and consequent failure of various material classes. The Mohr-Coulomb, Tresca, von Mises, and Drucker-Prager are some of the most known criteria describing specific materials' yielding under particular conditions.[8,9] These above-cited yield laws show some critical drawbacks such as the necessity to evaluate shear and tensile yielding stresses to define ranges of applicability, the approximation to homogeneous material's properties, and the non-exhaustive behavior prediction in certain regimes. For these reasons, over the years, several yield criteria have been proposed. In particular, Bigoni D. and Piccolroaz A. developed a modulable criterion for which is possible to modify the yield function.[10] The model is based on a phenomenological based yield criterion (the yield function is directly obtained from interpolation of experimental data) valuable in predicting the mechanical behavior also of ceramic materials

*Table 1 : Overview of products, functions, properties, failure mechanisms, lifetime, and some of the compositions for tundish's refractories.[4,6,7,14]*

| | APPLICATION | PRINCIPAL FUNCTIONS | MAIN FAILURE MECHANISMS | LIFETIME | COMMON COMPOSITION |
|---|---|---|---|---|---|
| Steady flow control | Dam/wire/multilayer filters | Ensure uniform liquid steel flow and temperature distribution also preventing inclusion flow | Corrosion<br>Erosion<br>Thermal shock | 5-20 heats | Alumina-magnesia-carbon<br>Alumina-silica-carbon<br>High purity alumina/magnesia |
| | Impact pad | Control molten steel from ladle impact and reduce inclusions spread | Corrosion<br>Erosion<br>Thermal shock | 5-20 heats | High alumina or magnesia<br>Alumina-magnesia spinel<br>Magnesia-chrome |
| Flow control | Submerged Entry Nozzle (SEN)<br>Submerged Entry Shroud (SES) | Feed molten steel from tundish to mold, suppress oxidation and nitrogen pickup, reduced heat loss | Corrosion<br>Thermal shock<br>Clogging | 10-30 hours | Alumina-silica-carbon (body)<br>Magnesia-carbon (seat SEN)<br>Zirconia-graphite (sleeve SES) |
| | Tundish slide gate | Control liquid steel flow rate from tundish to molds | Bore hole erosion<br>Surface abrasion<br>Steel infiltration | 5-10 heats | High alumina/magnesia<br>Alumina-magnesia spinel<br>AZC (alumina-zirconia-carbon) |
| Lining | Working line | Contain molten steel ensuring operations quality and safety | Corrosion<br>Cracks propagation<br>Spalling | 5-20 heats | High purity alumina/magnesia<br>Zirconia-carbon (slag line)<br>Magnesia-Chrome |
| | Insulating line | Reduce the thermal diffusion in steel shell and energy losses | Permanent shrinkage/densification<br>Tensile/compressive failure<br>Working/safety lines failure | 20 heats - 1 sequence | Vermiculite<br>Alumina-silica fibers<br>Magnesium-silicate |

sensitive to pressure. The flexibility shown by the criterion is appreciated in the field of refractories since, during their processing and working conditions, many changes occur.

**Fatigue and Failure Modes, Effects, and Criticality Analysis**

Experimental and numerical modeling are not always sufficient for failure prediction and materials' behavior foreseen. Commonly, lifetime evaluation is a complex practice in the field of refractories used in continuous casting process due to their heterogeneous nature, complex geometry, and strong variety of stresses to which they are subjected. Additionally, the possible failure mechanisms associated to a particular product in a specific application are not due to a single parameter. Different failure mechanisms can be observed for the same refractory application. Although in recent years, the research on refractories has made great strides obtaining strongly performant materials, few researchers have applied the fatigue theory to refractory materials. This kind of analysis is widely used in many engineering fields to predict the lifetime of ductile materials such as metals. Examples are the Goodman-Haigh and Gerber diagrams frequently adopted by structural engineers in case of low- and high-cycle fatigue cases. Previous studies on refractory materials have reported several mechanical failure mechanisms under cyclic loadings. The identification of preferential cracks propagation paths, damage saturation, cracks coalescence and interlocking, and grains relocation mechanisms are a result of fatigue inside the material.[11] Furthermore, the turning point has been the link of these individuated energy dissipation mechanisms with the key thermomechanical properties of the material to define the lifetime of the material.[12]

Failure Mode, Effects, and Criticality Analysis, FMECA, is a strategy adopted in the last century to assess the operativity and reliability of a product through inductive reasoning. Essentially, the analysis consists in individuating the ways or modes in which the product could fail, understand the consequences of such failures on the products operativity and on the overall system, and finally define criticality and severity levels for each of the individuated failures and related effects.[13] The adaptation of this approach could enable a more rigorous and statistic treatment of failure analysis allowing the incorporation of fatigue in the investigation. The frame of this strategy is to improve the utilization of a product enhancing the re-use by identifying the proper actions to reduce waste generation. In this context, it is possible to perform both qualitative and quantitative analysis because of the integration of significance measure through criticality analysis. By generally adapting the quantitative evaluation of each $i$-th failure mode, the related criticality number, $C_i$, can be defined as:[13]

$$C_i = \alpha_i \beta \lambda_n t \qquad (1)$$

It is worth specifying each of the parameters composing the equation. The failure mode ratio $\alpha_i$ can be defined as the probability (expressed in decimal fraction) that the product or a part of it will fail in the $i$-type mode. It represents the diverse ways a system or a part of it fails. This number is statistically derived and is given as a percentage of the total observed failures. The condition probability, $\beta$, of operational failure represents the probability that the identified failure mode will cause the product failure due to the ageing or degradation of the key properties related to the identified $i$-type failure mode. The component failure rate $\lambda_n$ represents the number of particular $n$-parts of the product which are subjected to the $i$-type failure mechanism. At last, $t$ corresponds to the total operational time the product has been utilized.

Afterwards, a severity classification of the operational conditions is built. To do so, the numerical modeling already performed will assist the purpose. The outputs from Finite Element Analysis are the maps of stresses, strains, pressures, and other parameters. From these, is then possible to quantify operative conditions severity. Comparing the output fields to the experimentally determined key properties of the material prior usage, it is possible to classify the severity in four categories: negligible, marginal, critical, and catastrophic. Finally, the lifetime space (figure 2), including a criticality function proper for the product in the specific application, represents the link between severity conditions and probability of occurrence, or criticality number, for each system's failure modes and parts. Four different levels can be thus defined related to the fatigue and the lifetime of the material: i) unacceptable criticality, the product is considered no more suitable for that specific application, ii) high criticality, the product can be considered in necessity of repair (at the specific $n$-part) before further use, iii) and iv) moderate or low criticality, the product's resulting properties can be considered appropriate for an additional life cycle, thus tackling re-use target.

**Multi criteria approach for refractories recycling**

As previously said, during steel production the smelted material passes into several furnaces and vessels. Each of these containers has its own type of refractories used for specific needs. Thus, at first glance, the collection sorting and categorizing step is one of the first bottlenecks for refractories waste recycling. An additional blocking point in refractories recycling consists in the crushing/pulverization of the materials to remove impurities or better homogenize the end-of-life materials. But, besides these steps, it is strictly necessary from an environmental point of view and for energy and resources usage, to identify the convenience of recycling. Thus, it is important also to distinguish recycling practices. Indeed, two ways of recycling exist: closed-loop and open-loop. In closed-loop recycling, the value of the waste is considered not far from primary raw materials' value. Hence, it is possible to reprocess the materials and reintroduce them in the same circle of production. Conversely, in open-loop recycling, the operative conditions lead the material to a dramatic change resulting in lower value with respect to the primary raw materials. This latter case is common for all the refractories recycling practices put into operation currently. In literature, many cases of open-loop recycling can be found. Most of the postmortem refractories are recycled in roadbeds, slag additives or conditioners, aggregates for clinker and for the cement industry, and as soil neutralizers and flowerbeds.[14] It is evident that the closed-loop recycling has the potential to hold end-use materials' value and functionality constant. Furthermore, closed loop recycling contributes in a significant way to the development of

65

*Figure 2: Criticality space representing the criticality number and the severity relation defining refractory product's lifetime.*

circular economy. That is why the development of more powerful strategies may help in keeping up the value of the spent material as much as possible. Since there is a wide variety of aspects to consider, a multiple criteria decision analysis could be the key. After processing, refractory materials can have, for example, oxides and/or elemental impurities, steel residues, crystallographic phases developed during the operations, structural instabilities, morphological variations. Thus, it is necessary to assess the additional properties and specifications for the end-of-life material that can have an impact on further applications if inserted in a specific refractory formulation. To distinguish between valuable compositions in terms of purity, economic value, possible resulting thermomechanical properties in a refractory product, or other parameters, an interesting approach may be the adoption of multi criteria decision approach (MCDA). This latter is a strategical method to evaluate the best option or the set of more convenient options in the framework of problems involving many variables. In brief, the multi criteria problem can be mathematically seen as the need of maximization for a global value function, $U_{d_{(g_l)}}$, dependent on a marginal value function of the $x$-component possessing a certain $l$ attribute, $u_{(d_{(g_l)})}$, and the relative attribute weight, $p_l$:

$$U_{(u_d)} = \sum_{l=1}^{s} p_l u_{(d)} \tag{2}$$

where $d_{(g_l)}$ corresponds to the evaluation vector of the $x$-component with $l$-th attributed in the level $g$.

With this strategy, a study has been recently performed on the feasibility of the application of a linear multicriteria decision analysis coupled with an on/off criteria to sort spent refractories, also in the frame of sustainable targets. [15] The study proved the good versatility of the method and the possibility of its adaptation to end of life refractories case. Big rooms for improvement are still needed and a proper adaptation to the case of recycling is necessary but a glimpse of feasibility has been observed.

## CONCLUSIONS

European Green Deal has set big technological and scientific challenges for steel making sector to achieve sustainability, circularity, and environmental impact requirements for 2050. CESAREF consortium aims to help in creating breakthroughs in the field of refractory materials for steel making transferrable also to other sectors. For this research, focus will be put on the refractory materials for the tundish linings. One of the possible strategies to tackle the European challenges considering as reference key steps, the waste hierarchy can be the identification of the key properties to be assessed depending on the refractory application requirements. The tested properties may be used as inputs in numerical simulations to obtain a clear view of failure and yielding phenomena occurring in refractories. Furthermore, key properties aging, obtained from the comparison of pre- and post-usage refractories, linked with fatigue theory could help refractory producers in more rigorous evaluation of products lifetime. The dependency of properties degradation, operational conditions, and statistical information may be considered for an adapted Failure Modes Effects and Criticality Analysis to obtain reliable qualitative and quantitative investigations of the refractory materials conditions. Moreover, a linear algorithm has been proposed and further tests in that way will be presented soon to optimize it for specific cases. Besides prevention and re-use, to tackle recycling in literature, a large variety of cases have been observed in the frame of open-loop recycling. Hence, big efforts are needed to progress in closed-loop recycling. Many factors must be considered to efficiently solve the recycling reliability problems related to the spent refractory materials. To take forward this bottleneck, a Multi Criteria Decision Analysis (MCDA) has been proposed. This latter approach has recently proved to be efficient for refractories wastes disposal in sustainable framework. Therefore, it opened possibilities for its adaptation in the case of reliable and predictive recyclability determination.

## ABSTRACT
Refractories based on MgO are the dominating lining materials for vessels in steelmaking and refining plants. To preserve limited resources and establish regional raw material supply chains, alternative resources for graphite are required. Pellets from sunflower seed hull and wood were converted into carbon and added to a MgO-C batch. After hardening and carbonizing the MgO-C samples, their phase composition, microstructure, cold crushing strength, refractoriness under load, and oxidation resistance were investigated. The addition of carbonized wood and sunflower seed hull pellets reduced the CCS due to an inhomogeneous microstructure. The RuL is at the same level as the reference samples. The addition of carbonized biomass pellets has in particular a positive effect on the oxidation resistance, resulting in 30 % less carbon oxidation of wood pellet coke compared to carbon black at 1600 °C.

## INTRODUCTION
Refractories based on MgO and C are the dominating lining materials in steel making and refining plants, like basic oxygen furnaces (BOF), electric arc furnaces (EAF), and steel ladles [1]. The MgO and carbon raw materials are bonded by high carbon-containing pitch or resin and may contain some metallic powder as antioxidants to protect the carbon from oxidation. Due to the carbon portion, MgO-C bricks possess excellent thermal shock resistance by the increased thermal conductivity and reduced thermal expansion as well as a microstructure-flexible binding characteristic of the carbon bond. Carbon also reduces the slag corrosion due to the non-wettability resulting in a reduced interaction and infiltration depth. Furthermore, carbon serves as a pressing aid during production, whereby the open porosity of MgO-C bricks is greatly reduced in comparison to fired MgO bricks. Hence, carbon plays a key role in the production of MgO-C refractories. The refractory industry is by far the largest consumer of natural graphite, accounting for approximately 46 % of global consumption of 947,000 t in 2018 [2]. Natural flake graphite is commonly used as a carbon carrier since it is the most stable modification of carbon [3]. Due to the resulting low surface energy of the flakes, their reaction potential is very low and is poorly wetted by all kinds of liquids such as slags and molten metals. A further advantage of graphite is its structural high oxidation resistance [4]. Recent investigations showed an improvement in MgO-C bricks by partially replacing flake graphite with expanded graphite [5,6]. However, the expanded graphite has a high specific surface, which limits the amount to less than 1 % without reducing the oxidation resistance. Carbon black is another main carbon source for refractories. However, carbon black is only limited used in MgO-C due to its low primary particle size. The low particle size increases the amount of liquid binder needed to be added to the batch and has lower oxidation resistance, but enables an optimal pore filling of the bricks resulting in higher corrosion resistance. New types of MgO-C have been developed using nano carbon black, especially for the production of MgO-C with low carbon content. The nanometer carbon black favours the dispersion of carbon particles, which filled the tiny spaces, pores, and gaps in the matrix between the MgO particles and thus improves the properties [7–9]. The predicted surge in demand for natural graphite by the growing battery industry marks serious competition in raw material supply for the refractory industry. But this can be a great opportunity for the refractory industry to focus on alternative carbon sources. In this regard, carbon black was partially replaced by wood and sunflower seed hull pellet coke and the impact of the carbonized biomass on the properties of MgO-C was investigated. The use of biomasses, which are zero $CO_2$ emission resources that only release the amount of $CO_2$ that was picked up during their lifetime, as a carbon source in MgO-C refractories would support the refractory industry in their effort in establishing regional raw material supply chains, saving fossil raw materials, and reducing the $CO_2$ emission.

## MATERIALS AND METHODS
Representative subsamples of the pellets were ground to particle sizes below 200 µm. During a long-term pyrolysis (carbonization) at 750 °C for 2 h (heating rate of 10 K·min-1), the biomass raw materials were thermally converted in the absence of air (nitrogen atmosphere) to liquid products such as pyrolysis oils, which were evaporated and had left the retort furnace, and solid secondary products such as pyrolysis coke including ash. The latter can serve as a carbon source in a refractory mixture. Next to MgO-C with the carbonized wood and sunflower seed hull pellets, MgO-C with carbon black and nano carbon black, respectively, were prepared as reference materials. All compositions contain coarse flaky graphite as a fixed carbon source. The compositions are displayed in table 1.

Tab. 1: Composition of the test specimen.

| Raw material | Composition (wt.-%) | | | |
|---|---|---|---|---|
| | MgO-C_CB | MgO-C_nCB | MgO-C_WP | MgO-C_SFSH |
| MgO 98 2-4 mm | 17.0 | 17.0 | 17.0 | 17.0 |
| MgO 98 1-2 mm | 29.7 | 29.7 | 29.7 | 29.7 |
| MgO 98 0-1 mm | 34.3 | 34.3 | 34.3 | 34.3 |
| MgO 98 powder | 16.8 | 16.8 | 16.8 | 16.8 |
| Graphite NFL | 1.1 | 1.1 | 1.1 | 1.1 |
| Carbon black N991 | 1.1 | - | - | - |
| Nano CB N-220 | - | 1.1 | - | - |
| Wood pellets coke | - | - | 1.1 | - |
| Sunflower seed hull pellets coke | - | - | - | 1.1 |
| Powder resin | 1.5 | 1.5 | 1.5 | 1.5 |
| Liquid resin | 1.5 | 1.5 | 1.5 | 1.5 |
| Hardener | 0.3 | 0.3 | 0.3 | 0.3 |

The raw materials used for the preparation of the MgO-C samples were the in-house produced wood (WP) and sunflower seed hull

pellets (SFSH) cokes, magnesium oxide with a purity of 98 % (QMAG, Parkhurst, Australia), flaky graphite NFL (Graphit Kropfmühl AG, Hauzenberg, Germany), carbon black MT Thermax N-991 Powder (Lehmann & Voss & Co.KG, Hamburg, Germany), and nano carbon black N-220 (Penta Carbon GmbH, Haltern am See, Germany). Liquid resin 9308-FL, powder resin 0235 DP, and hexamethylenetetramine hardener (all Hexion, Duisburg, Germany) were used as binders. The liquid resin was heated up to 70 °C in a temperature control unit and added to the coarse MgO fractions. After mixing for 5 minutes, the MgO powder, carbon sources, powder resin, and hardener were added and mixed for another 5 minutes to achieve a homogeneous distribution of the raw materials in the mixture. After the mixing process, cylinder-shaped samples with a height of 50 mm and a diameter of 50 mm were pressed with a uniaxial press and an applied pressure of 120 MPa. After pressing, the samples were hardened by a three steps thermal treatment with a maximum temperature of 180 °C. Afterwards, the samples were placed in SiC retorts, covered by petrol coke (0.2–2 mm, Müco, Essen, Germany), and carbonized in an electrically heated furnace at 1000 °C for 5 h.

The density and open porosity of the carbonized samples have been analysed according to EN 993-1 using toluol as the test medium. The microstructure has been examined utilizing an SEM equipped with EDS (Philips XL 30 ESEM FEG, Eindhoven, The Netherlands). The phase composition of milled powders of the samples after carbonization was performed by X-ray diffraction analysis (XRD) using a PHILIPS diffractometer (CuKα-radiation, K-alpha1 [°A] = 1,54060), whereas the evaluation and the portion of phases were calculated by Rietveld refinement method using the High-Score Plus 4.8 software (Malvern Panalytical B.V./NL). The cold crushing strength (CCS) has been evaluated using the TIRATest 2420 machine (TIRA, Schalkau, Germany) according to EN 993-5 with a 100 kN load cell. The loading rate was 2 mm·min-1 till a preload of 10 N and henceforward 1 N·mm2·s 1 till a maximum load of 100 kN or a dF of 50 % (load drop after reaching maximum load FH). The determination of the refractoriness under load (RuL) was carried out according to DIN EN 993-8 up to 1600 °C with a constantly applied load of 0.2 MPa under an oxidizing atmosphere with a heating rate of 10 K·min-1. One of the main focuses of the work is the impact of biomass coke on the oxidation resistance, as it has been found, that potassium causes an increase in the Boudouard reaction rate in the temperature range of 800–1200 °C [10]. For the oxidation resistance test, the cylindrical samples were placed in an electrically heated furnace (heating rate of 10 K·min-1) under ambient conditions at 1600 °C with 2 minutes of dwell time. During the test run, the weight loss of the samples was detected by a scale. Additionally, the samples were cut into halves and the degree of oxidation (area of carbon combustion $C_{loss}$) was calculated by

$$C_{loss}=(A_s-A_c)\cdot A_s^{-1}\cdot 100\ \% \qquad (1)$$

with the initial sample area $A_s$, and the area of carbon-containing sample portion $A_c$, both detected using a digital light microscope (VHX-2000 D, Keyence International, Mechelen, Belgium).

## RESULTS AND DISCUSSION
### Microstructure, phase composition, and physical properties of MgO-C with different carbon raw materials

None of the applied carbon sources (carbonized wood and sunflower seed hull pellets, carbon black, and nano carbon black) showed a negative effect on the manufacturing of the MgO-C samples. For instance, no differences in the mixing process, sticking at the pressing tools, or sticking of petrol coke at the samples could be observed. In the SEM, at low magnification, no significant differences in the microstructure of the samples with varying carbon sources could be detected. The microstructure consists of coarse and fine MgO grains, flaky graphite, and a MgO-

and carbon-containing matrix. Differences in the homogenization or a distinct pore-filling effect compared to the MgO-C reference material could not be observed. Within the MgO grains, for instance, monticellite (CaO·MgO·SiO2 – CMS) as a single impurity and CMS enclosing a FeP-rich phase together with merwinite (3CaO·MgO·2SiO2 – $C_3MS_2$) could be detected. The carbonized wood pellet coke grains appear very porous, which results from the loss of the volatile components of the biomass pellet.

Due to its comparatively low accuracy, no differences in the phase composition of the MgO-C samples by the addition of different carbon sources could be detected with the XRD method. The X-ray diffraction spectra show intense peaks of MgO and carbon. Secondary phases with a low peak intensity are calcium magnesium silicate impurities of the MgO raw material such as monticellite, merwinite and iron-containing phases. Potassium-containing phases originating from the biomass coke ash could not be detected with the XRD method and hence would represent a portion with an amount of far below 1 wt.-%.

*Fig. 1 Bulk density (black squares) and open porosity (triangle) of the MgO-C samples after carbonization at 1000 °C.*

Figure 1 displays the bulk density and open porosity of the MgO-C samples after carbonization at 1000 °C. The reference MgO-C material with carbon black as a fine graphite source has a bulk density of 2,89 g·cm-3 and an open porosity of 16.8 %. The addition of nano carbon black slightly reduces the density to 2.76 g·cm-3 and increases the porosity to 17.2 %. In contrast, with the addition of carbonized wood and sunflower seed hull pellets, respectively, no significant change in the density and porosity compared to the MgO-C reference material is detectable. Hence, the amount of the added porous wood pellets coke is too low to have a negative impact on the porosity of the whole MgO-C sample. Additionally, the volatile components of the cokes would have left the system through the pore channels during the carbonization of the MgO-C samples without generating additional porosity

### Thermomechanical properties of MgO-C with different carbon raw materials

*Fig. 2: Cold crushing strength of the MgO-C samples after carbonization at 1000 °C.*

Figure 2 shows the cold crushing strength of the samples with different carbon sources after the carbonization at 1000 °C. The reference MgO-C sample with 1.1 wt.-% carbon black addition has the highest CCS of 19.65 MPa. Even if the addition of 1.1 wt.-% carbonized wood and sunflower seed hull pellets doesn't have a notable effect on the bulk density and open porosity, a significant decrease in the cold crushing strength could be detected. Here, a trend is notable, that the carbonized SFSH pellets with a lower amount of carbon and higher amount of ash result in an even lower CCS of 12.36 MPa compared to the carbonized wood pellets (14.56 MPa). The lower CCS of sample MgO-C_SFSH compared to the reference sample MgO-C_CB could be explained by the lower amount of carbon in the raw material (approx. 96 wt.-% in carbon black vs. 85 wt.-% in the carbonized SFSH), which is vital in the degree of the carbon-bond.

However, this doesn't explain the lower CCS of the sample MgO-C_WP with the carbonized wood pellets with a similar carbon content to carbon black. But the WP coke has a higher $d_{50}$ grain size of 150 μm compared to carbon black of 57 μm, which will reduce their contribution to the bonding. The CCS of the sample MgO-C_nCB with nano carbon black addition queues with 7.64 MPa between the reference sample and the biomass-based carbon sources.

Table 2 summarizes the results of the RuL testing. The MgO-C samples with carbon black and nano carbon black haven't shown compression until the maximum test temperature of 1600 °C, which underlines the very high refractoriness of MgO-based refractories. As expected, the addition of 1.1 wt.-% wood pellet coke with an ash content of 2.76 wt.-% slightly reduces the refractoriness, whereby the maximum elongation has been reached at a temperature of 1595 °C ($T_{00}$). The first characteristic temperature of the RuL testing ($T_{01}$) of sample MgO-C_WP is above the maximum testing temperature of 1600 °C, indicating still very good refractoriness. Also as expected, the sunflower seed hull pellet coke with a higher ash content of 10.45 wt.-%, which predominantly contains potassium, has an impact on the refractoriness of MgO-C, resulting in a maximum elongation at 1584 °C. But again, a $T_{01}$-value could not be detected, which means that the softening doesn't occur suddenly but takes place over a longer range of increasing temperature. With $T_{01}$-values above 1600 °C, the samples MgO-C_WP and MgO-C_SFHS exhibited very good refractoriness. Especially in the case of sample MgO-C_SFHS containing about 0.06 wt.-% $K_2O$, this is a positive finding. Hence, the biomass coke won't remarkably lower the maximum operating temperature of MgO-C.

Tab. 2: Maximum elongation $dL_{max}$ and its temperature ($T_{00}$) of the MgO-C samples after the RuL testing.

| Sample | $dL_{max}$ (%) | $T_{00}$ (°C) |
|---|---|---|
| MgO-C_CB | >1.85 | >1600 |
| MgO-C_nCB | >1.79 | >1600 |
| MgO-C_WP | 0.983 | 1594.5 |
| MgO-C_SFSH | 0.969 | 1583.5 |

**Impact of carbon raw materials on the oxidation resistance of MgO-C**

*Fig. 3: Mass loss of the samples during heating to 1600 °C.*

In figure 3, the mass loss of the samples during heating to 1600 °C is displayed, which is equivalent to the loss of carbon and hence the resistance against oxidation. The starting temperature of the oxidation of the carbon and its degree is complex and strongly depends on the type and modification of the carbon such as being present as crystalline graphite or in an amorphous state, the grain size and the specific surface of the raw material, the carbon-bond type, and the microstructure (porosity) of the composite [11]. The oxidation of the porous wood pellet coke (Sample MgO-C_WP) starts at a temperature of 418 °C, whereas the sunflower seed hull pellet coke in sample MgO-C_SFSH start to oxidize at 447 °C, the carbon black in the reference sample MgO-C_CB at 491 °C, and the nano carbon black in sample MgO-C_nCB at 520 °C, respectively. All samples exhibited a comparatively high oxidation resistance indicated by not being fully oxidized during the oxidation test. Sample MgO-C_nCB with nano carbon black showed not only the latest starting temperature of oxidation but also the highest resistance against oxidation with a total mass loss of 1.87 %. The biomass pellet cokes exhibited a similar oxidation resistance with a mass loss in the range of 2.3-2.35 %. But taking the higher amount of fixed carbon into account, the porous wood pellet coke has some advantages in oxidation resistance compared to the sunflower seed hull pellet coke. Furthermore, both samples with biomass coke had a higher oxidation resistance than the reference sample MgO-C_CB, where a mass loss of 2.75 % was detected. Next to the mass loss, the oxidized area $C_{loss}$ as an additional degree of oxidation resistance was detected. After cutting the cylinders after the oxidation resistance testing, no significant differences are visual. Table 3 lists the area of carbon combustion calculated using Eq. 1 (mean value of both cut cylinder halves) and additionally summarizes the starting temperature of carbon oxidation and mass loss. Based on the light microscope evaluation, sample MgO-C-nBC with nano carbon black addition showed an oxidized area of 8.9 % and hence the highest oxidation resistance. Sample MgO-C_WP containing the coarse porous wood pellet coke exhibited an oxidized area of 10.8 %. The lowest oxidation resistance was identified at the reference sample MgO-C_CB (15.0 %) and sample MgO-C_SFSH (16.5 %).

Tab. 3: Area of carbon combustion ($C_{loss}$), temperature of starting carbon oxidation ($T_{ox}$), and mass loss of the samples during heating to 1600 °C.

| Sample | $C_{loss}$ (%) | $T_{ox}$ (°C) | Mass loss (%) |
|---|---|---|---|
| MgO-C_CB | 15.0 ± 1.5 | 491 | 2.75 |
| MgO-C_nCB | 8.9 ± 1.5 | 520 | 1.87 |
| MgO-C_WP | 10.8 ± 1.0 | 418 | 2.35 |
| MgO-C_SFSH | 16.5 ± 1.6 | 447 | 2.30 |

**CONCLUSIONS**

The carbonization of wood pellets results in a porous coke with a $d_{50}$ particle size of 150 μm, a carbon content of 94.78 wt.-% and 2.76 wt.-% of a $SiO_2$, and CaO-rich ash. The sunflower seed hull pellets coke is fine-grained with a $d_{50}$ of 57 μm and is composed of 84.92 wt.-% carbon and 10.46 wt.-% of ash containing approx. 50 wt.-% $K_2O$. The addition of 1.1 wt.-% of the alternative carbon sources hadn't influenced the manufacturing, the microstructure, and the phase composition. Also, no significant change in the density and porosity compared to the MgO-C reference material by using carbonized wood and sunflower seed hull pellet coke could be detected, whereas the nano carbon black slightly increases the open porosity from 16.8 to 17.2 %. However, compared to carbon black, the wood pellet and sunflower seed hull coke reduce the CCS of MgO-C by 25 to 35 % due to higher particle size or lower amount of carbon, respectively. As expected, the addition of 1.1 wt.-% wood pellet coke or sunflower seed hull pellet coke with an ash content of 2.76 and 10.46 wt.-%, respectively, slightly reduces the refractoriness, but with $T_{01}$-values above 1600 °C, both samples surprisingly exhibited very good refractoriness. Especially in the case of sample MgO-C_SFHS containing about 0.06 wt.-% $K_2O$, this is a positive finding. Both biomass cokes start to oxidize at lower temperatures than carbon black and nanometer carbon black but exhibited still a comparatively high oxidation resistance. Sample MgO-C-nBC with nano carbon black addition showed the highest oxidation resistance. The lowest oxidation resistance was identified at the reference sample MgO-C_CB and sample MgO-C_SFSH. Thus, the results show, that for MgO-C with a low amount of C, the carbon black could be replaced by biomass coke without a significant reduction of the properties. An ideal biomass coke for the refractory industry shouldn't be porous and should exhibit a particle size below 40 μm, a high carbon content of more than 95 wt.-% and a low ash content of less than 30 wt.-% with a minor amount of alkalis. Biomass cokes which meet these requirements will be appropriate to replace parts of the natural graphite portion of a MgO-C batch, which would support the refractory industry in their effort in establishing regional raw material supply chains, saving fossil raw materials, and reducing $CO_2$ emission.

# SQUARING THE CIRCLE: CHALLENGES & OPPORTUNITIES IN RECYCLING REFRACTORY MINERALS

Mike O'Driscoll

IMFORMED, Epsom, United Kingdom

The strive towards the Circular Economy has boosted the evolution of recycling industrial waste, and spent refractories are no exception. The drive for sustainability has increased the potential of recycling refractory minerals as technical and economic challenges in their sourcing, processing, cost, and distribution receive growing attention and solutions. While refractory recycling is not new, it is now fast becoming a mainstream activity, even a necessity, rather than its previous perception as an esoteric sideshow. There are several drivers for recycling refractory minerals, among which are overreliance on limited sources, increasing challenges and costs in opening new mines, and logistics. The upshot is that a new supply chain option of recycled refractory minerals is now evolving to meet both market demand and environmental expectations. At the same time it has also encouraged growth in a parallel sector developing and supplying technology and equipment for refractory recyclers. Although there is much interest in recycling, it still remains a fledgling sector, with a small but expanding group of pioneers, regional contrasts, and with many challenges. Some big players are only just starting to get into action, while many others are still assessing their strategic approach. Today's waste sources will be tomorrow's new mineral resources, and the refractory industry needs to make this happen. This paper will outline the current status, the main players, and spotlight the key challenges and opportunities in recycling refractory minerals.

# LATEST ADVANCED DEVELOPMENTS IN THE IMPLEMENTATION OF CIRCULAR ECONOMY STRATEGY IN THE REFRACTORY WASTE MANAGEMENT

Aintzane Soto, David Maza, Miguel Ángel Mangas, Sidenor Investigación y Desarrollo S.A, Basauri, Spain.

## ABSTRACT

The reinforcement of the environmental policies that started taking place during last decades, has pushed steel producers to implement Circular Economy criteria in their waste management. However, in the case of refractory waste, a great part of it is still being dumped into landfills, since the valorisation solutions developed for every kind of refractory waste are not thoroughly implemented.

In Sidenor, the research work developed through internal continuous improvement projects and the European LIFE 5RefrAct and RFCS E-CO-LadleBrick projects, has allowed to implement systematically the Circular Economy 4R Model in the routine of the refractory waste management. This approach includes advanced solutions for every kind of refractory waste considering the potential "Reduce", "Reuse", "Remanufacture" and "Recycle" available alternatives.

On the one hand, several laser based technological equipment have been tested in Sidenor´s plant in order to optimise the ladle life and thus, "Reduce" the amount of refractory waste that is generated. Commercial equipment allow to have information about the wear rate in hot conditions and it can be joined with the process variables in order to optimise and extend the life of the refractory lining.

On the other hand, for the different kind of refractory waste generated in the meltshop, a number of innovative "Reuse", "Remanufacture" and "Recycle" applications have been identified and implemented in the routine, taking into account the economic and environmental benefits associated to them. A Decision Algorithm has also been developed to assess the selection of the best valorisation alternative in every case.

**Keywords:** refractory waste, bricks, Circular Economy, 4R Model, laser, thickness, valorisation.

## INTRODUCTION

The economic system known as Circular Economy that aims at minimising waste, has been widely integrated and applied in the steel sector, specifically in the valorisation of Electric Arc Furnace (EAF) slag, EAF dust, Ladle Furnace (LF) slag or iron scale. However, hardly any work has been developed in the management of refractory waste, at least in a systematic and integral way.

*Fig. 1: Teardown of the ladle in Sidenor*

Considering the potential for valorisation of spent refractories (see the waste condition in Fig. 1), in 2012 Sidenor meltshop operational staff found a very unexplored and unexploited market. At that moment, in Sidenor only the 7% of refractory waste was valorised, while the rest was directly sent to landfill. This scenario seemed to be similar in the rest of the steelworks, and prompted the research of possible actions that could lead to increase the valorised percentage.

This is how Sidenor started a continuous improvement initiative with the aim of minimizing the refractory waste disposal in landfills. At first, a working group involving staff from the Steelworks and the Environmental and Purchasing departments was created. At that time, from the total amount of refractory waste generated (Fig. 2), the recoverable fraction corresponded to MgO-C bricks and High Alumina waste (bricks and ladle consumables).

*Fig. 2: Refractory waste distribution*

With the aim to increase the recoverable fraction, Sidenor initiated in 2017 the local ISOVAL project (co-funded by IHOBE, the Basque Government Environmental Department) valuing the waste from the Isostatic refractory parts.

Considering that MgO masses (not recoverable so far) accounted for almost half of the refractory waste generated in the steelworks, Sidenor started in 2018 the coordination of the European project 5REFRACT LIFE Programme, where, in cooperation with refractory manufacturers such as MAGNA or Refralia, developed high value added refractory products incorporating a significant amount of recycled refractory. It included solutions for the Magnesia-Carbon and High Alumina waste (increasing the value added with respect to the previous solutions), and for the Isostatic scraps and Magnesia masses.

In parallel to this work, Sidenor also started in 2019 another coordination work related to the European RFCS project E-CO-LadleBrick, where, according to the 4R model, combined a Reduction of the volume of Magnesia-Carbon waste by means of monitoring the ladle refractory consumption with a laser developed by Tecnalia (via remaining brick thickness optimisation), with new processes for Reusing, Remanufacturing and Recycling the ladle spent bricks. The final optimized application came from an expert decision algorithm performed by the FGF and the LCA studies done by the Danish company 2.0 LCA Consultants.

## CIRCULAR ECONOMY IMPLEMENTATION

The main actions that were required to start implementing the Circular Economy model in the refractory waste management in Sidenor, are the following:

1) Adopt the 4R model: Reduce, Reuse, Remanufacture and Recycle.

2)  Separate the waste directly in its points of generation: through containers in a devoted colour, labelled with the name of each type of waste for the small volumes, and a bunker separated with walls and its corresponding labelling for the large volumes.

3)  Include all the partners in the value chain: refractory manufacturers, external valorisation agents and steel producers.

## 1R: Reduce

To reduce the amount of waste generated in the meltshop, specifically in the case of MgO-C bricks from the ladles, the useful life of the bricks must be extended as much as possible. To do so, and always working on safe conditions, it is necessary to optimize the consumption of refractory material during the processes involved in the steelworks.

First, it is necessary to know the wear rate of the refractory lining during its operation, at high temperature conditions. So far, the only information available was the remaining refractory thickness measured after the selective demolition of the ladles, in cold conditions, and after the end of their useful life. The problem is that this does not allow the life of the ladle to be extended or reduced depending on the process conditions.

To monitor the remaining refractory thickness of the ladles during the operation, in the E-CO-LadleBrick project, Tecnalia developed a low cost 3D laser scanner. Due to some process limitations, within the project, it was necessary to use a commercial equipment to obtain a significant amount of immediate measurements (Fig. 3) with which to make decisions. In the case of Sidenor, Ferrotron's LaCam Mobile equipment was rented for 3 months.

*Fig. 3: Ladle remaining thickness measurements with the Ferrotron equipment*

Thanks for the knowledge of the remaining thickness in every point inside the ladle, heat by heat, it was possible to analyse the effect of the secondary metallurgy operating variables on the wear, and thus build a Machine Learning predictive model of refractory wear in ladles.

## 2R: Reuse

Bearing in mind the environmental and economic impact of the valorization of refractory waste, it is important to search for the biggest amount of refractory waste to be internally reused (without any processing operation on the waste involved).

As a usual practice, Magnesia-Carbon and Alumina spent bricks obtained from the EAF and LF lining are separated and palletised in a systematic way, and placed in a specific area inside the meltshop for the pallets disposal.

MgO-C bricks are directly reused in application such as the EAF Pre-Wall, the emergency ladle, the EAF wear lining reparation and the upper rows or the slag pot lining. In the case of Alumina bricks,

they can be reused in the ladle tapping spout or in the lining of the pits built for cooling or safety purposes in the meltshop.

## 3R: Remanufacture

This alternative requires a processing operation by an external valorisation agent and the consequent return of the transformed reclaimed refractory to be used again in the meltshop. For that reason, the Purchasing department of Sidenor contacted and negotiated with different waste companies to apply the necessary processing of the material to be used in a new application.

As a remanufacture application can be highlighted the EAF breast (Fig. 4), replacing the usual mixture material composed of dolomite lime and magnesia masses, by a transformed Magnesia base new recycled and more efficient refractory at lower cost. Other alternatives could be the routes, the pavements, EBT filling, backfiller in the ladles, the vacuum shield filling or slag formers and conditioners.

*Fig. 4: EAF Breast remanufactured refractory*

## 4R: Recycle

Most of the refractory waste that could not be internally reused, or remanufactured for a different use in the steelworks, was definitely sent to an external valorisation agent that, after some transformations, delivered the material to other companies (mainly refractory manufacturers) in order to make a different product. This is the case of the MgO-C in bulk (including the finest parts), the alumina consumables, the isostatics and the MgO masses.

With MgO-C in bulk and with the MgO masses, a new gunning product incorporating up to 70% of refractory waste was developed and industrially employed in the EAF slag line gunning and in the ladles top ring gunning. Other Magnesia base materials were also produced for the EAF steepbank or the EAF breast.

In the case of Alumina waste and Isostatics, a new recycled refractory concrete incorporating up to 65% of spent material was produced. This new product is already implemented in the routine in applications like the ladle lip, the ladle lip segments, the Continuous Casting cooling chamber or the tundish lids.

## CONCLUSIONS

The excellent and coordinated work performed in Sidenor during the last 11 years in this field, has positioned our company as a

73

world benchmark in the Refractory Waste Management, reaching global refractory recovery levels over 95%.

In addition, all of the valorisation solutions that were developed and summarized in this paper, are currently implemented in the routine in the meltshop of Sidenor.

It was also demonstrated that the methodology applied required the commitment of managers and employees in the adequacy of the facilities and procedures in order to achieve a correct segregation of the different refractory waste and the further employment of the recycled products.

It was also of paramount importance to allocate more resources and to bet on new ambitious research projects where, with the collaboration of refractory experts, it could be possible to continue investigating and exploring other non-recoverable fractions, like some years ago happened with the MgO masses (successfully recycled for the first time by Sidenor).

# ESTABLISHING CIRCULAR ECONOMY FOR REFRACTORIES IN CEMENT APPLICATIONS BY ADVANCED RECYCLING TECHNOLOGIES

Sandra Königshofer, Martin Geith,
RHI Magnesita GmbH, Leoben, Austria.

## ABSTRACT

RHI Magnesita is committed to sustainability and the establishment of a circular economy for the refractory industry. However, extending recycling strategies and the use of secondary raw materials can be challenging due to the manifold of used products in tailor-made lining concepts for various industries withstanding tremendous conditions. Consequently, spent refractory bricks are subjected to intensive material alteration and infiltration, matrix conversion and microstructural changes. Further considering mixed storage of different breakout materials, adhering impurities, and adjacent lining materials, it becomes evident that sorting and cleaning is crucial. Typically hand sorting is still the standard to allocate spent refractory bricks into different secondary raw material categories. This paper illustrates how the 3.5-year ReSoURCE (Refractory Sorting Using Revolutionizing Classification Equipment) project funded by the EU in June 2022, led by RHI Magnesita, aims to innovate the full process chain of refractory recycling by the development of an automated sorting system with AI-supported multi sensor equipment as its core technology. Focussing on the example of the recycling of spent refractory bricks from cement rotary kilns, representative sampling, material characterization and appropriate treatment will be presented that allows RHI Magnesita to provide sustainable products with significantly lower carbon footprint and to support customers from cement industry in reducing $CO_2$ emissions.

## THE RESOURCE PROJECT

Establishing a circular economy for the refractory industry by extending recycling and the use of secondary raw materials is indispensable. The reuse of spent refractories by the refractory producers is already a standard for selected product types of certain industries with no significant level of contamination, and the recycling business itself has continuously grown during the last years. However, to further extend the use of, especially high-quality, secondary raw materials and to develop innovative and economic recycling technologies is challenging for different reasons. One complication is that within a lining multiple refractory product types with different chemistries are combined individually for each customer to achieve the required performance. During service the original installed refractories wear because of occurring stresses or dissolve due to the harsh process conditions and environments of the customer's process. Besides, refractories are subjected to material alteration and infiltration, matrix conversion and microstructural changes. When considering the complex mix of remaining materials, including impurities stuck to their surface and materials nearby, it becomes clear that hand sorting often provides the most effective method of processing these materials. However, manual sorting is strongly dependent on the experience of trained personnel, who classify the material based on visually recognizable secondary characteristics such as colour or particle shape, and can only be used for the sorting of the coarse particle size fraction of spent refractory bricks (~ >80 mm). The finer parts (~ <80 mm), currently manually unsortable, are either landfilled, used as metallurgical additive or raw meal addition. Automated sorting per se, potentially capable of determining also primary characteristics such as chemistry, is a standard processing method for several mining applications and conventional recycling branches (e.g., glass, plastics) already. However, reliable automated sorting solutions for this intricate task of refractory recycling could not be established so far. Hence, a multitude of proof-of-principle trials have been performed by RHI Magnesita, confirming the need

for combining different sensor technologies as commercially available sensor-based sorting solutions were not able to achieve the required product qualities. Therefore, RHI Magnesita has initiated the ReSoURCE project and applied for the Horizon Europe funding program together with a team of globally leading technology partners (LSA GmbH, Norsk Elektro Optikk AS, Innolas Laser GmbH, Fraunhofer ILT, Montanuniversität Leoben, SINTEF AS, CPI Centre for Process Innovation Ltd, Crowdhelix Ltd.). The project with an overall budget of 8.5 million EUR was funded by the European Union totalling 6 million EUR and aims to revolutionize the entire process chain of refractory recycling by introducing AI-supported multi-sensor sorting equipment as the central technology. Combining laser-induced breakdown spectroscopy, hyperspectral imaging and 3D object recognition with optimized pre-processing, and automated ejection systems will lay the foundation to set a new state-of-the-art for refractory sorting. Besides allowing a fast integration in the present established daily business, during this 3.5-year project a reliable and robust sorting system will be developed that allows to handle the entire particle size fractions by building two demonstrator units to sort the breakout materials precisely. On top further possible application areas for residues will be explored. ReSoURCE aims to improve the current recycling situation by increasing the share of recycled material reusable in refractories from 15 % to about 37.5 %, decreasing landfilling from 30 % to 5 % and enhancing downcycling from 5 % to 7.5 %. Reaching these ambitious goals will lead to massive annual $CO_2$ reductions (up to 800 kilo tonnes), energy savings (up to 760 GWh) and saving in landfill capacity (up to 800 kilo tonnes) in the European Union (see Figure 1). The continuous monitoring of the economic and ecologic benefits by techno-economic analysis and life cycle assessment will ensure the green and digital transformation of the refractory recycling value chain. [1], [2]

*Fig. 1: Ambitious goals set in the ReSoURCE project [1].*

## RECYCLING OF SPENT REFRACTORY BRICKS FROM CEMENT ROTARY KILNS

One of the first tasks in ReSoURCE, was the selection of appropriate breakout materials as feedstock based on the evaluation of the refractory market in terms of volumes, availability, and lining compositions to determine materials having the highest impact regarding environmental and economic benefits to be used during the project. Here, spent cement rotary kilns bricks proved to

be one of the most suitable choices with high potential for refractory recycling as large quantities in sufficient quality are readily accessible on an annual basis with a high number of installed aggregates worldwide. This was also confirmed at on-site visits of cement producers by evaluating the breakout procedure during their winter repairs. Furthermore, sustainability and the associated reduction of $CO_2$ emissions play a key role in the cement industry, and environmental friendly refractories will contribute to decarbonize their supply chain and related scope 3 emissions. It is well known that spent refractories from cement rotary kilns contain substantial process-related contaminations, such as high levels of Na, K, S or Cl originating from the clinker primary raw materials [5] or the enhanced use of alternative fuels, especially in Europe. The evaporation of related volatile phases in the burning zone of the kiln in conjunction with the transport into cooler kiln areas connected with the formation of recondensation products lead to the formation of so-called alkali-sulphate-circles. Therefore, spent cement rotary kiln bricks are infiltrated with alkali salts (-sulphates and -chlorides), even penetrating the pore structure of the refractories. To tackle these challenges that diminish quality, and to enhance recycling practices to be able to offer sustainable solutions to cement customers, RHIM has pioneered a patented treatment method. [3], [4]

**Representative sampling**

An extensive material characterization is the foundation for the development of innovative processing methods. For performing such detailed investigations, representative samples of these inhomogeneous breakout material streams are required. Spent refractories can differ considerably from the originally produced refractory material. For instance, they are subjected to intensive material alteration and infiltration, which affects the chemical and mineralogical composition and leads to matrix conversion and microstructural changes from the hot to the cold face. Moreover, after dismantling often large tonnages of mixed product types in different size fractions and of a different degree of contamination are stored together in outdoor material boxes without weather protection. Consequently, all these circumstances effect the reliability and validity of the analytical results of the samples for quality control and material characterization purposes. Hence, finding appropriate sampling procedures is a declared target of the ReSoURCE team. To draw representative samples certain instructions and standards exist that were evaluated to be applicable for this special case of spent refractories. Sampling should be done randomized and follows a probabilistic approach, so that every grain has theoretically the same probability of becoming part of the representative sample. The prerequisite for this is that the entire quantity of the material to be sampled is accessible. Thus, the entirety of the breakout material (in this case about 50 tons) was spread out and a sampling scheme was created depending on the size of the heap by dividing the grid area into subsections. Based on data from initial inspection, the particle size of the spent bricks was determined and the number of individual samples and their quantity to take within the subsections was calculated. Before combining the individual samples to one combined sample, several steps of sample processing and splitting were performed for each sample. The described sampling scheme and the sampled sections are shown in Fig. 2. [6]

*Fig. 1: Sampling scheme (top) and sampled sections (bottom).*

**Chemical and mineralogical material characterization**

The performed investigations and analyses for the chemical and mineralogical characteristics proved, as expected, that the sampled breakout material consists of different magnesia-spinel based product types, typically installed in cement rotary kilns. The major components of the combined sample are MgO >80 % and $Al_2O_3$ ~10 %, and the main mineral phases are periclase, and spinel. As concerns the degree of infiltrated alkali salts the total amount of $Na_2O$, $K_2O$, $SO_3$ and Cl varied up to ~8 % in examined brick sections of the hot, middle and the cold face. Tab. 1 gives an overview about the chemical analysis of the combined sample, taken from the cement rotary kiln breakout material. It is clearly visible that additionally to the main refractory oxides infiltration by alkali-sulphates and alkali-chlorides can be detected.

Tab. 1: Average analysis of cement rotary kiln recycling material from representative sampling, 1) analysis by XRF, 2) elementary analysis.

| components | [wt%] |
|---|---|
| MgO [1] | 85.5 |
| $Al_2O_3$ [1] | 8.6 |
| CaO [1] | 1.4 |
| $SiO_2$ [1] | 0.8 |
| $Fe_2O_3$ [1] | 1.8 |
| MnO [1] | 0.07 |
| LOI | 3.8 |
| Na [2] | 0.1 |
| K [2] | 2.0 |
| SO3 [2] | 0.8 |
| Cl [2] | 1.0 |

The chemical analysis was confirmed by detailed microscopic investigations of polished sections by incident light and SEM, showing besides magnesia and spinel as main mineral phases the

presence of chloride- and sulphate-bearing reaction phases (alkali salts) in Fig. 3-5, e.g., sylvite (KCl), calcium-langbeinite ($K_2Ca_2(SO_4)_3$), arcanite ($K_2SO_4$), anhydrite ($CaSO_4$), aphthitalite $K_3Na(SO_4)_2$.

*Fig. 3: Microscopical overview of a cement rotary kiln recycling material: magnesia (1). spinel (2). alkali salt (3).*

*Fig. 4: Detail of cement rotary kiln recycling material by SEM: periclase (1), spinel solid solutions (2), forsterite (3), calcium sulphate (4) and calcium-langbeinite (5).*

*Fig. 5: Detail of cement rotary kiln recycling material by SEM: periclase (1), spinel solid solutions (2), forsterite (3), sylvite (4) and arcanite (5).*

Hence, for the development of the ReSoURCE's automated sorting equipment, material characterization is of key importance for the definition of sorting criteria and classes as well as for validating the accuracy and performance of the sorting equipment.

**Developed and patented treatment method [3]**
As stated previously, usually spent cement rotary kiln bricks are infiltrated with alkali salts and therefore exceed the specifications as concerns the limit values for the contents of Na, K, Cl and S. (see chem. analysis in Tab.1). Thus, these have been considered unsuitable for the use as recycling materials in the past due to the negative influence on the brick properties and related brick production problems. For this reason, RHI Magnesita has developed a patented treatment method to minimize the alkali salt contamination of spent cement rotary kiln bricks and to enable the reuse as recycling materials for high-quality brick brands. R&D Leoben carried out comprehensive studies on spent bricks from different European cements plants, showing a diverse degree of contamination and included contaminants, with the result that a treatment by washing was most promising as the vast majority of contaminants, as described in the material characterization section before, proved to show a good water solubility. Various lab trials and parameter studies towards the development of an effective and efficient washing procedure were conducted with crushed material. The efficiency increased with decreasing particle size and improved process execution. For the effectiveness the appropriate water quantity and washing time, also considering the saturation limit of water by adjusted process control, are decisive. Fig. 6 provides an overview on the achieved alkali salt reduction, whereby an overall reduction of ~70 % of all salts could be achieved. On closer examination of the reduction of the individual constituents, it revealed that the washing treatment was most efficient for chloride-bearing phases and lower for sulphate-bearing phases explicable by their lower water solubility.

*Fig. 6: Alkali salt reduction for the washing of five different spent cement rotary kiln bricks (0-5 mm) [3].*

The washed material and the untreated material were used for brick production trials, applying the same recipe (20 % recycled material) and process parameters (firing at 1,600 °C in a tunnel kiln), in comparison to standard bricks only consisting of primary raw materials. With increasing content of recycling material, also problems during brick production could be observed (e.g., bricks sticking together, evaporation of volatiles, crack formation) leading to the defined value of 20% recycling content tested in these trial series. Bulk density (BD), open porosity (OP), cold crushing strength (CCS), and refractoriness under load (RuL) were measured to assess the physical properties of the produced bricks. Tab. 2 shows that due to the application of the newly developed and patented washing process, the physical properties could be

improved compared to the untreated material, and also no problems during brick production could be observed. Bricks containing untreated recycling material showed a decrease of the BD, an increase of the OP and reduced RuL (T0) compared to bricks containing virgin raw material or washed material. This enhancement is caused mainly by the reduction of volatile substances and low melting phases. In comparison to the untreated material, especially the RuL (T0) reached similar values to the standard bricks. The CCS values of the bricks were within the usual range of the standard production of this brand for all investigated samples.

Tab. 2: physical brick properties comparing washed with untreated material and standard bricks [3].

| Recycled material content | BD [g/cm³] | OP [%] | CCS [MPa] | RuL T0 [°C] |
|---|---|---|---|---|
| virgin raw materials (0%) | 2.95 | 15.3 | 68 | 1,520 |
| untreated material (20%) | 2.90 | 17.6 | 65 | 1,396 |
| washed material (20%) | 2.93 | 16.2 | 77 | 1,502 |

## ESTABLISHMENT OF A CIRCULAR ECONOMY – THE ANKRAL LC SERIES

Circular economy will be one of the main drivers to significantly reduce $CO_2$ in the refractory industry, as the energy-intensive primary raw material production has by far the highest impact on the product's carbon footprint. The use of washed secondary raw material in the ANKRAL LC (low carbon) series paves the way to products with significantly lower $CO_2$ footprint without compromising technical requirements and specifications by the partly substitution of primary raw materials, such as magnesia. However, to establish circular economy and to ensure the high-quality of recycled materials, customer collaboration is required, as depicted in Fig. 7 RHI Magnesita actively assists cement plants when breaking out the lining. Separate and dry storage of different brick types after demolition is preferred to support manual sorting and cleaning at RHI Magnesita's recycling hubs before the recycled materials are re-introduced to the brick production process. [4]

While the described solutions provide satisfactory results, the projected strong growth of recycling demand in future makes it inevitable to work on the next generation of recycling technologies. Automated sensor supported sorting of various grain size fractions will not only allow to increase the feedstock availability but will as well indicate contamination levels required for further optimization of the subsequent post-treatment.

## CONCLUSIONS

There's no question that one of the biggest challenges the industry faces today is decarbonization. RHI Magnesita is taking the initiative to reduce $CO_2$ emissions to provide diverse customers with sustainable products. The automated sensor-based sorting will be pivotal in significantly boosting recycling volumes in the future, all while maintaining the quality of secondary raw materials and thereby also the performance of the recycling containing final product.

Due to the enormous complexity of this task, RHI Magnesita has established the ReSoURCE project, aiming to redefine the standard for refractory sorting and leverage this new technology to benefit related processes. Ensuring a consistent, representative sampled supply of feedstock materials is critical for realizing these innovative steps.

The significance of thorough R&D work becomes evident when considering RHI Magnesita's ANKRAL LC series. This is a prime example of how one can achieve high-quality secondary raw materials, which will be crucial in further enhancing the recycling content in refractory products.

## ABSTRACT

Forced by economic, ecologic, or even legal causes, refractory producers want to, need, or must increase the use of secondary raw materials. It is unclear, however, how impurities which are being carried over into refractory materials from secondary raw materials influence the behavior of those refractory materials, either during the processing state or during their use in high temperature environments.

The research was carried out using a primary high alumina raw material that was selectively spiked with typical elements found in secondary raw materials. These artificially spiked raw materials were processed into cement-free high alumina monolithics by 1:1 substitution of the corresponding high alumina matrix fraction in the formulation. Regardless of the impurity, the rheology and setting behavior of the developed model refractory castables showed a very high degree of comparability with the reference material. Comparable workability allowed the production of comparable test pieces for hot wedge splitting tests. The effects on high temperature fracture behavior observed in this study can therefore be attributed solely to the impurities.

## INTRODUCTION

The literature indicates that impurities, even at low concentrations, have a significant effect on the thermal behavior of high alumina monolithic materials [1, 2]. Due to the production process, iron, titanium, and silicon are typically present in concentrations below 0.1 wt.-% (traces). Secondary high alumina raw materials are expected to contain higher levels of impurities due to previous industrial use. In particular, calcium is significantly enriched in secondary raw materials, as Ca is a major component of metallurgical slags.

A first attempt to assess the effect of sodium on high alumina calcium aluminate cement-bonded refractories was made by Alex et al. [1]. They found that monolithics spiked with up to 1 wt% Na by the addition of sodium acetate show significant changes in the thermal evolution of the calcium aluminate phases, causing increased expansion of the materials, which significantly degraded the properties of the castables. Möhmel [2] shows that considerably higher impurity concentrations can actually improve the thermal stability and thermo-mechanical properties of high alumina monolithics, depending on whether the critical impurities are present in the coarse grains or in the matrix.

However, due to a lack of publications that take a systematic approach, it remains unclear how impurities from secondary raw materials affect the high temperature performance of refractories. It is not clear which processes cause changes in high temperature performance.

### Research method

The aim of this work is to spike cement-free monolithics with impurities as found in recycled raw materials, but in a controlled scientific procedure. During the previous use(s) of recycled high alumina raw materials, impurities will either have formed mixed oxides (e.g., hibonite in the presence of Ca), beta-alumina (in the presence of Na) or if impurities are present in higher concentrations, melt/glass phases. These reactions are therefore simulated in a controlled laboratory environment by mixing pure fine primary alumina (< 45 µm) with varying amounts of impurities (Na, Ti, Si, Ca, and Fe in oxidic form up to 2 wt%), homogenizing and pelletizing the mixtures and sintering them at 1600 °C. The sintering temperature refers to the average process conditions during the steel production. The sintered materials are then ground to a fraction of 0 to 45 µm, which is the typical open fine grain fraction in the matrix composition.

The intention was to create precursors with as many different mineralogical conditions as possible but making them involve a substantial amount of work. FactSage® was used to determine the critical amounts and mixtures of the impurities and to predict the reactions that occur in this concentration range. The precursors then substituted tabular alumina (0-45 µm) in the formulation of the model refractory castable. The influence of these spiked precursors on the working and setting properties (slump flow test and ultrasonic velocity measurement) and high temperature behavior (wedge splitting test) of the monolithics was systematically investigated.

Further thermomechanical investigations are the content of "Part II: Influence on thermomechanical behavior" of this research topic [3].

## EXPERIMENTAL SETUP AND SAMPLE TREATMENT

### Spiked alumina raw materials (precursors)

Refractory materials consist of a large range of particle sizes. Impurities are being enriched in the fine (matrix) fractions. The matrix behaves differently compared to the coarse-grain fraction and the matrix mainly controls the properties of a high performing refractory material what is especially critical for monolithics where the proportion of matrix is higher compared to shapes materials as reported by Samanta et. al. [4]. Therefore, a matrix component material was selected as basis material to be spiked with impurities. A tabular alumina in the matrix fraction of 0-45 µm ($d_{50}$ = 10 µm) was finally chosen, which is a typical open fine grain fraction in the matrix composition. The spiked materials (precursors) consist of 98 wt% alumina (0-45 µm fraction) and 2 wt% of impure material and were completely tailored in terms of the amount and type of the introduced impurities. Na, Ti, Si, Ca, and Fe were identified as common impurities. They were therefore selected for the present investigation based on their importance and relevance to the research objective.

The presence of impurities in the matrix increases the amount of the liquid phase. FactSage® was used to determine the critical concentration and mixing ratios of the oxidic components of the before mentioned elements using ternary or four component systems with alumina as the main component. The calculation was used to find the ratio where the highest amount of liquid phase will be formed when the temperature is above 1600 °C as the sintering temperature of the precursors was set to 1600 °C to simulate an application temperature to ensure the relevant phase transformations comparable to secondary raw materials. The final precursor formulations and measured $d_{50}$ values of the spiked materials thereof are listed in Tab. 1.

Tab. 1: Calculated composition (highest amount of liquid phase at 1600 °C) of selected five precursors; 98 wt% $Al_2O_3$ and 2 wt% in total of two or three of the oxides of the selected impurities ($Na_2O$, $TiO_2$, $SiO_2$, CaO and $Fe_2O_3$) and their $d_{50}$ values measured by laser granulometry.

| Component | wt% | | | | |
|---|---|---|---|---|---|
| | 2CS | 2NS | 2FC | 2FCS | 2TCS |
| $Al_2O_3$ | 98 | 98 | 98 | 98 | 98 |

| $TiO_2$ | - | - | - | - | 0.3 |
| *Sum* | *100* | *100* | *100* | *100* | *100* |
| $d_{50}$ in µm | 14.88 | 18.87 | 22.03 | 18.64 | 17.77 |

### Castable design

The reference monolithic material (MHA-REF) chosen is a self-flowing, cement-free (hydratable alumina bonded – Alphabond 300), high alumina castable with a maximum grain size of 3 mm. The formulation contains different types of alumina raw materials supplied by Almatis GmbH, Germany. Using the prepared precursors (Tab. 1), five corresponding spiked model castables were developed by substituting the 0-45 mm pure tabular alumina grain fraction 1:1 with one of the precursors (Tab. 2). Calculated on the basis of the composition the resulting amount of impurities brought in the castable by the precursor is 0.18 wt%. All castables were mixed in an intensive mixer with the same water and dispersing agent content.

Tab. 2: Recipes of the reference castable MHA-REF and the impure formulations MHA-2CS, MHA-2NS, MHA-2FC, MHA-2FCS and MHA-2TCS, where the TA fraction 0-45 µm has been replaced by the precursors 2CS, 2NS, 2FC, 2FCS and 2TCS.

| Component | MHA-REF | MHA-* |

### Analysis of working and setting properties

The rheological properties of the resulting self-flowing castables were analyzed using the slump flow test. The use of a digital camera during the measurement allows a time dependent (10 min) investigation of the traditional slump flow test setup based on ISO 1927-4 as reported by L. Klein and O. Krause [5].

The time-dependent curing and setting behavior of the different refractory castables was investigated using ultrasonic velocity measurements according to the IP8-measuring system of the company UltraTest GmbH - Dr. Steinkamp & Büssenschütt, Germany. Curing conditions were 20 °C and 95 % relative humidity for 48 hours.

### Analysis of high temperature fracture behavior

The wedge splitting test (WST) was used to monitor and quantify the stable fracture process of test specimens to assess the ability of the castable to resist damage acc. to the description by Brochen et.al. [6]. 1000 °C and 1250 °C were identified as the temperatures of interest for the comparison of the materials investigated, as a drastic change in the energy required to fracture this cement-free high alumina castable is assessed between 1000 °C and 1250 °C.

## RESULTS AND DISCUSSION

The rheological investigations showed a correlation between the end of flow (stoppage time) and the slump flow diameter, confirming that lower viscose mixtures show a higher flow rate if the PSD is properly adjusted. There was only one exception. Mixture MHA-2FC had the smallest final spread but took almost the longest. This is probably due to the highest $d_{50}$ value of the corresponding precursor 2FC (Tab. 1). The setting and curing behavior measured by ultrasonic velocity is comparable for all castables and has no technological influence on the preparation of the castable. These results confirm the assumption that the ions are no longer water-soluble and are already bound by the sintering process of the precursors at 1600 °C. On the other hand, the addition of impurities to the castables leads almost systematically to a deterioration in their high temperature mechanical properties and a reduction in their damage tolerance (ductility). A notable exception is the combination of Fe and Ca (MHA-2FC), which appears to toughen the material and increase its ductility. From the FactSage® calculations a correlation with the expected formation of the lowest liquid phase content at the test temperature of 1250 °C can be seen.

## CONCLUSIONS

In the present work no significant effects of the systematically spiked raw materials on the working properties and curing of the investigated refractory castables were found. Due to the sintering of the precursors at 1600 °C, all ions are bound and are no longer water-soluble and therefore have no influence on the flow and setting properties of the castables. The slight variations observed are most likely due to the different particle size distributions of the precursors which in turn have a significant influence on the flow behavior, as can be clearly seen in the case of MHA-2FC. Nevertheless, the workability and setting behavior were comparable to the pure high alumina reference material.

The situation was different for the high temperature fracture behavior where the addition of the precursors reduced the mechanical properties and decreased the ductility of the material, as emphasized by the results of the wedge splitting tests. The only exception was the material containing the precursor with Fe and Ca (MHA-2FC), which formed the least amount of liquid phase at the temperature investigated and therefore toughened the material. From the results it will be possible to obtain an indication of the mutual proportions of impurities for which the deterioration of the high temperature fracture behavior will not be critical.

## ABSTRACT
The present work investigated the effect of relatively small additions of impurities originating in secondary raw materials on the thermomechanical properties of alumina castables bonded with active alumina. Castable compositions containing impurities for testing were selected on the basis of predictions from thermochemical calculations of their phase composition and the formation of large amounts of liquid phase at the temperature of 1600 °C. Viscosity of the emerging liquid phase was also calculated. The selected alumina castables with impurities from the systems: $CaO$-$SiO_2$. $Na_2O$-$SiO_2$. $Fe_2O_3$-$CaO$. $Fe_2O_3$-$CaO$-$SiO_2$ and $TiO_2$-$CaO$-$SiO_2$ were tested for thermomechanical properties by analysing the effect of impurities on refractoriness under load (RUL) creep in compression (CiC) and resonant frequencies and damping changes versus temperature (RFDA). Real composition of tested material via high temperature X-ray diffraction (HT-XRD) were verified. The obtained results indicate that impurities introduced into the refractory castables in a total amount of 0,18 wt.% (2 % in the fraction 0-45 µm) and in the most unfavourable ratio from the point of view of phase equilibria have an observable effect on the properties of the material at elevated temperature. The obtained results show that in the case of introducing impurities into the material with mutual proportions of shares limiting the formation of the liquid phase. It will be possible to maintain the thermomechanical properties of alumina castables at a satisfactory level (compared to the pure one) from the industrial process perspective in which it will be used. The obtained results shed new light on the possibilities of the conscious use of secondary raw materials in refractory monolithics technology.

## INTRODUCTION
Due to the depletion of natural resources and an overall endeavour to manage natural resources sustainably, there is a need to increasingly use recycled materials. In the case of refractory materials, which are used in various industries, the reuse of refractory materials after decommissioning of worn refractory linings as secondary raw materials is not easy. Refractory producers face a classic and basic dilemma to have to select between high purity, usually more expensive and less available raw materials that are expected to promote high temperature performance, or lower grad, less expensive raw materials, including secondary sources (i.e. recycled materials) but deem to lead to lower refractoriness. More broadly, refractory producers need reliable data on the influence of impurities on the high temperature performance of refractory products in order to develop formulations suitable for specific applications with targeted refractoriness and tailored admissible level of impurities, and hence promote the use of recycled raw materials.

On the whole, refractory industry need to better understand of how critical impurities (in terms of nature and concentration) affect the thermomechanical stability at high temperature, and of how and when a certain level of impurities will lead to malfunctions of the refractories in use.

The aim of this work was therefore twofold. To determine how critical impurities (in terms of nature, concentration and interaction) affect the high temperature performance of refractories and to better understand the high temperature performance of refractories.

## TESTED MATERIALS
For the needs of the project, synthetic materials (precursors) imitating secondary raw materials with compositions, or more precisely, mutual proportions of impurity oxides were produced and sintered at 1600 °C. The compositions of the precursors were chosen regarding their most , the most unfavourable from the point of view of the temperature of formation of the liquid phase in the material, its quantity and viscosity.

The selection of these compositions was based on thermochemical calculations in the equilibrium state using FactSage program. Based on these calculations, 5 precursors were prepared (compositions listed in table 2), which were then introduced into the reference material MHA-REF (chemical composition present Table 1). The matrix fraction 0-45 µm (tabular alumina) with the amount of 9 wt.% was substituted 1:1 by the precursor material. The sum of impurity oxides in these spiked alumina's was 2 wt.% and resulted in 0.18 wt.% relative to the whole castable formulation. The castable design is described more detail in the Part I paper of the research topic. The phase compositions of the reference material and the precursors measured by X-ray diffractometry are presented in table 3.

## TESTING METHODS

### Refractoriness under Load (RuL) and Creep in Compression (CiC)

The high temperature performance of refractory products is basically assessed using the testing standards EN ISO 1893: Determination of refractoriness under load, and EN 993 - 9: Determination of creep in compression. Both testing standards are carried out with the same testing equipment and similar testing procedure. A cylindrical refractory sample is subjected to a constant load (0,2 MPa) while increasing the temperature (5 °C.min$^{-1}$) in air. The deformation (height) of the sample is recorded continuously, usually with the differential method. For the determination of refractoriness under load (RuL), the test is stopped once a prescribed deformation is attained, typically 5% of its initial length ($T_{0.5}$). For the determination of creep in compression (CiC), once a specified temperature of the sample has been reached, the temperature is maintained constant for a given time. The deformation of the sample at this constant temperature over time is then recorded. In both tests, temperatures corresponding to a characteristic degree of deformation are identified from the deformation against temperature/time curves.

In the present study, the testing conditions specified in the standards were extended. Variable load conditions were selected and applied on cylinders ($\phi$35 x 50 mm) with an axial hole of $\phi$12 mm. The measurements were performed in a NETZSCH 421 device heated by an electric furnace. For CiC measurements, the test pieces were heated to $T_{0.5}$ - 100 °C, $T_{0.5}$ °C, $T_{0.5}$ + 100 °C at a rate of 5 K/min and three different loading forces (0.2, 0.8 and 1.2 MPa).

### Resonant Frequencies and Damping Analysis (RFDA)

The Impulse Excitation Technique (IET) was used for the non-destructive determination of the elastic properties. The Young's modulus was determined dynamically by resonance frequency and damping analysis according to ASTM E1876-15, ISO 12680-1, EN 843-2. This method allows the frequency and damping parameters of the vibration to be determined. Damping represents the absorption and dissipation of energy by the material. Here, the relationship between the change in modulus of elasticity in a temperature range depending on their refractoriness under load, based on the criterion $T_{0,5}$ - 100 °C, has been determined.

The dimensions of the specimens were 25 x 35 x 150 mm, the heating and cooling rate was set at 3 K/min and the specimens were soaked at the maximum temperature for 2 hours to achieve an equilibrium state in the material at the temperature T0.5 - 100 °C. Each test was repeated twice.

### Fracture energy

The fracture energy was measured using the three-point bending method up to high temperature (Hot Modulus of Rupture / Netzsch HMOR422) for prismatic test pieces (25 x 25 x 150 mm) with a notch depth of 7 mm and a 0.5 mm width and a loading rate of 20 µm/min. The system's deformation was corrected for all measurements.

### Creep in Compression (CiC) based on the Norton-Bailey concept

The CiC was measured under variable load conditions in a NETZSCH 421 device heated with by an electric furnace.

The test pieces were prepared in the shape of a cylinder of dimensions $\phi$35 x 50 mm with an axial hole with a diameter of $\phi$12 mm. The test pieces were heated to $T_{0.5}$ - 100 °C,. $T_{0.5}$ °C,. $T_{0.5}$ + 100 °C at a rate of 5 °C/min and three different loading forces (0.2, 0.8 and 1.2 MPa).

### Scanning electron microscopy (SEM/EDS)

Microstructure analysis was performed using a TESCAN Mira 3 LMU electron microscope equipped with an Energy Dispersive Spectrometer (EDS) from Oxford Instruments. Images were collected using secondary electron (SE) and backscattered electron (BSE) detectors. The measurements were carried out on the samples coated with a 5 nm of Cr layer using a Quorum Q150T instrument.

### RESULTS AND DISCUSSION

The temperature of the appearance of the first drop of the liquid phase for the investigated materials as well as the amount and viscosity of the melt in the temperature range 1200 to 1300 °C are given in Table 4. The formation of the liquid phase is one of the reasons for the reduction of the refractoriness under the load, and especially $T_{0.5}$, of the investigated materials. It was found that during the first test all materials displayed significantly reduced refractoriness under load (Table 5) compared to corundum castables, even the reference material which contained no impurities (fluxes) and consisted mainly of alumina (Table 1). The repetition of the RuL measurements on the same test pieces showed that the refractoriness under load, in each case, increased by up to several hundred degrees after the second heating (table 5 and figure 1). This indicates that the amount of the liquid phase is not the only and the main factor influencing the thermomechanical properties of these materials. Reactive alumina and its sinterability play an equally important role in this type of material.

Studies of the microstructure of the samples show that in order to give the material high refractoriness, a bonded microstructure and growth of alumina grains in the matrix must occur (Figure 2). Loading the test piece which contain reactive alumina with 0.2 MPa (standard RuL tests) during the formation of the appropriate microstructure in the castable is destructive to the material, and the liquid phase appearing in the system at a certain temperature further affects the deterioration of thermomechanical properties. The influence of the phenomenon of the formation of the material microstructure during the first firing is also evident in other studies of the thermomechanical properties [1]. Figure 3 shows an example of the temperature dependence of the changes in the flexural vibration frequency and damping of the MHA-2TCS material during heating and cooling to the temperature $T_{0,5}$ -100 °C. The observed changes with temperature, particularly visible in the damping values, are most likely the result of changes occurring in the microstructure of the material: sintering, crystal growth, melting and crystallisation from the liquid phase, opening and closing of microcracks. Different mechanisms of cracking during this process are illustrated in figure 4. Table 6 shows the changes in the Young's modulus obtained in the RFDA test performed to the temperature $T_{0.5}$ -100 °C. The results also show that only the MHA-REF had a higher Young's modulus after the test than at the beginning. It decreased for the spiked materials. It was also found that spiked materials had a twice as high Young's modulus after setting and drying, proving that impurities introduced into the material also play a role in the setting process of the castables.

The results of the determination of the fracture energy obtained by the three-point bending method show that all the spiked materials have inferior properties compared to the reference material at the temperature of $T_{0.5}$ (figure 5). Below this temperature, the composition of the impurities may lead to improvement of the thermomechanical properties. Taking into account that

unfavourable combinations of compositions of impurities were introduced into the tested materials in order to produce as much of the liquid phase as possible at high temperature (eutectic compositions), it is possible, that by moving the composition away from the eutectic, the detrimental effects of impurities near the working temperature will be much more limited.

Tab. 4: The temperature of the appearance of the liquid phase in individual systems and its amount and viscosity.

| | First drop of liquid phase, ºC | Amount of liquid phase, g | Viscosity of liquid phase | | |

| MHA-2FCS | 74 | 53 | Single. short | Moderately numerous. mainly at the grain/matrix interface and also visible through the grains themselves |
| MHA-2TCS | 74 | 53 | Numerous. at the grain/matrix interface and through the matrix itself. of various lengths | Numerous. mainly through the matrix. sporadically at the grain/matrix boundary |
Fig. 5: Evolution of the specific fracture energy and bending force before fracture as a function of the temperature (the maximum temperature corresponds to $T_{0.5}$ for each material).

Creep rate was also measured using a newly developed method based on the Norton-Bailey concept and works [2, 3] to identify the different stages of creep. The first two stages of creep described by the Norton-Bailey theory were identified in these studies. Despite the application of the maximum load allowed by the capabilities of the testing equipment, i.e. 1.2 MPa, the third stage of creep of the tested materials leading to their destruction was not observed (figure 6). In some cases, when using a heavy load at T0.5 and T0.5 +100 °C, the tests had to be stopped due to excessive strain beyond the measuring range of the device (figure 7). The fact that the material has not failed up to this point is indicative of the extensive thermoplastic properties of the material and is the most likely explanation for the lack of a failure step for the material subjected to mechanical stress.

Fig. 6: Creep rate of MHA castables under load, 0.8 MPa at a temperature of $T_{0.5}$.

Fig. 7: Creep rate of MHA castables under load, 1.2 MPa at a temperature of $T_{0.5}$.

## CONCLUSIONS

The introduced impurities affect the mechanics of cracking and facilitate the sintering of the tested materials at low temperature by forming of small amounts of liquid phase. This also affects the thermomechanical properties of the tested materials.

However, the active alumina binder plays an important role in the sintering process allowing the material to sinter at low temperatures. This has an impact on the sintering process of the alumina castables tested. The material is in a viscoplastic state during the sintering process.

The conclusion from these studies is that processes such as grain growth in the material matrix and the formation of ceramic bonds, which increase the thermomechanical strength of the tested materials, do not keep up with the effects caused by the applied load. This is a valuable clue that materials of this type, i.e. on active bonding with alumina, should not be use in those applications where there is a high mechanical load during initial heating.

The combination of impurities selected in these studies represent the most unfavorable cases in terms of thermomechanical properties due to liquid phase formation. However, the obtained results show that it should be possible to deduce mutual proportions of impurities for which the deterioration of thermomechanical properties should not be critical.

## ABSTRACT

Recently, one of the main topics in refractory research is eenvironmental issues related to waste treatment and resource recycling, as is research in other industries. Especially, much interest have focused on the recycling of MgO-C refractories. It can be used as raw materials for refractories according to processing methods, and their use is expanding. In the case of the MgO-C refractory spent, the remaining Al and C must be treated for recycling. Al remaining during the reuse process causes structural collapse due to hydration and C weakens the bond of refractories.

In this study, the properties of MgO-C refractories with a new recycled MgO-C raw material which shows better MgO purity and physical properties compared to the existing recycled raw material were investigated. From this research, we could obtain a high-quality MgO-C refractories with same or similar corrosion resistance and structural spalling resistance. In addition, by applying the recycled MgO-C as a raw material in the MgO-C refractory, it was possible to achieve the effect of reducing manufacturing costs and virtuous cycle of resources at the same time.

## INTRODUCTION

In steelmaking processes, such as the blast furnace, electric furnace, and ladle, high refractoriness is required, leading to the predominant use of MgO-C refractory materials as the lining bricks. However, over time, the surface of these refractory bricks gets eroded and the residual amount decreases, resulting in a loss of their refractory function. As a result, after a certain number of uses, the bricks need to be replaced with new ones, thereby generating a significant amount of waste refractory materials, which poses environmental issues.[1][2] Many refractory companies are making efforts to reuse waste refractory materials. To minimize waste, recycling waste refractory materials is the most appropriate approach. However, when using MgO-C refractory materials without pre-treatment, issues such as cracking and damage occur during refractory manufacturing. This limits the amount of material that can be effectively recycled, resulting in only a small quantity being reused, while the rest finds other applications. For instance, waste refractory materials have been incorporated into slag in steelmaking processes or included in the non-standard composition of repair and reuse materials for refractory linings. However, such usage is inherently limited, and there is still a need for separate investment to manufacture new refractory bricks using fresh raw materials. Waste MgO-C refractory can be produced as a raw material by supplying high-temperature steam. The residual Al and $Al_4C_3$ within the refractory materials are stabilized as $Al_2O_3$ under high-temperature steam conditions, preventing structural collapse when reusing them as refractory material. The treatment with steam preserves the form of the refractory product.[3] This indicates that areas where small-sized raw materials or carbon materials are agglomerated remain intact, which can lead to a decrease in the density and strength of the final product. Additionally, residual Al and $Al_4C_3$ that have not fully reacted through steam treatment can result in weakened bonding strength during subsequent refractory manufacturing. These issues contribute to the limited usage quantity of regenerated materials produced through steam treatment. To address the issues with steam-treated waste MgO-C regenerated materials, it is possible to remove carbon and unstable metallic components. This removal ensures that the raw materials do not cause cracking and structural collapse during MgO-C refractory manufacturing and usage. Regenerated materials produced through this method exhibit chemical stability, but they suffer from the problem of non-uniform density and chemical composition among individual particles. The inclusion of a matrix in aggregate materials, leads to a reduced density and MgO purity compared to MgO clinkers. Such non-uniformity among different raw materials becomes a contributing factor to the degradation in quality of refractories where regenerated materials are used.

In this study, carbon and metal oxides were removed from the MgO-C refractory, resulting in the production of regenerated material similar to new MgO feedstock. This regenerated material maintains high purity and density, ensuring no degradation in the quality of the refractory. As a result, the use of regenerated materials in refractories is increased while achieving comparable performance to that of fresh MgO-C refractories in actual furnace applications.

## EXPERIMENT

### Experimental procedure

Characteristics of the raw materials for MgO-C refractories manufacturing are as follows:

- Fused Magnesia MgO 97.5%(FM) in the grain size fractions 0–1, 1–3, and 3–5 ㎜

- Graphite, flakes, ≥98% carbon basis

- Alumium powder, ≥99%

- Phenilic Resin (Resol)

- MgO-C recycled Materials (RA, RB1, and RB2 in the fractions 0-4 ㎜)

Phenolic resin was utilized as a binder in this study. The Fused Magnesia(FM) and Recycled materials(RA, RB1 and RB2) can be seen in *Fig. 1*. The recovered MgO-C is crushed and processed to create refractory raw materials(*Fig. 2*).[4] RA is produced through a high-temperature steam treatment process. During this process, the Al and $Al_4C_3$ present inside the raw materials are converted to $Al_2O_3$. Manufactured through the process, RB1 and RB2 do not contain carbon components. *Fig. 3* presents microscopic images of the produced raw materials. Each sample was embedded in epoxy resin, polished, and observed under a JSM-7610F scanning electron microscope. The chemical compositions of the FM and three recycled products were measured using S8 TIGER(Bruker). The density of the materials was measured according to Archimedes' principle, and the apparent porosity values were obtained using the same measurement method. Table. 1 presents the measured values for the characteristics of the raw materials. RA, as shown in Fig. 3, has a similar structure to refractory materials, with fines and graphite adhered to large aggregate particles.[5] The binder that existed between the raw materials is lost, and $Al_4C_3$ is converted to $Al_2O_3$, resulting in a decreased bond strength in the matrix portion. RB1 forms porosity by removing graphite in the fines and contains
*Fig. 1: The appearance of the raw materials a) FM  b) RA  c) RB1 d) RB2*

*Fig. 2: A manufacturing process for recycled raw materials utilizing spent MgO-C refractories*

Al$_2$O$_3$ and SiO$_2$ derived from the antioxidant. RB2 has minimal fines and is primarily composed of aggregates.

*Fig. 3: The microscopic images of the produced raw materials. a) FM  b) RA  c) RB1  d) RB2*

Tab. 1: The measured values for the characteristics of the raw material

| | Density (g/m³) | Porosity (%) | Chemical composition (%) | | | |
|---|---|---|---|---|---|---|
| | | | MgO | Al₂O₃ | SiO₂ | TC |
| FM | 3.46 | 3.2 | 97.5 | 0.2 | 0.4 | - |
| RA | 2.89 | 8.5 | 74.2 | 5.5 | 0.6 | 17.5 |
| RB1 | 3.32 | 5.7 | 93.2 | 2.7 | 1.5 | - |
| RB2 | 3.44 | 2.9 | 96.3 | 1.4 | 0.7 | - |

**Experimental method**

Based on the mixture formula of the MgO-C currently being used, a test blend was designed. Due to the inclusion of graphite in the recycled raw material (RA), the graphite content was adjusted in the mixture formula. The formula for manufacturing bricks, which includes graphite, antioxidants, and binders, can be found in Table. 2.

The raw materials were mixed using a laboratory-scale Irich mixer. Subsequently, they were manufactured by applying uniaxial pressure in a 3200-ton press to obtain specimens with dimensions of 800 x 50 x 50 ㎤. The molded products were subjected to a temperature treatment at 180℃ for 24 hours in ambient air. After curing and after coking, the bulk density of the specimens was determined from the mass and geometric dimensions. The apparent porosity values were also obtained by the last-mentioned measurements. And CCS were conducted by subjecting cubic-shaped specimens to uniaxial pressure.

Tab. 2: Mixture formulations and resulting content of recycled material

| Composition (%) | Desination | | | | | | |
|---|---|---|---|---|---|---|---|
| | A | B-1 | B-2 | C-1 | C-2 | D-1 | D-2 |
| FM | 81 | 74 | 65 | 72 | 62 | 72 | 62 |
| RA | | 10 | 20 | | | | |
| RB1 | | | | 10 | 20 | | |
| RB2 | | | | | | 10 | 20 |
| Graphite | 17 | 15 | 14 | 17 | 17 | 17 | 17 |
| Aluminum | 2 | 2 | 2 | 2 | 2 | 2 | 2 |
| Phenilic Resin | 3.5 | 3.5 | 3.5 | 3.5 | 3.5 | 3.5 | 3.5 |

A specially designed apparatus was devised for the evaluation of corrosion resistance. The specimens were machined into disc shapes and were rotated along the vertical axis, subjected to chemical and physical corrosion by molten slag. After being subjected to an hour-long test at 1650℃ with a C/S ratio of 1 slag, they were subsequently discharged from the rear. This process was repeated 10 times over a duration of 10 hours(*Fig. 4*)

*Fig. 4: Schematic representation of the rotating corrosion test*

**RESULTS AND DISCUSSION**
**Lab test**

Table. 3 shows the properties of MgO-C specimens after curing and coking. An increase in the content of recycled raw materials leads to a decrease in density. This trend is more pronounced in specimens using RA and RB1 compared to RB2.

Tab. 3: The measured values for the mechanical properties after curing(after coking)

| Properties | Desination | | | | | | |
|---|---|---|---|---|---|---|---|
| | A | B-1 | B-2 | C-1 | C-2 | D-1 | D-2 |
| Bulk Density (g/m³) | 2.97 (2.87) | 2.94 (2.83) | 2.92 (2.82) | 2.96 (2.96) | 2.94 (2.83) | 2.96 (2.86) | 2.95 (2.84) |
| Apparent porosity (%) | 1.6 (10.1) | 3.2 (11.0) | 2.0 (11.2) | 1.9 (10.4) | 2.0 (10.7) | 2.8 (10.4) | 2.1 (10.6) |
| CCS (kg/m³) | 544 (305) | 462 (236) | 439 (225) | 508 (246) | 443 (236) | 533 (284) | 470 (254) |

The decrease in density can be attributed to the increase in porosity. Fig.3 shows that both RA and RB1 have a significant amount of porosity within the raw material particles. This high

porosity of these raw materials is maintained in the final product even after the pressing, curing, and coking stages. Unlike sintered refractories, MgO-C refractories primarily utilize FM raw materials, with a low possibility of material consolidation occurring before usage. The utilization of recycled raw materials with high porosity can lead to a decrease in the compressive strength of refractories. [6]

Tab. 4: The measured values for the corrosion rate

| | Desination | | | | | | |
|---|---|---|---|---|---|---|---|
| | A | B-1 | B-2 | C-1 | C-2 | D-1 | D-2 |
| corrosion rate (mm/ch) | 0.79 | 0.88 | 1.01 | 0.84 | 0.88 | 0.81 | 0.80 |
| corrosion rate index | 100 | 112 | 128 | 106 | 111 | 102 | 101 |

The results in Table. 4 demonstrate that the corrosion resistance is enhanced when RB2 is applied compared to RA/RB1. The corrosion on the refractory surface of the furnace occurs due to a combination of chemical and physical factors. RB2, after undergoing a purification process, achieves high purity and can effectively suppress chemical corrosion even under conditions with low alkalinity slag.[7] Additionally, the low porosity and reinforcement of the matrix contribute to increased resistance against mechanical erosion.

**Field test**

*Fig.5* shows the appearance of MgO-C bricks containing RB2 after their use in Ladle equipment. The specimen exhibited similar corrosion resistance to conventional MgO-C bricks. Even when applied to MgO-C refractories containing a low amount of graphite as a raw material, they showed comparable performance to the conventional product. When RB2 was added to MgO-C for RH applications at a 20% level, it was verified that excellent residual performance was achieved with minimal spalling(*Fig.6*).

As described above, it has been confirmed that MgO-C bricks utilizing refined recycled materials can be used for actual furnaces, with the potential for further enhancement of their functionality in the future.

*Fig. 5: The appearance after conducting a performance test of MgO-C bricks containing RB2 in ladle equipment: the boundary between conventional MgO-C bricks and RB2-containing MgO-C bricks*

*Fig. 6: The appearance after conducting a performance test of MgO-C bricks containing RB2 in RH*

**CONCLUSIONS**

The differences in processing methods for recycling MgO-C refractory raw materials were investigated, and the resulting substitutions were evaluated. Regenerated materials treated with steam to remove reactivity were found to contain carbon, allowing for a reduction in graphite addition. However, the high porosity of the raw materials affected the final quality. Simply combusting graphite to address this issue resulted in carbon removal but exposed structural weaknesses in the raw material. When using refined raw materials with removed graphite and increased structural and chemical stability, there were no major issues in replacing pure FM. Tests are being conducted to apply a higher content of these materials and improve manufacturing yields.

Alexander Leitner
RHI Magnesita, Leoben, Austria

Barbara Zocratto
RHI Magnesita, Rotterdam, Netherlands

## ABSTRACT

Recycling usage can bring several benefits including less dependency of imported raw-materials, cost reduction and proposition of a circular solution for the customers. Nevertheless, the carbon footprint reduction has been the key driver for the utilization ramp-up, fostering technical development of refractories producers and the implementation of a sustainable portfolio for refractory users. This paper presents an overview on the technical challenges currently faced to boost recycling utilization rates, from pre-sorting during dismantling, to refractory classes selection and contaminants removal or stabilization, finally discussing on preparation for product application.

## INTRODUCTION

The contribution of refractory linings to steel and cement carbon footprint is relatively small [1], being most of the efforts of those industries linked to new production processes and carbon capture, utilization and storage – CCUS (scope 1 emissions [2]) [3,4]. Nevertheless, once the novel processes are implemented, scope 3 emissions [2] will represent most of the emissions and refractories would turn into one of the main contributors.

Therefore, some refractory consumers are already demanding products with lower carbon footprint, quantifying its content, with safe application and reduced environmental impact, including waste management.

Recycling is a key strategy to cope with these market demands, ensuring emissions reduction from raw material production and closing the loop of by-products management. The raw material aggregate represents from 70 to 90% of the refractory's $CO_2$ emissions [1]. Additionally, from the refractory producer perspective, it is one of the shortest-term solutions to move ahead with eco-friendly products, once changes in production process and CCUS depends on technologies still under development, solutions for legislation disputes, and a long time frame for implementation [5,6,7].

Table 1 shows the carbon footprint of selected refractory raw materials, representing the potential reduction on emission upon their replacement [8].

Tab. 1: Refractory Raw Materials $CO_2$ Footprint

| Raw Material | Estimated $CO_2$ Footprint (t/t) |
|---|---|
| Dead Burned Magnesia | 1,5 – 1,9 |
| Fused Magnesia | 2,6 – 5,0 |
| Chamotte | 0,7 |
| Silicon Carbide | 5,8 |
| Calcined Alumina | 0,7 |
| Tabular Alumina | 2,9 |
| Brown Fused Alumina | 1,0 – 1,2 |
| White Fused Alumina | 1,0 – 1,3 |
| Recycling | <0,1 |

While carbon footprint reduction is an important benefit for recycling utilization, there are other advantages both for refractory consumers and producers. By using recycling, the raw material supply chain can be simplified, reducing the dependency on imported goods and the complexity and risks linked to it. Moreover, closing the loop for the product life cycle reduces the amount of residues to be disposed, leading to lower costs for landfilling and waste management. Finally, refractory companies with advanced recycling strategies can propose to customers full circular contracts, a competitive advantage for a market demanding environmentally sustainable products [8,9].

## CHALLENGES FOR RECYCLING PROCESSING AND UTILIZATION

The amount of recycling to be used in a refractory composition is dependent on the proper dismantling and sorting at the source, quality and selectivity of its processing, and the original raw materials being replaced.

The recycling process until its final utilization back to refractories can be separated in sub-processes for a better illustration. Firstly, the dismantling at the refractory consumer (and spent refractory generator) is carried out and an initial sorting per equipment being relined may be performed, alongside magnetic separation and screening to remove small particles normally contaminated with impurities and difficult to process on the downstream processes. The next step is the logistics to a recycling processing facility. Inside the recycling processing facility, the sorting of different material families is carried out for a more stable and proper chemical and mineralogical composition. After the separation, different beneficiation steps might be necessary, as carbides hydration, salts solubilization and magnetic particles removal. Finally, with the materials in proper quality and homogeneity, the particles are comminuted and sized for the suitable addition on refractory formulations, usually engineered to replace virgin raw materials without impacting product performance.

The challenges of each process step are commented and illustrated, while examples of solutions being explored by the industry are presented.

### Refractory Lining Dismantling

The refractory lining dismantling process and sorting has a strong influence on the quality and complexity on the recycling downstream processes. The better the selectivity during the dismantling processes, separating the refractory families according to the lining project, the higher the quality and therefore the recycling utilization can be maximized. This is especially important in cases where the recycling materials are difficult to sort out from each other and the chemistry is a limitation due to the cross-contamination. An example of this situation is the steel ladle recycling.

The lining concept of a steel ladle often comprises magnesia-carbon and alumina-magnesia-carbon bricks in different positions (steel and slag lines). With a selective dismantling these different families can be separated by the brick position directly at the site. However, if everything is broken down and sent to the recycler all together, the sorting among those bricks mixture is very difficult and the cross-contamination limits the usage at a new refractory product.

A selective dismantling would contribute for a better circularity and lower carbon footprint of refractories. Nevertheless, most of the

consumers are still prioritizing a fast dismantling in order to quickly return the equipment for operation, normally using a contractor not impacted by a higher or lower recyclability.

Therefore, the selective dismantling is an opportunity to improve the recycling utilization, but a compromise must be reached among availability of the vessel and quality of separation, even better if performed by a company targeting both speed and material separation quality.

**Logistics and Legislation**

One important challenge for recycling is the transport distance from the spent material generation to the recycling processer and finally to the recycling user. The economic feasibility of the spent refractory utilization has a strong dependency on the cost and complexity of this supply chain.

In countries and regions with significant distance among the refractory users and producers (e.g., United States and Brazil) the logistic cost is an important factor, especially when the material losses throughout the recycling processing are relatively high.

Another challenge faced is the cross-border transport of the materials, especially if they are considered hazardous waste. Some spent refractories are classified as such and face limitations to cross borders between countries, even if it's further processed to stabilize the material and to be used to reduce carbon emissions.

Therefore, it is necessary to evaluate and discuss specific legislation for recycling processes, simplifying (and in some cases even allowing) the supply chain of spent refractories since the processing and producing site locations are rather limited.

Additionally, the adoption of incentives and carbon taxation will help to improve the recycling competitiveness, which will become a key factor with the advance of utilization. The higher demand for recycling will lead to sourcing in further places, increasing logistic cost, and more elaborated processing to remove contaminants, increasing processing expenditures.

**Sorting of Recycling**

The sorting of spent refractories in different recycling groups is the most important and most used processing step, guaranteeing the material chemical and mineralogical homogeneity.

The vast majority of refractory recycling companies rely on manual sorting processes. In almost every new dismantling received at the plant, a sample of each spent refractory with distinct visual characteristic is collected and sent for chemical and mineralogical analysis. According to the results, a selection instruction is built, and the sorters are trained for the specific lot received. After selection, a new analysis is made on the lots to ensure quality and release for the downstream processes (or decide on blending or reprocessing in case the results are not according to the specification). Figure 1 shows a sorting plant in Brazil.

Fig 1 – Spent recycling sorting plant in Brazil.

A key development invested by recycling companies is on automated sorting processes. The benefits from this breakthrough technology are the better quality of separation (allowing to sort materials not possible by visual inspection), increased productivity and cost competitiveness, especially for regions with high labor cost. Additionally, finer particles (<80mm) could be sorted, not possible with the current manual process due to financial and technical constrains.

Automated sorters are available commercially for other industries, as mining and electronic waste. The sensors use color, for visible and NIR (near infra-red) wavelength ranges and chemistry, with XRT (x-ray transmission) and LIBS (laser induced breakdown spectroscopy) sensors [10].

Nevertheless, conventional devices present constrains that prevents a direct utilization for refractory recycling. Firstly, the carbon content which is part of the formulation of a significant volume of available materials, cannot be sorted simply by color and the carbon and impurities disturb the response for the XRT sensor, drastically reducing the sorting efficiency.

Secondly, most of the devices can only separate the feedstock in two product streams, while most of the spent materials received comprises five to ten different material types. Fitting a two streams equipment to multiple products increases the complexity of the flowsheet, set-up time, and material handling, finally reducing the productivity and increasing investment and cost.

Another limitation for the current technology is the necessity of removing any fine material covering the coarse fraction, normally adopting water sprayed screening. This additional step brings another complexity for the plant design, and for refractories susceptible for hydration as magnesian and dolomitic bricks, would make the process unfeasible.

Therefore, the current studies are targeting automated methods which surpasses these limitations from out-of-the-shelf equipment, improving yield, quality and economics of recycling.

**Stabilization and Beneficiation of Recycling**

The stabilization and removal of undesired mineralogical phases from recycling particles is essential to increase or even allow its utilization. A few classical examples of contaminants are alkali salts from cement kilns bricks, slag and steel infiltration from steel spent refractories, and magnesia carbon bricks containing aluminum carbide from the original aluminum powder added as antioxidant [11,12].

For the alkali salts and carbides contamination, the challenge is to mechanize the process for a higher productivity, lower lead-time and reduced footprint for high tonnage plants. The current method relies on spraying water over piles of material and wait for days, some cases months, until the reaction or dissolution takes place (Fig 2). Moreover, it is necessary a good control to prevent hydration (besides the aluminum hydration) or that hydrated particles do not reach the refractory production. Preventively, drying at temperatures surpassing 300°C are adopted to ensure proper treatment, increasing the processing cost.

Fig 2 – Water spraying process for aluminum carbide stabilization.

For steel and metallic particles removal, magnetic separators are normally used. However, when oxides and non-magnetic alloys contaminate the recycling grains, specific development is necessary for their removal.

**Engineering of recycling containing products**

After separation, contaminants removal and quality determination, the recycling grains are prepared for utilization and a proper product design is necessary to achieve similar performance replacing virgin raw materials by recycling grains.

A common challenge is to define how many and which size fractions can be used back into refractories. For a proper particle packing, similar sizes to the original raw materials are preferred, however the amount of silos available is an usual constrain for the implementation. Hence, a compromise is searched reducing the amount of different sizes, but also limiting the maximum replacement for a good particles packing.

Another design constrain is the variation in chemistry from recycling grains. Despite the processing steps and quality controls, the specs for a secondary raw material are normally broader than for a virgin one, since a recycling grain is a piece of the originating brick and its mix of raw materials. It is expected higher variation for a secondary material, being a task for the product developer to surpass the challenge imposed by this natural difference.

A final example of difference to be addressed in the product design is the grain density and porosity. Normally the virgin raw materials present higher density than recycling aggregates, leading to the necessity of adjusting processing and pressing parameters to achieve similar brick green density. In addition, for fired bricks, the combination of different chemistry, particles packing, and aggregate density might lead to adjustments on the temperature profile to achieve similar ceramization.

Therefore, the research and development capability of a refractory producer is directly linked to its capacity to increase recycling utilization, especially for increased recycling rates, since the market is demanding lower $CO_2$ footprint but similar product performance. Once achieved the refractory composition, it is important to report on the product datasheet the final carbon footprint, giving awareness and transparency to the customer to decide among the product options. Fig 3 exemplifies a recycling containing brand from RHI Magnesita.

Fig 3 – Technical datasheet with product carbon footprint.

**RESULTS OF MAJOR REFRACTORY COMPANIES**

Two of the most important refractories companies have included recycling on their strategic targets and published the results on their sustainability reports. Fig 4 displays the results presented by RHI Magnesita and Vesuvius [13,14].

RHI Magnesita has demonstrated strong development on their recycling rate, combining strategic push from the executive management team, product development drive, process innovation and novel business models. As a result, already in 2022, the target set for 2025 (10% recycling rate) was surpassed.

It is important to notice the decision of the market leaders on including recycling targets for the company shareholders report (10% until 2025 for RHI Magnesita and 7% until 2025 for Vesuvius), reinforcing to the market the importance of the topic and driving initiatives to foster recycling adoption by refractory consumers.
Fig 4 – Reported recycling rate result of RHI Magnesita e Vesuvius.

**CONCLUSIONS**

The recycling utilization is one of the quickest and most cost-effective strategies to reduce the carbon footprint of recycling products. Additionally, by closing the loop, the amount of material to be landfilled and controlled is reduced.

To improve the recycling rate and contribute to this essential goal, technological constrains need to be addressed and novel business models need to be elaborated to improve the material availability and quality.

In the dismantling, a compromise among refractory user, service provider and recycling company is necessary to extract the full potential from the spent material, ideally with a circular business model integrating refractory supply and recycling return to the producer.

Sorting is the major focus in the current set-up. Finding an automated process is essential to support significant increase in recycling rates, simplifying the material handling, improving the overall yield and improving quality. Additionally, the development of sensors specific for refractory recycling challenges is key to sort out among the different spent materials, overcoming the limitations from out-of-the-shelf equipment.

Another necessary technology upgrade is for the stabilization of undesired mineralogical phases and removal of contaminants. The mechanization of existing processes is key to increase productivity, reduce lead-time and guaranteeing quality, at the same time reducing the necessary footprint for the production upscaling.

Additionally, engineering refractory products containing recycling grains is a task that demands research and development capability and process know-how to use available resources at production plant, taking advantage of the benefits of a lower product $CO_2$ footprint without impacting performance. Limitation in silos and modification on process parameters to keep similar product properties demand creativity from the refractory development team, attempting to increase recycling content without major investments, increased production complexity and keeping cost-competitiveness. Finally, logistics and limitations of supply chain imposed by legislation to spent materials is a topic to be addressed, currently reducing the competitiveness of recycling compared to primary raw materials. Adoption of incentives and carbon taxation are necessary for high recycling consumption, which will demand higher expenses for transportation and more complex processing steps.

The major refractory producers have set targets for recycling rate, demonstrating a trend in the industry to migrate to lower carbon footprint products. RHI Magnesita has already achieved its target for 2025, surpassing 10% already in 2022, benefiting from a strong strategic focus, investment and synergies with different companies along the recycling supply chain.

# A NEW APPROACH TO ACHIEVE ROBUST AND EASY TO USE NCC

Frédéric Lacoue*, Quentin Collomb, Chunfeng Liu, Christoph Wöhrmeyer
Imerys S.A., Paris, France
* Presenting author

## ABSTRACT

The key drivers for the development of silica sol based No Cement Castables (NCC) over the last two decades are their fast drying ability and the in-situ formation of an almost pure mullite matrix composition at high temperature. It then leads to faster onsite installation/repair and a high refractoriness and thermal shock resistance that improve durability of such castables [1, 2]. Nevertheless, the main drawbacks of this solution compared to the largely used calcium aluminate binder, are the more difficult control of setting, low green mechanical strength, the need to handle a temperature sensitive liquid product at the job site. To overcome some of these drawbacks of silica sol, small amounts of magnesia or calcium aluminate are commonly added in formulations. Magnesia is introduced as a gelling or coagulating agent for faster structuration while small amount of cement allows to increase green mechanical strength [3, 4, 5]. From there, this study will show that calcium aluminate could be, as well, a suitable binder to formulate NCC castables with equal or less than 0.2 wt% CaO as required by the classification. This solution doesn't require a separate liquid colloidal binder, works simply with water and provides similar robustness and formulation flexibility as traditional ultra-low cement castables (ULCC).

## INTRODUCTION

A bauxite refractory castable formulation is used to compare different binders such as commercial colloidal silica, calcium aluminate Secar® 71, and a new calcium aluminate based laboratory prototype LP660. For each binder, flow behaviour, structuration kinetics, and physical properties after curing and drying are investigated. Dry-out behaviour is also compared through macro thermo gravimetric analysis on 10 cm$^3$ cubes. Hot properties such as refractoriness under load and hot modulus of rupture are also compared. The matrix mineral composition of the castables is analysed by X-ray diffraction to qualitatively assess mullite formation after calcination.

## EXPERIMENTAL PROCEDURE

### Model formulas

In this study, all binders are tested in castables with the same particle size distribution of bauxite aggregates, the same amount of water and the same silica content (Table 1). Then, same open porosity is expected after complete drying. As dried powder, Secar® 71 and LP660 are added in the same amount in ULCC and NCC-1K formulas. In NCC-2K, commercial silica sol used is Ludox 50TM and consists of 50 wt% SiO$_2$ nanoparticles. Then, 10 wt% of Ludox entirely replaces micro silica and brings 5 wt% of needed water. Additional 0.5 wt% of water is required to keep the same amount of liquid between all formulations. Main changing parameter within this benchmark is CaO content from almost 0 wt% for NCC-2K to 0.75 wt% for ULCC. The value for the NCC-1K is placed just below the standard limit for a no cement castable (i.e. ≤0.2 wt %).

### Test methods and equipments

- Flow decay: measured after 4 minutes mixing of raw materials with water. The sample is placed and tamped in a trunconic ASTM mould (inner diameter of 100 mm at the bottom, 70 mm at the top and 50 mm height). Then the mould is removed and the sample is vibrated for 30 seconds with an amplitude of 0.5 mm on a Sinex table. The resulting diameter of the sample is measured in three different positions. The flow value is the average of the three measurements expressed in % increase versus the initial 100 mm base diameter. Flow decay is given by repeating the test after 30 and 60 minutes.

- Ultrasonic profiles: measured with the Ultratest IP8 during castable curing at 20°C for 24 hours.
- Mechanical strength: cold compressive strength is measured according to NF EN196-1 after 24 hours curing under 20°C, 90% relative humidity and after drying at 110 °C for another 24 hours.

Tab. 1: Bauxite model castables.

| Raw materials (weight%) | ULCC | NCC-1K | NCC-2K |
|---|---|---|---|
| Calcined Bauxite 0-6 mm | 85 | 85 | 85 |
| Calcined alumina | 7,5 | 7,5 | 10 |
| Micro Silica Elkem 971U | 5 | 5 | 0 |

- Open porosity: determined by water immersion according to Archimedes' method.
- Permeability: discs of 100 mm in diameter and 25 mm height, have been prepared by casting into a plastic mould followed by curing at 20°C, 90% relative humidity. A permeameter has been used to measure the air permeability. From the pressure change in the chamber over time and the sample dimensions, the average permeability K has been calculated. Results are expressed in mDarcy as explained in [6].
- X-Ray Diffraction (XRD): performed on a Bruker D8-Advance diffractometer under Cu radiation in the 2Θ range 5°-80° using samples milled less than 100μm.
- Hot modulus of rupture are done on samples with following dimensions, 40x40x160mm$^3$. Samples are first calcined at 1450°C for 5 hours. Measurements are done at 1450°C with a heating rate of 5°C/minute and a holding time of 30 minutes.
- For refractoriness under load, cylinders with following dimensions are prepared: 50mm±0.5mm in diameter, 50mm±0.5mm in height, and a centred hole of ~12mm in diameter. After a first calcination at 1450°C during 5 hours, measurements are done with 5°C/minute heating rate and a load of 0.2MPa.

## RESULTS AND DISCUSSION

### Rheology and structuration

As a reminder and in order to compare later drying ability of the samples, the three formulations are casted with the same amount of water. Figure 1 shows it was possible to adjust a very similar flow behavior for these three formulations with the help of different commonly used dispersant, accelerator and retarder. Having this property allows to ensure a proper placing of the samples during casting for the further mechanical strength development. However, previous tests adding Ludox silica sol and micro silica in the same formula failed to find an adjustment of the additives to get a good flow behavior and a satisfactory structuration kinetics. This confirms that the use of colloidal silica is very sensitive and not trivial. This is

93

why the best compromise finally retained is that one with 10 wt% Ludox 50, but without the use of micro silica.

*Fig. 1: Flow values for the different castables.*

Structuration kinetics between the castables are quite different depending on the binder used. Figure 2 clearly shows that the structuration of NCC-2K bonded with colloidal silica starts earlier than NCC-1K, but progresses more slowly. The velocity signal reaches a maximum value of only 2300 m/s despite the high amount of silica sol used. Besides, the use of magnesia as a gelling agent only allows to adjust the starting point of signal increase but not its maximum value. This indicates the efficiency limit of silica sol as a binder. On the contrary, the ultrasonic propagation speed in NCC-1K reaches within a few hours up to 3000 m/s, indicating a noticeable structuration of the castable that can be easily controlled by citric acid as a retarder. As expected, ULCC ultrasonic profile is faster and higher due to the presence of calcium aluminate in a higher quantity.

*Fig. 2: Ultrasonic profiles.*

After a drying at 110°C according to table 2, water loss and open porosity values for ULCC castable indicate the lowest free water release from the sample at this step. At higher drying temperature, the amount of bonded water in calcium aluminate hydrates will release from the sample and will contribute to the increase of apparent porosity to a similar value as NCC-2K. For NCC-1K, a higher water loss and intermediate value of porosity indicates higher amount of free water and lower amount of calcium aluminate hydrates compared to ULCC. As for ULCC, by increasing the drying temperature, the open porosity should increase by the same order of 18% like NCC-2K. In the case of silica sol, water loss is only 4.8%, probably due to mass measurement error between demoulding and drying step as a small part of water may release from the sample. On the other hand, porosity is already at maximum. These results, in static conditions at 110°C along 24hours, already show the different drying behaviours between these formulas depending on the different kinds of bonding system involved. Macro thermo gravimetric

analyses will complete these results in dynamic conditions over a wider range of temperature.

Tab. 2: water loss and porosity after drying at 110°C

| Samples | Water Loss (wt%) | Apparent Porosity (%) |
|---------|------------------|-----------------------|
| ULCC | 4,4 | 14,2 |
| NCC-1K | 4,9 | 16,6 |
| NCC-2K | 4,8 | 18,3 |

**Drying ability**

The drying behaviour of the castables is compared through a macro thermo gravimetric analysis with the help of the equipment below (figure 3). Samples are casted in a cubic mould of 10 cm side with a thermocouple inside, near its centre. After a curing of 24 hours under 90% relative humidity and demoulding, the sample is then placed in a kiln and suspended on a balance by the thermocouple. A steel box prevents damage to the kiln in case of explosion.

*Fig.3: macro thermogravimetric equipment and sample mounting.*

By simultaneously controlling the kiln temperature and measuring the mass of the sample, the macro thermo gravimetric curves are obtained as shown in figure 4. To test repeatability of the experiment, 3 trials are usually done for each formula with a heating rate of 300°C/hour until 600°C. As a reminder, table 2 indicates a mass loss between 4.4 and 4.9 wt% after 24 hours at 110°C for all samples. On figure 4, NCC-2K curve confirms the same mass loss of water and complete drying in the ebullition range of temperature (i.e. 4.5 wt% around 110°C). On ULCC and NCC-1K curves, mass losses are respectively around 1 wt% and 1.8 wt% in the same range of temperature. This already indicates the slower release of water vapour for these two formulations compared to NCC-2K. In parallel, this is well correlated with low permeability values measured at 110°C on figure 5, while NCC-2K already exhibits more than 5 mDarcy. In case of NCC-2K, release of boiling water directly creates high permeability in the castable due to bonding mechanism of colloidal silica. In case of ULCC and NCC-1K, presence of crystalline hydrates from hydration reactions before drying and from in-situ hydration reactions during drying under different hydrothermal conditions [6], lead to a lower permeability (figure 5) and prevent free water to release easily from the castable. Indeed, while temperature is increasing on figure 4, ULCC curve shows the lowest slope of mass loss and drying process is only complete after around 280°C, once free water and bonded water from calcium aluminate hydrates have released. NCC-1K curve shows a higher slope of mass loss and complete drying is done at around 200°C. This is well correlated with the increase of permeability between 110 and 200°C for NCC-1K (figure 5), in which free and bonded water can be released from the castable slightly more easily than ULCC for which permeability values keep very low. We assume NCC-1K castable presents higher values of permeability due to a lower amount of crystallised hydrates compared to ULCC. But, from our experience during the technical development of Refpac® Mipore product [7], these values are not enough to ensure safe drying at very high heating rate without spalling or explosion. Therefore, a second formulation of NCC-1K is also tested with Mipore permeability enhancement concept and shown as NCC-1K Mipore curve on figure 4. The result

clearly shows the same behaviour as NCC-2K with a main mass loss in the ebullition temperature range. Figure 5 also confirms the increasing of permeability values compared to NCC-1K with a value of around 3 mDarcy.

Fig.4: mass of 10 cm3 cubes versus inner temperature.

Fig.5: permeability measurements after 110 and 200°C.

Figure 6 shows the cubes after the drying experiments until 600°C. On one hand, ULCC and NCC-1K are free of cracks, on the other hand NCC-2K cube shows large cracks on sides and bottom. As it concerns NCC-1K Mipore only small and few cracks are noticeable. In the case of NCC-2K, these cracks should be due to initial low mechanical strength just after demoulding (figure 7) while a high amount of water is released from the sample during drying period until 105-110°C. In other words, the kinetic of the increase in mechanical strength is slower than the kinetic or mass transfer of the water vapour release from the sample, which leads to the formation of cracks. To avoid this, heating rate must be adapted to more usual values like 50°C/hour. In NCC-1K Mipore formula where cracks form in a lesser extent, higher initial mechanical strength must help in supporting this high water vapour release at ebullition temperature. Similarly, a slower heating rate should avoid this. Finally, due to the low permeability depending on calcium aluminate bonding in ULCC formula, free water is more difficult to remove during drying. Then, ULCC formula will need the highest temperature for a complete drying that occurs around 280°C. Nevertheless, as calcium aluminate cement develops strong mechanical strength, the formula is able to support high pressure increase from water vapour inside porosity, limiting the risk of explosion. As NCC-1K develops slightly higher permeability compared to ULCC, removing free water is easier and will require a lower temperature as the complete drying is done at around 200°C. On the other hand as it develops lower mechanical strength, the risk of steam spalling is still present in case of too fast pressure increase. Thus, a drying with an adapted heating rate is recommended. In the end, NCC-2K and NCC-1K Mipore will require the lowest temperature for complete drying, as in both cases, it occurs at 100-110°C, and where the risk of high steam pressure build-up is

low. Systems like colloidal silica as well as LP660 with Mipore concept are able to develop bonds with low dehydration temperature and creating high permeability. Then, spalling or explosion risk is much lower, but cracks formation can still be an issue in case of too high heating rate due to lower mechanical strength compared to ULCC.

Fig.6: Cubes after drying until 600°C.

Fig.7: Green and dried Cold Compressive Strength on 3x3x16cm³ specimens.

**Thermo-mechanical properties**

Beside a fast drying ability, another key expectation for a binder is its compatibility with hot properties of a castable. In addition to the other raw materials used in a refractory castable, the binder itself can have a great impact on refractoriness, thermal shock and maybe corrosion resistance. It is well known that a good approach to improve hot properties is to limit calcium content brought by the nevertheless very useful calcium aluminate cement [8]. Figure 8 confirms low values of hot modulus of rupture in both cases, after a curing of 110°C or after a first calcination at 1450°C, for ULCC samples compared to NCC-1K and NCC-2K. These ones exhibit similar results in both cases. Same trend is also confirmed through refractoriness under load on figure 9. For every rates of deformation of the samples, ULCC shows lower temperature values indicating its lower refractoriness. NCC-1K has a very close behaviour compared to NCC-2K, indicating an almost similar refractoriness. These tests confirm the low impact of less than 0.2 wt%CaO in NCC-1K compared to castable NCC-2K.
*Fig.8: Hot Modulus of Rupture (HMoR) at 1450°C after drying and after calcination at 1450°C during 5h.*

*Fig.9: Refractoriness under load after calcination at 1450°C during 5h.*

96

*Fig.10: XRD diagrams of fine fraction of castable (<100µm) after calcination at 1400°C during 6h.*

Finally, XRD diagram for ULCC sample on figure 10 clearly shows the presence of anorthite after cooling due to approximately 0.75 wt% of calcium oxide. The presence of anorthite with a low melting temperature is well in accordance with refractoriness under load and hot modulus of rupture results. XRD diagrams for NCC-1K and NCC-2K don't reveal the presence of anorthite and exhibit much higher mullite compared to ULCC. Still presence of cristobalite also indicates that mullite formation is not totally complete at 1400°C. Small differences noticed on refractoriness under load results

between NCC-1K and NCC-2K over 1550°C should come from differences in quantity, composition, and viscosity of the liquid phase. Also, difference in distribution and reaction of the liquid phase inside the fine matrix of the castables, between small crystals of mullite and nature of excess alumina particles, should affect high temperature property. Additionally, it is to notice that with only 5 wt% of micro silica in our castable formulations, we may not have maximized mullite formation.

## CONCLUSIONS AND PERSPECTIVES

The dry powder NCC-binder prototype LP660 shows robust properties for setting and flow ability compared to colloidal silica which needs magnesia as a setting accelerator. Although it seems contradictory, this calcium aluminate based LP660 prototype concept shows the possibility to use it as binder for no cement castables. It creates sufficient green strength comparable to silica sol/gel, but in a more predictable and shorter time frame. Under fast drying conditions, a castable requires a good compromise between mechanical strength development and creation of permeability to support release of high water vapor pressure. The use of the LP660 prototype in NCC-1K under fast drying conditions (300 °C/h) showed intermediate behavior compared to ULCC and NCC-2K. Nevertheless, lower heating rates are recommended to avoid steam explosion, especially for thicker linings and big precast shapes. Moreover, the combination of LP660 prototype with Mipore permeability enhancement concept showed that similar drying profile like colloidal silica can be reached. Concerning the thermomechanical properties, the usage of LP660 gave nearly the same results as the NCC-2K which is using a silica sol/gel bond. This demonstrates that 0.2 wt% CaO in a castable are not detrimental to the refractoriness. Nevertheless, this low presence of calcium oxide in combination with other impurities like $TiO_2$ and $Fe_2O_3$ coming from bauxite fine powder, as well as the amount of $SiO_2$ in that kind of matrix formulation, will be further studied to better understand its impact on mullite and liquid formation at high temperature.

## ABSTRACT

Carbon is used in different configurations in refractory materials because of its property-enhancing effects, such as increased thermal shock resistance and wear reduction. In this context, organic carbon in particular is frequently criticized for its partly carcinogenic and mutagenic impact on human health, which arises especially in the presence of PAH. But despite decades of research, there is still no standardized analytical strategy for the detailed investigation of the complex organic phases in refractory materials apart from the analysis of some single defined compounds. Therefore, in this work, a non-target analytical strategy for characterization and classifications of refractory materials is presented. This is particularly challenging because the organic phase in these materials is often present in only a very small proportion and along with many other substances so that highly sophisticated analytical methods have to be used. The focus in this work is on the generation of a large amount of high-quality data using high resolution time-of-flight mass spectrometry as well as a targeted reduction, evaluation and interpretation of these data using multivariate statistical approaches. In addition to the clear classification of the materials based on their structure and chemical composition, characteristic features of each sample could be identified and extracted to provide a comprehensive understanding of the investigated refractories in order to evaluate their quality and even foresee their behavior in the future.

## INTRODUCTION

Carbon has been used in refractory materials for a long time due to its property-improving effect. These include, in particular, a wear reduction by reducing the infiltration depth of melts and slags, an improvement in thermal shock resistance by increasing thermal conductivity while reducing thermal expansion, as well as a characteristic structural flexibility. Carbon is introduced into the microstructure through two forms. On the one hand, through inorganic carbon carriers, such as graphite or carbon black, on the other hand, in the form of organic binders, such as synthetic resins or pitches. The latter are increasingly the focus of attention of authorities, industry and science due to their known hazardous properties to health and the environment. However, despite decades of research, the exact chemical composition of these carbon mixtures has still not been fully clarified. This deficit is particularly caused by their complexity. In addition to the large number of compounds, their structural and chemical similarity as well as their largely non-volatile character are particularly challenging [1–3]. In addition, the complex carbon mixtures in the field of refractory applications are precisely not present isolated. Instead, they are a minor component of a refractory batch, which further increases the complexity of the sample. However, in the analysis of refractory materials, the focus of previous studies has been predominantly on maintaining and optimizing the chemical, mechanical, and thermal properties of refractory systems while reducing harmful emissions by combining and substituting different binders [4–9] and characterizing oxide and non-oxide inorganic constituents [10]. In contrast, a characterization of the organic constituents of already manufactured refractory materials has hardly been carried out. Therefore, in this work, the organic phase of refractory materials will be investigated in more detail. For this purpose, three MgO-C samples were first analyzed by DIP-HR-TOFMS, which in previous studies showed great potential to overcome the listed challenging properties [11–14]. For example, the studies showed a decrease in the effective boiling temperature of the analytes from

T = 330-350 °C [12–14], which can be attributed to the reduced pressure in the system during the measurement. In addition, an applied temperature gradient and the high resolution of the mass spectrometer were able to separate the analytes and thus reduce the complexity of the samples [12]. However, since this method leads to a large amount of data, a reduction was performed using multivariate statistical methods such as hierarchical cluster analysis (HCA) and principal component analysis (PCA) to classify the samples based on their organic phases and extract characteristic structural features.

## EXPERIMENTAL

### Sample material

In this work, three magnesia-carbon bricks MgO-C with a graphite content of 10 wt.-% and different binders with a content between 2.5 wt.-% and 3.0 wt.-% were analyzed. In MgO-C1, a mixture of fused magnesia and sintered magnesia was used as raw material. In MgO-C2 and MgO-C3, only fused magnesia served as raw material. All bricks were dried at T = 200 °C. For further analysis, the MgO-C bricks were first coarsely crushed and then finely ground for t = 10 min using a Pulverisette 0 vibratory micro mill (Fritsch, Idar-Oberstein, Germany).

### High-resolution mass spectrometry, DIP-HR-TOFMS

The samples were analyzed by high-resolution time-of-flight mass spectrometry (HR-TOFMS) on a Pegasus GC-HRT 4D (Leco, St. Joseph, USA) with an equipped direct inlet system (DIP, SIM GmbH, Oberhausen, Germany). Approx. m = 5 mg of the solid samples were transferred to the ion source without any further sample preparation and heated with a temperature gradient to T = 400 °C and a dwell time of t = 3 min, resulting in a total analysis time of t = 540 s. Seven replicates were measured for each sample.

### Data processing and statistical analysis

DIP-HR-TOFMS data were processed with home-build Matlab scripts (R2020b, The MathWorks, Natick, USA). Briefly each detected feature was assigned to a molecular formula $C_cH_hN_nO_oS_s$ based on its exact mass with $2 \leq c \leq 100$, $2 \leq h \leq 100$, $0 \leq n \leq 2$, $0 \leq o \leq 2$ and $0 \leq s \leq 1$ and a maximum number of three heteroatoms. If no assignment was possible within an error window of 5 ppm, the corresponding feature was removed. The assigned features then served as input for further statistical analysis.

For statistical analysis, the abundance data were first normalized to total intensity and then power transformed to reduce heteroscedasticity. For hierarchical cluster analyses (HCA), with Ward's minimum variance algorithm and Euclidian distance as metric, the intensities were mean centered.

To investigate differences in bricks, a supervised principal component analysis (PCA) was performed. For this purpose, significantly different *m/z* were extracted by ANOVA with p = 0.05 followed by Bonferroni correction. The extracted ions intensities were then mean centered and served as input to PCA.

## RESULTS AND DISCUSSION

### Chemical and structural investigation of the samples

The mean relative mass accuracies and assignment ratios of the data processing of the seven replicate measurements with the associated sample standard deviations are shown in Tab. 1.

97

*Tab. 1: Assignment rate, relative mass accuracy and standard deviations after data processing*

|  | MgO-C1 | MgO-C2 | MgO-C3 |
|---|---|---|---|
| **Assignment rate in %** | 83.8 (± 1.5) | 77.6 (± 12.5) | 78.2 (± 2.2) |
| **Relative mass accuracy in ppm** | 2.03 (± 0.03) | 1.60 (± 0.09) | 1.81 (± 0.05) |

The contour plots in Fig. 1 show the m/z of the ions as a function of analysis time. The color scale represents the intensity normalized to the total ion current. Sum spectra were obtained by adding the intensities per m/z over the total analysis time, while the ion current describes the added intensity per second.

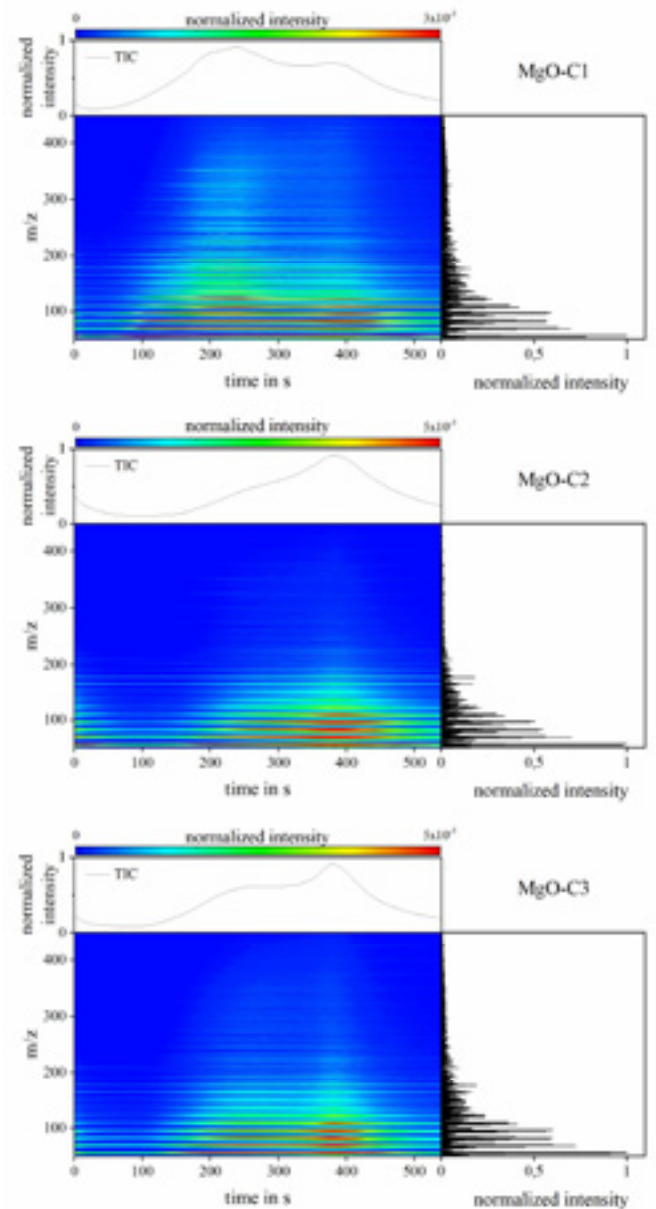

*Fig. 1: Contour plots with normalized intensities of detected m/z as a function of analysis time, total ion currents (TIC) as a function of analysis time and sum spectra over the entire measurement [14]*

In all samples, ions with m/z < 120 are detected directly at the beginning of the measurement, before the intensity of the total ion current decreases again. In the further course of the measurement, two peaks of the TIC can be observed. For MgO-C1, these are clearly separated and occur at t = 240 s and t = 390 s. In the case of MgO-C2 and MgO-C3, an overlapping occurs, with the first peak occurring as

the shoulder of the maximum. Overall, it is evident that ion currents of these two samples are very similar, in contrast to MgO-C1. This is also reflected in the contour plots. In MgO-C2 and MgO-C3, mainly ions with m/z < 200 are measured over the entire measurement period, while in MgO-C1, especially between 150 s < t < 450 s, higher molecular weight ions up to m/z < 400 also appear with low intensities. Over the entire measurement, MgO-C1 shows the highest average m/z with m/z 183 ± 16, followed by MgO-C3 with m/z 140 ± 7 and MgO-C2 with m/z 118 ± 7. It is remarkable that in none of the samples a strong increase of the maximum m/z with increasing measurement time and thus increasing temperature can be observed. Even at the end of the measurement, mainly ions with *m/z < 120* appear with strong intensities, indicating a strong fragmentation or thermal decomposition of the contained compounds.

To investigate the chemical composition, the detected compounds were assigned to a compound class on the basis of their integrated heteroatoms N, O, and S. Fig. 2 shows the distribution of all assigned mass traces in the three different samples as the mean value of the seven replicates. In all samples, more than 70 % of all detected features are attributed to ions without integrated heteroatom. The largest difference between the samples is observed in the intensity distribution of the heteroatomic compound classes. MgO-C2 shows higher relative intensities of the oxygen-containing compounds of classes O and O₂ compared to MgO-C1 and MgO-C3. In contrast, in MgO-C1 and MgO-C3, ions with a nitrogen and a sulfur atom, respectively, are also detected in higher intensities than in MgO-C2.

*Fig. 2: Normalized intensities of all assigned compound classes for the three samples studied. The error bars show the sample standard deviations of the seven replicates. [14]*

In summary, the results indicate a very similar structure for all samples. At the same time, differences in molecular mass distribution and elemental composition can be observed. Furthermore, comparatively high standard deviations of the relative abundances of the individual compound classes can be observed within the samples in the seven replicate measurements. On the one hand, this can be explained by the low mass fraction of the organic phase and the associated low intensities. On the other hand, it has to be considered that the samples are crushed refractory products based on natural raw materials. Even if a complete pulverization and homogenization of the sample was aimed at in the course of the sample preparation, variances in the sample composition of the individual replicates cannot be excluded. Taken together, this makes it difficult to intuitively determine significant differences and makes the use of statistical methods essential for a reliable classification of MgO-C samples.

**Classification by multivariate statistical data analysis**
Fig. 3 shows the result of the hierarchical cluster analysis (HCA) of all assigned ions with all variables mean centered. This data preparation leads to the fact that the intensities of the individual variables have a direct influence on the model. A cophenetic correlation

98

coefficient of $c_{coef} = 0.73$ confirms an adequate reproduction of the data set by the applied cluster model. The seven replicates of MgO-C1 are clustered together by the model and are also clearly separated from the other two samples. However, this unsupervised cluster analysis is not able to distinguish between the samples MgO-C2 and MgO-C3. This is in good agreement with the results of the contour plots, which also showed a visually greater similarity between these two samples. At the same time, this also shows that intense ions occur with comparable intensities in both samples. These compounds are therefore neither suitable for classification nor as characteristic structural elements, but rather overlap such elements. Therefore, to reduce the data to potential classifiers, an ANOVA was performed. This reduced the original 725 features to 299 potential classifiers. Only the potential classifiers extracted by ANOVA were then used as input for a supervised principal component analysis to determine characteristic structural elements for each sample.

Fig. 3: Dendrogram of hierarchical cluster analysis (HCA) of the three MgO-C bricks and their seven replicates, using the mean-centered DIP-HR-TOFMS data as input. [14]

The results of the principal component analysis (PCA) are shown in the form of biplots in Fig. 4 and Fig. 5. Here, the scores are represented by black diamonds and the loadings by circles. The color coding shows the different properties of each variable, such as its number of DBE (Fig. 4) or its association with a particular compound class (Fig. 5). A clear clustering of the three MgO-C samples and their seven replicates can be seen. The first principal component clearly separates MgO-C1 from MgO-C2, while the separation of MgO-C3 is additionally based on the second principal component. The color highlighted loadings in Fig. 4 show a distinctive influence of the number of double bond equivalents on the classification of the MgO-C samples. Almost all features with DBE $\geq 10$ have a strong negative influence on the first principal component and are thus correlated with MgO-C1. This is in good agreement with the higher average molecular mass of this sample compared to the other two.
Fig. 4: Biplot of the scores and loadings of principal component analysis (PCA). The color scale classifies the features according to their number of DBE. [14]

In addition to molecular size, individual compound classes are also essential for distinguishing the samples. Fig. 5 shows that, apart from four features, all oxygen-containing compounds are located in the right half of the biplot and thus have a positive influence on PC1. Furthermore, compounds of the $O_2$-class additionally show an exclusively negative influence on PC2. This proves a strong positive correlation of oxygen compounds with MgO-C2. In contrast, sulfur-containing features have an exclusively negative influence on PC1 and are thus significant for MgO-C1. When analyzing the S-compounds, it can be observed that they are predominantly organic compounds with DBE $> 9$. Features of the N-class are only observed in the upper two and the lower left quadrants of the biplot. This proves the negative correlation of nitrogenous features with the sample MgO-C2, whose scores occur exclusively in the lower right quadrant. Overall, these results are in good agreement with the relative abundances of the compound classes in the respective samples shown in Fig. 2.
Fig. 5: Biplot of the scores and loadings of principal component analysis (PCA). Features with a major influence on the first two principal components are highlighted in color, classified according to their substance classes. [14]

## CONCLUSIONS

Multivariate statistical methods such as HCA und PCA for the analysis of complex DIP-HR-TOFMS data represents a powerful tool for characterization and classification of refractory materials. It was shown that the investigated refractory products can be distinguished without any doubt despite the low mass fraction of the organic phase and a basically similar structural composition. By applying a supervised PCA, it was also possible to identify and extract characteristic structural features of each sample. In addition to the size of the aromatic system, heteroatomic structures in particular were of major importance in distinguishing the samples.

## ABSTRACT

In connection with the development of the manufacture of monolithic refractories containing zirconium dioxide it has become necessary to carry out investigations into the hydraulic binder systems containing $ZrO_2$. One of these systems is $CaO$-$SrO$-$Al_2O_3$-$ZrO_2$ (C-S-A-Z), especially in the regard the components of high melting point. Thus, complementary experiments of X-ray diffraction analysis (XRD) and scanning electron microscopy (SEM) were used to analyse the properties of state-of-the-art cements belonging to the C-S-A-Z system. Strontium zirconium aluminate cement and strontium calcium zirconium aluminate cements were prepared as multiphase materials. Moreover, strontium aluminate cement with high content of $SrAl_2O_4$ as the main clinker phase was prepared by milling and calcination of the equimolar mixture of strontium carbonate and aluminium oxide. This work also compare the properties of $SrAl_2O_4$-bonded alumina-based castables, and of the equivalent castables containing calcium aluminate cement (CAC).

*Keywords: refractories, special inorganic cements, castables, microstructure, synthesis, new solutions for monolithics*

## INTRODUCTION

Calcium aluminate cement (CAC) is the most widely used binder for monolithic refractories, especially castables [1]. During the hydration process, calcium aluminates CA, $CA_2$ and $C_{12}A_7$ (C=CaO, A=$Al_2O_3$) undergo hydration and form a network of hydration products in the matrix, connecting fillers i.e. the fines and the refractory aggregates [2]. This process is crucial for development of the high-quality cement-based monolithics.

An increasing tendency to use the monolithic refractories over the past decade has been accompanied with the parallel trend of the improvement of cement-containing castables by introducing Zr-containing compounds, e.g. $ZrSiO_4$, $CaZrO_3$, $ZrO_2$ or AZS and AZ materials (A=$Al_2O_3$, Z=$ZrO_2$, S=$SiO_2$) as aggregates or modifying binder systems by introducing Zr, Sr or Ba elements [3-6]. In this regard, the system of $CaO$-$SrO$-$Al_2O_3$-$ZrO_2$ (C-S-A-Z) will form large group of hydraulic binders under the aegis of this project.

### Motivation and goal of this work

Thus, in this study, composite cements belonging to the S-A-Z, C-S-A-Z and S-A systems were obtained and evaluated as alternatives to CACs for use in the refractory monolithic technologies, especially castables.
Thus, the main goals of this work are:
- to synthesize and investigate new cements belonging to the S-A-Z, C-S-A-Z and S-A systems,
- to investigate and compare the properties of alumina-based castables made of CAC or strontium monoaluminate (S-A)-containing cement.

## EXPERIMENTAL PART

### Synthesis

For the preparation of refractory cement clinker (Table 1), stoichiometric quantities of $SrCO_3$, $Al_2O_3$ and $ZrO_2$ (sample $S_7A_3Z$); $CaCO_3$, $SrCO_3$, $Al_2O_3$ and $ZrO_2$ (sample $C_{3.5}S_{3.5}A_3Z$); $SrCO_3$ and $Al_2O_3$ (sample SA) were used. The powders were then ball milled using monoclinic zirconia balls for 1 h at a speed of 400 r/min. After milling, the batches were pressed at 50 MPa, to produce cylindrical green compacts of about 20 mm diameter. These cylindrical-shaped samples were heated at 2°C/min and calcined at 1300°C for 10 h. After calcination, samples were

crashed using mortar and pestle. The crashed powders were again ball-milled for 1 h, pressed and sintered at sintered at 1500°C for 1 h ($S_7A_3Z$ sample), at 1430°C for 10 h ($C_{3.5}S_{3.5}A_3Z$ sample), and at 1550°C for 10 h (SA sample) to obtain sintered bodies. Moreover, commercially available calcium aluminate cement Górkal 70 from Górka Cement was also used in further investigations.

*Table 1. Composition of samples.*

| Sample abbreviation* | Composition |
|---|---|
| $S_7A_3Z$ | $7SrO \cdot 3Al_2O_3 \cdot ZrO_2$ |
| $C_{3.5}S_{3.5}A_3Z$ | $3.5CaO \cdot 3.5SrO \cdot 3Al_2O_3 \cdot ZrO_2$ |
| SA | $SrO \cdot Al_2O_3$ |
| CAC70 | Commercially available calcium aluminate cement Górkal 70 from Górka Cement |

*C=CaO, S=SrO, A=$Al_2O_3$, Z=$ZrO_2$

### Castables preparation

The raw materials for alumina-based castables are different sizes of tabular alumina, spinel AR90 and reactive alumina from Almatis, microsilica 971 from Elkem, calcium aluminate cement Górkal 70 (CAC70) from Górka Cement (Trzebinia, Poland) or strontium aluminate cement (SA) synthesized under laboratory conditions and additives. Details of these compositions are listed in Table 2.

*Table 2. The composition of $Al_2O_3$-based castables (wt. %).*

| Raw materials | CAC70-Castables | SA-Castables |
|---|---|---|
| Tabular alumina 0.2-6 mm | 50.86 | 50.86 |
| Spinel AR90 0-0.5 mm | 20.89 | 20.89 |
| Electrocorundum < 0.1 mm | 6.31 | 6.31 |
| Reactive alumina | 15.5 | 15.5 |
| Reference CAC Górkal 70 | 5.35 | - |
| As-synthesized SA cement | - | 5.35 |
| Microsilica 971 | 1.09 | 1.09 |
| Additives | 0.1 | 0.1 |
| Water | 4.5 | 4.5 |

The castable compositions were weighted, dry and wet homogenized, poured in a mold and compacted through vibration. Then, samples were kept in the molds for 24 h to set completely and then they were removed from the molds, dried at 110°C for 24 h and heat treated at 1500°C for 10 h.

### Sample preparation and methods of investigation

The microstructure of the $S_7A_3Z$, $C_{3.5}S_{3.5}A_3Z$ and SA cement clinkers was characterized by SEM-EDS method. For this purpose, the scanning electron microscopy NOVA NANO SEM 200 of FEI, equipped with a EDS system of EDAX was used. Samples were embedded in resin, cut, grinded, polished and coated with carbon to be conductive and then examined. The clinkers were crushed and milled to obtain fine powders, with particle size below 63 µm. Phase identification for the as-synthesized $S_7A_3Z$, $C_{3.5}S_{3.5}A_3Z$ and

SA cement clinkers was carried out using X-ray diffraction (XRD) on a ProPANalytical X'Pert X-ray diffractometer, with Cu Kα radiation (λ = 0.15418 nm), with 0.02° per step and 3s time per step (2theta range from 10° to 50°).

The CAC70-Castables and SA-Castables heat treated at 1500°C for 10 h were investigated in term of their physical properties including apparent porosity (AP), cold modulus of rupture (CMOR) and cold cursing strength (CCS) according to the procedures presented in the PN-EN ISO 1927-6:2013-06 standard.

One of the most important instrument for the analysis of microstructural characteristics of castables was the scanning electron microscope (SEM). For this purpose, the samples were cut, immersed in resin, grinded, polished and coated with carbon.

## RESULTS

### Phase composition and microstructure of cement clinkers

XRD patterns for the as-synthesized the $S_7A_3Z$, $C_{3.5}S_{3.5}A_3Z$ and SA cement clinkers are shown in Figs 1, 3 and 6, respectively. The main crystalline phases identified in the $S_7A_3Z$ clinker, were $Sr_3Al_2O_6$, $SrAl_2O_4$ and $SrZrO_3$ (Fig. 1). The $C_{3.5}S_{3.5}A_3Z$ sample contains $(Ca,Sr)_3Al_2O_6$, $SrAl_2O_4$, $SrZrO_3$ and $CaZrO_3$ (Fig. 3), whereas the SA sample was found as monophase (Fig. 6).

Fig. 1. XRD pattern of the $S_7A_3Z$ sample after sintering at 1500°C for 1 h.

Fig. 2. SEM image of microstructure of the $S_7A_3Z$ sample after sintering at 1500°C for 1 h. EDS analysis: 1-$SrZrO_3$, 2-$SrAl_2O_4$, 3-$Sr_3Al_2O_6$.

Moreover, Fig. 5 compares (a) the XRD peaks corresponding to $SrZrO_3$ and $(Sr,Ca)ZrO_3$ in the samples $S_7A_3Z$ and $C_{3.5}S_{3.5}A_3Z$, respectively, and (b) XRD peaks corresponding to $SrAl_2O_4$ and $(Sr,Ca)Al_2O_4$ in the samples $S_7A_3Z$ and $C_{3.5}S_{3.5}A_3Z$, respectively.

As it can be noticed in Fig. 5, the XRD peaks shifts revealed features between two samples $S_7A_3Z$ and $C_{3.5}S_{3.5}A_3Z$. It can be seen that the main XRD peaks of $SrZrO_3$ and $SrAl_2O_4$ slightly shifted toward higher angles in the $C_{3.5}S_{3.5}A_3Z$ sample, suggesting decreased of the unit cell volume of $(Sr,Ca)ZrO_3$ and $(Sr,Ca)Al_2O_4$, when compared to the pure $SrZrO_3$ and $SrAl_2O_4$ in the $S_7A_3Z$ sample. This is attributed to the much larger ionic radius of $Sr^{2+}$ (132 p.m.) compared with $Ca^{2+}$ (114 p.m.).

Fig. 3. XRD pattern of the $C_{3.5}S_{3.5}A_3Z$ sample after sintering at 1430°C for 10 h.

Fig. 4. SEM image of microstructure of the $C_{3.5}S_{3.5}A_3Z$ sample after sintering at 1430°C for 10 h. EDS analysis: 1,2-$(Ca,Sr)Al_2O_6$ with different compositions, 3-$(Ca,Sr)Al_2O_4$, 4-$(Sr,Ca)ZrO_3$.

Fig. 5. (a) XRD peaks corresponding to $SrZrO_3$ and $(Sr,Ca)ZrO_3$ in the samples $S_7A_3Z$ and $C_{3.5}S_{3.5}A_3Z$, respectively. (b) XRD peaks corresponding to $SrAl_2O_4$ and $(Sr,Ca)Al_2O_4$ in the samples $S_7A_3Z$ and $C_{3.5}S_{3.5}A_3Z$, respectively.
Fig. 6. XRD pattern of the SA sample after sintering at 1550°C for 10 h.

Fig. 7. SEM image of microstructure of the SA sample after sintering at 1550°C for 10 h.

SEM was used to characterize clinkers produced under laboratory conditions. SEM images for the as-synthesized the $S_7A_3Z$, $C_{3.5}S_{3.5}A_3Z$ and SA cement clinkers are shown in Figs 2, 4 and 7, respectively. The composition of the raw materials and conditions of synthesis greatly affect the clinker microstructure, and the distribution and sized of the phase grains. SEM revealed the phases in the $S_7A_3Z$ clinker, which include $Sr_3Al_2O_6$ and $SrAl_2O_4$ (coarse and fine), and agglomerated and partially sintered particles of $SrZrO_3$ (Fig. 2). On the other hand, Zr-rich phases were homogeneously distributed throughout the $C_{3.5}S_{3.5}A_3Z$ matrix (Fig. 4).

### Physical properties and microstructure of castables

The physical and mechanical properties of the two castables heat-treated at 1500°C are listed in Table 2. It can be seen that both the mechanical properties and apparent porosity of the alumina-based materials depends on the cement type.

Table 2. Physical and mechanical properties of the castables heat-treated at 1500°C.

| Samples | AP / % | CMOR / MPa | CCS / MPa |
|---|---|---|---|
| CAC70-Castables | 15.75 | 40.54 | 152.98 |
| SA-Castables | 17.80 | 30.62 | 222.82 |

Fig. 8. SEM image of microstructure of the CAC70-Castables after firing at 1500°C for 10 h.

Fig. 9. SEM image of microstructure of the SA-Castables after firing at 1500°C for 10 h.

SEM images for the as-synthesized the CAC70-Castables and SA-Castables after firing at 1500°C for 10 h are shown in Figs 8-9, respectively. The cement type affects the microstructure of the bonding interfaces between the matrix and aggregates in castables.

### CONCLUSIONS

A group of novel cements from the S-A-Z, C-Sr-A-Z and S-A systems was proposed and investigated. The strontium zirconium aluminate, strontium calcium zirconium aluminate and strontium monoaluminate cements were successfully synthesized by a two-step solid state reaction route and characterized by XRD and SEM-EDS.

The as-synthesized S-A cement was used to prepare alumina-based castables. The properties of $SrAl_2O_4$-bonded alumina-based castables, and of the equivalent castables containing calcium aluminate cement (CAC) were stablished. The SA-Castables exhibit better results in terms of CCS.

**Abstract**

In recent years, silica sol solutions have been increasingly used as cement-free binders in refractory unshaped products. The silica sol solutions are aqueous colloidal dispersions of nanoscale amorphous $SiO_2$ particles. Compared to conventional high alumina cement-bonded concretes, the silica sol-bonded products are characterized by good alkali and acid resistance. The main advantage, however, is that no calcium aluminate hydrate phases are formed during the setting process and thus these concretes can be heated much faster.

A major disadvantage of silica fume solutions is that they must be stored in separate containers, protected from frost and light. To avoid this, a new system in which the silica sol formation takes place "in-situ" in the refractory matrix is introduced. For this purpose, a microscale amorphous $SiO_2$ powder is mixed directly into the refractory mass. By adding water, the silica sol formation is generated within the matrix. This eliminates many of the major disadvantages of using aqueous silica sol solutions. The addition of < 1.0 % of this binder leads to good green strengths of the refractory castable. To compare the binding of cement-free and cement-containing refractories, the physical and chemical properties of a nearly pure alumina product was tested. For this purpose, all tests were carried out on the cement containing products and their non-cement counterparts bonded by liquid sol-gel or by the in-situ sol-gel formation. Furthermore, an example of application will be given proving the efficiency of the in-situ sol-gel technique for practical use.

**Introduction**

The most common binding system for unshaped refractories is based on calcium-aluminate-cement (CAC) which involves the formation of low melting phases like for example anorthite during firing [1, 2]. Therefore, a reduction of the CAC content is desirable. To achieve this, various alternative binding systems like the gel bindings were investigated in the past [3, 4]. The technique of gel binding is known since the 1990's and is mostly used in ultra-low cement castables (ULCC) and no-cement castables (NCC) [3, 5]. Instead of gaining the green strength by the hydration of CACs forming calcium alumina hydrates in sol-gel bonded systems the strength is achieved by creating a 3D-network by polymerization of amorphous silica particles immersed in water. Commonly a dispersion of $SiO_2$ in water is used as sol-gel for casting. This leads to lower green strength after drying [6]. After firing at temperatures above 900 °C, however, the strength of sol-gel bonded castables is higher than the one observed in cement-containing bonding systems [3]. Due to the absence of calcium hydrate phases during setting, the refractory castable can be heated at a higher rate [7, 8]. Furthermore, sol-bonded products show a higher alkali and acid resistance compared to cement bonded ones. The downside of using sol-gel as binder is its complex storing in separate canisters for liquids. To avoid the difficult storage of the silica fume solutions due to its vulnerability to light and frost, < 1 % microscale amorphous silica powder can be added to the mixture [9]. By casting it with water, a process of "in-situ sol-gel" formation occurs and leads to a sufficiently high green strength. This binding system can be applied to any kind of raw material-based refractory mix, and due to the low addition of silica powder, results in a pure chemical composition that does not impact the melting temperature of the refractory.

**Methods**

A high alumina thixotropic ULCC product was used as reference and modified to a NCC variant using a liquid sol-gel (NCC-L) and to another NCC variant by adding a microscale amorphous silica powder (NCC-P). After hydration, the microscale amorphous $SiO_2$ powder in combination with fine MgO as a gelling agent accounted for a binding in an otherwise pure $Al_2O_3$ system (Table 1). Consequently, the $SiO_2$ and MgO content is slightly raised, and the CaO content is lowered compared to the ULCC. In case of the NCC-L, a sol-gel with the composition of 30 % $SiO_2$ and 70 % water was added to the modified base recipe (Table 1). Compared to the NCC-L, the $SiO_2$ content in the NCC-P is 1.5 % lower, which leads to a $SiO_2$ content of below 1.0 % in the NCC-P (Table 2).

*Table 1: Composition of the tested products*

|  | **Raw material** | **Mixing agent** |
|---|---|---|
| **ULCC** | alumina, CAC (0.45 %) | 4.5 % water |
| **NCC -P** | alumina, fine MgO, fine SiO2 | 5.4 % water |
| **NCC-L** | alumina | 7.0 % sol-gel (30 % silica, 70 % water) |

Three bars and one cylinder were casted for each recipe. These were dried at room temperature as well as at 110 °C for 24 h, respectively. Afterwards two of the samples were burned at temperatures of 1000 °C and 1500 °C. All three bars of each product were used to measure the PLC (permanent linear change), the CCS and CMOR by using a standard test machine from Form+Test.

Pieces of each bar were pulverized and investigated via X-ray diffraction (XRD) measurements. For this purpose, a PANalytical X'Pert[3] diffractometer with a Cu $K_\alpha$ X-ray tube was used.

For the refractory under load measurement, the casted cylinders were pre-fired at 1000°C for 24 h and polished on the surface. The measurement was performed with a machine from Netzsch Gerätebau GmbH with a uniaxial pressure of 0,2 $N/mm^2$ during constant heating.

## Results and discussion

According to the X-ray diffraction patterns, the samples ULCC, NCC-P and NCC-L consist of 95.4 % - 96.0 % corundum and 3.7 % - 3.8 % β-alumina. After firing, the amount of corundum in the ULCC decreases from 95 % to 91 % and increases from 96 % to 98 % in the cement-free samples NCC-P and NCC-L. The latter is accompanied with the decrease of β-alumina to nearly 0 %. Beside this, the ULCC formed $CA_6$ (hibonite) consuming the cement phases at 1500 °C whereas in the NCC-L the relatively high amount of $SiO_2$ leads to the formation of mullite. None of these phases can be observed in significant amounts in the sample NCC-P due to the high purity of the system (Table 3). In contrast to that, a small amount of $SiO_2$ and $MgAl_2O_4$ (spinel) can be found due to the use of MgO as a gelling agent.

Due to the formation of calcium aluminate hydrate phases, the green strength of the ULCC is higher than that of the NCCs. Compared to the NCC-P, the green strength of the NCC-L is slightly higher. This is probably caused by the higher initial amount of silanol groups (Si-O-H) in the sol-gel compared to the powder (Figure 1, Figure 2).

After firing at 1000 °C, the CCS and CMOR of the cement-containing ULCC become lower than the ones of the NCCs, which is related to the decomposition of the CAH phases. The NCC-L has a significantly higher $SiO_2$ content compared to the NCC-P and thus the sintering temperature is lowered due to the lower melting point. For the same reason, the CCS and CMOR of the NCC-L are higher than the ones of the NCC-P (Figure 1, Figure 2).

With further increase of the temperature to 1500 °C, the CCS and the CMOR of the ULCC increases due to the formation of hibonite and the CCS overcomes those of the NCCs. In contrast to that, no large increase in the strength of the NCC-L can be observed (Figure 1, Figure 2). This can be also related to the high $SiO_2$ content, which not only lowers the sintering temperature, but also decreases the melting point. Without the high amount of $SiO_2$, melting occurs at a higher temperature. Thus, the strength of the NCC-P increases due to the sintering of the nearly pure $Al_2O_3$. This effect leads to a higher CMOR of the NCC-P compared to the NCC-L and ULCC (Figure 1, Figure 2).

The increase in the strength of the ULCC at 1500 °C is also related to a volume expansion at 1400 °C measured by the refractory under load test (Figure 3). This expansion might be related to the formation of hibonite. The NCC-L shows a lower refractoriness compared to the NCC-P (Figure 3). This can also be explained by the relatively high content of $SiO_2$ of approx. 2 % in the NCC-L compared to the NCC-P. Therefore, a suitable strength and refractoriness can be achieved in a nearly pure $Al_2O_3$ system with a $SiO_2$ content of < 1 %.

*Figure 1: Cold crushing Strength (CCS) of the tested ULCC, NCC-P and NCC-L castable.*

*Figure 2: Cold modulus of rupture (CMOR) of the tested ULCC, NCC-P and NCC-L castable.*

*Figure 3: Refractory under load measurement of the analyzed ULCC and the NCC variants with sol-gel and the in-situ sol-gel components.*

Apart from productions on a laboratory scale, the product based on the in-situ sol-gel binding has been used for casting well blocks in different shapes and dimensions, ranging from 370 mm to 470 mm in height and 360 mm in wide with a cylindrical hole with a diameter ranging from 118 mm to 199 mm (Figure 4). After casting and drying for 24 hours, the NCC-P showed sufficient green strength for demolding. In its application the NCC-P was used with a durability of 52 to 57 heating cycles at a plant site, which is comparable to the performance of spinel-containing alumina products.

Apart from this, the in-situ sol-gel binding system offers the advantages of using solely water for casting. Thus, the installation procedure is comparable to castables with a cement-based binding system. If $SiO_2$ is added as a powder and not as liquid sol-gel, the binder is already included in the dry-mixture and no temperature-

controlled storage of supplementary canisters is required. This saves storage space, reduces energy costs and simplifies the transport.

Furthermore, this binding system can be adapted to any products based on MgO, $SiO_2$ or $Al_2O_3$. This includes qualities from chamotte to high alumina raw materials. Even SiC can be added to the system. Further investigations of the in-situ sol-gel bindings system and adaptations to different applications are ongoing and will be discussed in the future.

## Conclusions

Besides the conventional binding system based on calcium-aluminate-cements, sol-gel can be used as an alternative approach. Disadvantages associated with the liquid sol-gel can be avoided by mixing a microscale silica powder in the dry-mixture initiating an in-situ formation of the sol-gel by adding water to the product. Compared to the liquid sol-gel, a significantly smaller $SiO_2$ amount of < 1.0 % is already sufficient to establish an adequate green strength through the silica powder addition. Due to the lower $SiO_2$ content, the number and the total amount of low-melting phases is diminished leading to higher refractoriness of the in-situ sol-gel bonded sample in a nearly pure $Al_2O_3$ system.

Based on the service live of the in-situ sol-gel bonded well blocks, the addition of the microscale silica is suitable for the intended application and thus can be used as an alternative to cement. In contrast to the use of the liquid sol-gel binder, the dry-mixture containing the microscale amorphous $SiO_2$ powder only needs water for casting, making the installation practice comparable to conventional cement-containing products. This delivers an "all-in-bag" solution for cement-free castables.

## ABSTRACT

This study combined fine MgO sinter with a novel aqueous dispersion of colloidal silica whose particles were surface modified with an epoxysilane agent. Their engineered surface reactivity produced self-flowing fine MgO sinter-colloidal-silica suspensions of easy mixing and suitable workability. Reference compositions containing plain water and conventional unsilanized colloidal silica were prepared and tested under the same conditions. After mixing, casting, and curing, the reactions between colloidal silica and MgO formed a packed $Mg_5Si_8O_{20}.8H_2O$ (magnesium silicate hydrate hydrate or talc) coating over MgO particles' surfaces hindering further hydroxylation and preventing their volumetric expansion. Therefore, the cast structures attained displayed suitable strength for demolding (12 MPa flexural strength) and safer drying (no explosive spalling). During thermal treatment up to 1600°C, silica particles softened and promoted viscous flow favoring MgO grains' densification. After sintering, the microstructure attained comprised dense MgO grains (84 % relative density) surrounded by small portions of $Mg_2SiO_4$ (2 wt%).

## INTRODUCTION

MgO-containing and colloidal silica-bonded are important classes of refractory castables. The former shows high refractoriness and resistance to corrosion by slag [1], whereas the latter involves straightforward mixing, curing, and drying processes [2]. However, their combination in a same system has not been synergistic so far. The hydroxylation reaction MgO particles experience during mixing releases $Mg^{2+}$ ions and triggers the colloidal silica gelling mechanism [3]. Therefore, whereas small additions of MgO (0.01-0.1 wt%) gradually harden typical high-alumina colloidal silica-bonded castables in a 1-hour time, solid amounts greater than 0.1-0.2 wt% instantaneously set the system hindering its homogenization and casting (Fig. 1a) [4]. Nevertheless, the potential for technological applications of colloidal silica-bonded MgO-containing castables suggests efforts to making such systems compatible are worthy [5].

Towards overcoming the poor workability drawback, authors investigated a novel grade of colloidal silica whose silanol groups at particles' surfaces were carefully modified with an epoxy silane-based coupling agent (gamma-glycidoxypropyltrimethoxysilane, GPTMS) [6]. The epoxy-ring opening reaction that occurred during the surface modification process resulted in a diol functionality at the end of each silane group, providing them with a hydrophilic character and superior steric stabilization in comparison to conventional unsilanized grades. As a consequence, high-solid load suspensions of fine MgO sinter particles could be prepared without instantaneous gelling [7,8].

In this study, aqueous suspensions of MgO sinter (MS) containing up to 17 wt% of silanized colloidal silica (SCS) were prepared and evaluated regarding mixing, dispersion, flowability, and workability. After casting and curing, the investigation focused on how SCS particles affected MgO hydroxylation. Drying behavior and evolution of physical properties (flexural strength, total porosity, and phases formed) and microstructure were evaluated during isothermal treatments from 120°C up to 1600°C. Reference compositions prepared with plain water and an equivalent unsilanized colloidal silica grade (similar particle diameter, solid load) were also tested under the same conditions.

## EXPERIMENTAL

Raw materials: fine MgO sinter (MS, High-Purity M30, RHI-Magnesita, Brazil; $D_{50} = 8$ μm, 98.3 wt% MgO), silanized colloidal silica (SCS, Levasil FX401, Nouryon, Sweden; $D_{50} = 11$ nm, 40 wt% of solids), unsilanized colloidal silica (UCS, Levasil CS40-222; $D_{50} = 9$ nm, 40 wt% of solids), and distilled water. The following three compositions were tested: a) 83 wt% of MgO sinter and 17 wt% of silanized colloidal silica (MS+SCS, 6.8 wt% of solid $SiO_2$, 0.95 MgO molar ratio), b) 88 wt% of MgO sinter and 12 wt% of distilled water (MS+$H_2O$, silica-free reference), and c) 83 wt% of MgO sinter and 17 wt% of conventional unsilanized colloidal silica (MS+UCS, 6.8 wt% of solid $SiO_2$).

After mixing (paddle mixer, 1000 rpm, 3 min), three sets of samples were prepared. The first remained in a closed vessel at 60°C for free-flowability measurements for up to 1 h; the second was cast as 70 mm length × 16 mm diameter cylinders for geometrical total porosity and three-point flexural strength tests, remaining 24 h at 60°C in a closed environment, 24 h at 60°C in a ventilated environment, and dried at 120°C overnight. Isothermal treatments were applied from 300-1600°C (1°C.min$^{-1}$ up to 300°C, 1 h hold, 2°C.min$^{-1}$ up to maximum temperature, 3 h hold; cooling rate of 5°C.min$^{-1}$ down to 800°C and 10°C.min$^{-1}$ down to room temperature). The third set was cast as 40 mm × 40 mm cylinders for drying tests and hydroxylation degree ($W_H$, wt%) and apparent volumetric expansion (AVE, %) measurements. They remained in a humid environment for up to 7 days at 60°C. Fractured green dried and sintered samples were observed by scanning electron microscopy and crystalline phases were identified by X-ray diffraction. References [1,3,8,9] describe the techniques.

## RESULTS AND DISCUSSION

The addition of MS to UCS led to its instantaneous gelling and the production of a flocculated material unsuitable for casting (Fig. 1a); the mixture with SCS, on the other hand, resulted in a highly fluid stable suspension (Figs. 1b and 2).

*Fig. 1: As-produced aqueous suspensions of MgO sinter with a) unsilanized colloidal silica or b) silanized colloidal silica; samples for AVE measurements (3 days, 60°C, [1]): MgO mixed with c) plain water (MS+H₂O) or d) silanized colloidal silica (MS+SCS).*

After mixing, the composition with SCS remained highly fluid and castable (FFI > 100 %) for up to 20 min longer than the silica-free reference even when the testing temperature was 60ºC. As discussed elsewhere, such a behavior was due to interactions amongst the positive charges at MgO particles' surfaces and the anionic character of SCS. The formation of a surface coating of $Mg_5Si_8O_{20}.8H_2O$ resulted in a system with high negative Zeta potential levels, and, hence, good stability [8].

*Fig. 2: Free-flow index for MgO sinter (MS) suspensions prepared with plain water (MS+H2O), silanized colloidal silica (MS+SCS), or unsilanized colloidal silica (MS+UCS) kept at 60ºC for up 1 h.*

Such protective coating remained (Fig. 3a) during 7-days curing and, therefore, samples prepared with SCS showed significantly lower hydroxylation degree ($W_H$) levels and no damages by apparent volumetric expansion (AVE) in comparison to the silica-free reference (Figs. 1c and 4). The anti-hydroxylation behavior also produced lower total porosity and higher flexural strength samples after drying and isothermal treatments (Fig. 5)

*Fig. 3: SEM/EDX images of a) green dried (120ºC) and b) sintered samples (fractured cross-section highlighting elemental analysis).*

*Fig. 4: a) Hydroxylation degree ($W_H$) and apparent volumetric expansion (AVE) for MgO sinter suspensions ($H_2O$ or silanized colloidal silica, SCS) after up to 7 days at 60ºC.*

The silica-free reference samples showed an intense strength reduction as the temperature of isothermal treatment increases above 120ºC due to the decomposition of the bridging points formed by magnesium hydroxide ($Mg(OH)_2$) particles during curing time [9]. Above 900ºC, the initial stages of sintering reduced total porosity and typical strength values were attained up to 1600ºC. Regarding SCS-bonded samples, on the other hand, strength increased continuously with the temperature of isothermal

treatment, attaining final levels slightly higher than those observed for the silica-free reference.

During sintering, $Mg_5Si_8O_{20}.8H_2O$ collapsed and evolved to $Mg_2SiO_4$ (forsterite). Rietveld quantification revealed a 98-2 wt% $MgO-Mg_2SiO_4$ ratio. Since the theoretical $MgO-Mg_2SiO_4$ maximum ratio was 17.3 wt% and no $SiO_2$-based crystalline phases were detected, most of the $SiO_2$ originally from SCS must have remained as a non-crystalline third phase amongst the other two (Fig. 3b)

*Fig. 5: a) Total porosity and b) flexural modulus of rupture for suspensions of MgO with water (MS+H2O) or silanized colloidal silica (MS+SCS) after isothermal treatments (120-1600ºC)*

## CONCLUSIONS

The combination of fine MgO sinter particles with an aqueous dispersion of silanized colloidal silica (0.95 MgO-SiO2 molar ratio) produced suspensions of high flowability and workability (approximately 30 min at 60ºC). During curing and drying, the formation of a protective coating of magnesium silicate hydroxide hydrate ($Mg_5Si_8O_{20}.8H_2O$ or talc) prevented damages caused by MgO hydroxylation. No explosive spalling occurred during drying. After isothermal treatments, the samples' flexural strength increased continuously due to the reduction in total porosity. The final microstructure after sintering contained dense grains of periclase ($\alpha$-MgO) surrounded by a thin layer of forsterite ($Mg_2SiO_4$) and non-crystallized $SiO_2$.

## ABSTRACT
In spite of all positive features of magnesia as a refractory material, the hydration of MgO and formation of Brucite are the main obstacles in using magnesia in monolithic refractories. To overcome this problem, the substitution of calcium aluminate cement for hydratable alumina (HA), and Nano MgAl$_2$O$_4$ addition on magnesia spinel castable have been investigated. The magnesia spinel castable has been prepared in presence of dead burned magnesia, reactive alumina, binders (calcium aluminate cement and hydratable alumina), and 6 wt.% water. The hydration resistance of castables investigated in sequential pH at 25 °C. Then, 0-5 wt.% of Nano-spinel, synthesized by citrate-nitrate route, substituted for part of fine magnesia. The optimized sample were fired between 1250 and 1700 °C, then characterized by TGA, XRD, SEM. Physical and mechanical properties of optimized sample have been investigated by PLC, AP, CCS, and thermal gravimetric according to ASTM C113 and C20 standards. The results approved that magnesia hydration could be reduced by replacing CAC with HA as a binder. The optimized amount of hydratable alumina was 5% according to TGA analysis. The reason is that HA addition could decrease castable's pH, and motivate Hydrotalcite phase formation on the surface of MgO that could decrease MgO hydration. Also, results showed that using HA cement with 3 wt.% Nano-spinel additive not only increased hydration resistance, but also encouraged spinel formation at 1500 °C which increased thermal shock resistance and mechanical properties during the application of refractories.

## INTRODUCTION
Refractory castables containing MgO are prone to material cracking because of their tendencies to react with water and form Mg(OH)$_2$ which could lead to volumetric expansion. Some researches indicate that the formation of hydrotalcite-like phases in this refractory could help the creation of more permeable castable structure by crystalline layers of Mg(OH)$_2$ and Al(OH)$_3$ which are separated by water molecules. Besides, the electric charges are neutralized by the anion located between the lamellas [1]. MgO and hydratable alumina interaction could produce hydrotalcite-like phases. To be more precise, Al(OH)$_3$ and Mg(OH)$_2$ reaction in aqueous medium form the hydrotalcite-like compounds [2]. It has been observed that the in situ hydrotalcite formation showed the higher mechanical strength than hydratable alumina-free compounds after curing. It has also been pointed out that hydrotalcite-like phases act as a binder. The outstanding roll of these compounds related to the formation of MgAl$_2$O$_4$ spinel. Calcium alumina cement (CAC) and hydrated alumina (HA) are the most commonly used binders in the formulation of castables. When alumina-calcium (CAC) cements are mixed with water, the cement is rapidly hydrated and various alumina-calcium hydrates with different morphologies are formed. Hydrated alumina castables behave like calcium alumina cement castables and require some water and similar additives. The curing mechanisms in both types of binders (CAC, HA) are based on hydration reactions in which the hydration of magnesite and the apparent volumetric expansion

(AVE) are influenced by the type and amount of binder. Also, due to the presence of CaO in the bond, the possibility of phases formation with low melting point is high. Hydratable alumina (HA) is a binder that commonly used for the situation where the CaO is not desirable. In this regard, the magnesia castables of the cement-free Forsterite bond (MgO-Al$_2$O$_3$-SiO$_2$ system) was investigated and the addition of micro silica was suggested in order to curing the castable magnesia refractory. Micro silica and magnesia form a hydrated gel in the presence of water and cause the curing of the refractory body [3]. Besides, the effect of hydrated alumina as a binder on the physical and mechanical properties of castable magnesia in spin-bond magnesia castables showed that the optimum amount of hydrated alumina in the refractory body is 5%. Also, the optimum amount of in-situ spinel formed for magnesium base mass was estimated to be about 25%. The hydraulic binders (calcium alumina cement and hydrated alumina cement) and changing the amount of these binders influence the magnesite hydration, pH, volumetric expansion, mechanical strength and porosity. Apparent volume expansion (AVE) is significantly affected by the type and amount of binder used in the composition. By replacing the hydrated alumina with cement and formation of hydrotalcite on the particle surface, both the hydration of magnesite and volumetric expansion halted. Also, the mechanical strength was at least 2.5 times higher than similar compounds containing cement [4].

This research addressed the role of calcium aluminate cement (CAC) and hydratable alumina (HA) as binders and evaluated the effect of Nano-spinel (MgAl$_2$O$_4$) addition as a nucleant agent on hydration behaviour of magnesia. In this regard, the MgAl$_2$O$_4$ Nano-spinel powder was synthesized by citrate-nitrate method. The distinct properties of Nano-spinel alumina-magnesia showed that the deleterious effects of magnesia hydration were greatly minimized.

## EXPERIMENTAL PROCEDURE
### Materials
Magnesium nitrate (Mg (NO$_3$)$_2$.6H$_2$O), aluminium nitrate (Al (NO$_3$)$_3$.9H$_2$O), citric acid (HOC(COOH)(CH$_2$COOH)$_2$) and ammonia solution (NH$_4$OH,30%) were used to synthesis MgAl$_2$O$_4$ spinel and provided by Merck Co., Ltd. All of the reagents used were analytical grade without further purification and all the aqueous solutions were prepared using deionized water. Commercially available magnesia (OMS, china), reactive alumina (Alcan, UK), hydratable alumina (Actibond 2005) and calcium aluminate cement (Secar 71) (Kerneos, France) sources also were used in this research.

### Synthesis of nanocrystalline magnesium aluminate spinel
Nano-sized MgAl$_2$O$_4$ spinel powders were synthesized through the citrate-nitrate route. A stoichiometric amount of magnesium nitrate and aluminium nitrate were dissolved in deionized water, and then a Citric acid as chelating-fuel agent added to the solution. The molar ratio of citrate to metallic ions in the solution was maintained at 0.5:1. Citric acid as a chelating agent binds metallic ions (Al$^{3+}$ & Mg$^{2+}$) and prohibits precipitation of solution during pH changing. Besides, Citric acid helps the progression of synthesis at a relatively low temperature. The solution was homogenized using a

magnetic stirrer for 1h at room temperature. pH of the solution was adjusted to six by adding ammonia. Then, the gel was heated at 110 °C for 24 h in an electric oven to get a pale yellowish mass. The obtained mass was ground into powder by a pestle and then fired at 900 °C with 10 °C/min heating rate and soaking time of 1 h [5].

## Sample preparation
The castable's composition was determined using Dinger&Funk equation [6]:

$$CPFT=100[(d^q-d_s^q)/(D^q-d_s^q)] \qquad (1)$$

Where CPFT is Cumulative Present Finer Than, D represent Maximum grain size, d is grain size, $d_s$ shows the Minimums grain size, and q is constant coefficient. The constant coefficient in these samples was 0.26. 5 wt.% of hydratable alumina as well as 5% wt.% of calcium aluminate cement was used as a binder. Varying content of alumina-magnesia Nano sized spinel were selected to be between 1 to 5 wt.% and the remaining amounts of reactive alumina and magnesia to form 25% of the spinel phase were calculated and experimental activities were performed accordingly. Based on Tables 1 and 2 contents, dry raw materials were mixed and then water was added to the required amount of 6 wt.% to form different batches of Nano composition. Also, the pH of the samples was recorded every 10 seconds for 4 hours at room temperature (25 ℃).

The samples were pressed into 5*10 mm cylindrical shape and were situated in refrigerated incubator shaker for 24h at 8 ℃. Hydration tests were performed on samples that were kept in a humid environment at 50 °C for seven days. Drying test were recorded on MgAl$_2$O$_4$ Nano spinl up to 600 °C with a heating rate of 10 °C/min and the percentage of weight loss (dw/dt, %wt/min) versus the temperature axis was evaluated in drying behaviour studies. Then, by selecting the optimal sample and in order to investigate the effect of temperature on the properties of castables, cubic samples (30*30*40) were prepared. After leaving the mold,

the samples were placed in the open air for 24 h and then in a dryer at 110 ° C for 24 hours. Then they were tempered at 1250, 1400, 1550, and 1700 °C with heating ratio of 5 °C /min.(summarized)

## Characterization
Samples morphology was observed by Philips CM10 transmission electron microscopy (TEM) and VEGA II TESCAN scanning electron microscope (SEM) equipped with EDS. To determine the crystallite phases of compounds X-ray diffraction (XRD) patterns were reported by Philips XPERT X-ray diffractometer with Cu kα radiation. In order to investigate the reactions that take place during firing and also to determine the approximate starting temperature of the reactions and the type of compositions, simultaneous thermal analysis (STA) Labsys-Setaram was used with a temperature capability up to 1600 ° C. The reference material in this experiment was alumina powder. Plant material was also made of alumina. pH meter (691 model, metrohm, Switzerland) was used to evaluate the pH during the experimental process.

## RESULTS AND DISCUSSION
### Phase composition and microstructural analysis of Nano-sized MgAl2O4 spinel
The XRD pattern of the as-prepared sample after heat treatment at 900 °C is shown at Figure.1. the spinel phases of MgAl$_2$O$_4$ had four main peaks, which can be ascribed to (440) and (511), (400), and (311) diffraction planes. The sharp diffraction peaks of MgAl$_2$O$_4$ indicates the good crystallinity. Besides, the intensity of his MgO peak against the spinel is negligible.

Fig.1: XRD pattern of the MgAl2O4 spinel powder calcined at 900 °C.

The morphology of Nano spinel was characterized by TEM (Figure .2). The image of the synthesized powder at 900 °C exhibited polycrystalline spinel with a crystal size of about 24 nm. The observed results are in good agreement with the crystallite size calculated by the Scherer equation.

Fig.2: TEM images of MgAl$_2$O$_4$ Nano-spinel powder calcined at 900 °C.

### Hydration resistance Investigation
#### pH investigation
pH changes of castables after mixing with water is an influential factor on magnesia hydration. Figure .3 and 4 shows the pH graphs versus time of samples containing calcium aluminate cement and hydratable alumina with different values of magnesia after mixing at 25 ℃, respectively. Lower amount of pH represents lower hydration of magnesia. The initial pH of samples was about 9.5 (before hydration) that increased smoothly and reached the maximum (about 11.3) after 30 minutes.
*Fig.3: pH value after mixing (at 25°C) of MgO containing castables prepared with CAC and different amounts of MgAl₂O₄ nanosized.*

Castables containing CAC in comparison with samples containing HA had the higher pH value of about 11.9 that could be caused by generation of $Al^{3+}$, $Ca^{2+}$, and $OH^-$ in water. In other words, when the binder is constant, increasing of Nano-spinel additive up to 3% caused decreasing of magnesia hydration.

*Fig.4: pH value after mixing (at 25°C) of MgO containing castables prepared with HA and different amounts of MgAl₂O₄ nanosized.*

CAC released OH- in the water and as a result pH of castable increases greatly during the hydration. Due to the chemical equilibrium shifting principle, this excess of $OH^-$ ions favours the magnesia hydration, as shown in Eq (2):

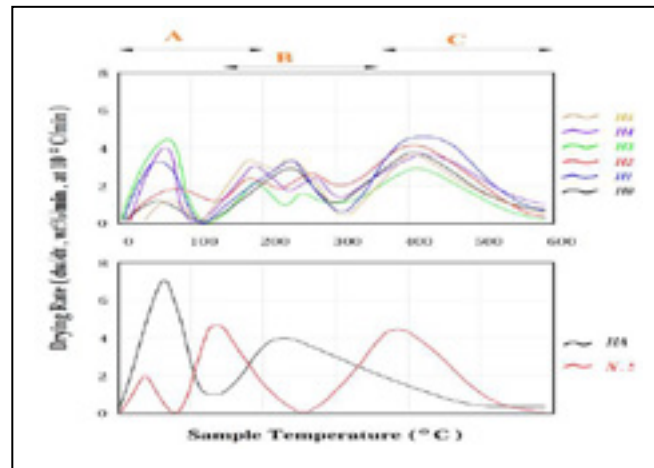
$$Ca\,(AlO_2)_2 + 4H_2O \rightarrow Ca^{2+} + 2Al(OH)^{4-} \tag{1}$$

$$Al(OH)_4 \rightarrow Al^{3+} + 4OH^- \tag{2}$$

$$MgO + H_2O \rightarrow MgOH^+ + OH^- \rightarrow Mg(OH)_2 \tag{3}$$
One of the main effects of CAC in comparison with HA addition in magnesia containing castables was the increase of the brucite formation rate due to the high alkaline environment. CAC hydration begins a few hours after mixing, whereas, for magnesia, it can last for days. Therefore, magnesia castables containing HA was selected for further investigation because its hydration was less than those of CAC.

*Thermal gravimetric analysis (TGA) investigation*
Thermogravimetric analysis (TGA) was carried out between 25–600 °C to investigate the thermal behaviours of Hydratable Alumina, MgAl₂O₄ Nano-spinel, and castables containing HA as binders and different amount of Nano size spine after 7days drying at 50 °C in environment. The TGA curves of all the synthesized samples are presented in Figure.5. The mass loss rate is categorized to three main peaks. Mass loss resulting from the removal of adsorbed water is observed from 25 to 150 °C. The mass loss in the 150–350 °C range resulted from the removal of Hydratable Alumina [7]. The continued weight loos from 350 to 600 °C is due the MgO and Nano-spinel hydration. This investigation shows that magnesia hydration was greatly reduce by replacing CAC with HA as binder and enhances the amount of nanosized MgAl₂O₄ up to 3%. This behaviour can be attributed to two main causes: firstly, the HA addition did not change the pH values of castable that could affect MgO hydration. Therefore, the driving force of magnesia hydration was not significantly increased. Secondly, the combination of magnesia and HA results in formation of

hydrotalcite (*HDTC*). The HDTC is preferably formed on the surface of the magnesia particles where the $Mg^{2+}$ concentration is



higher.

*Fig.5: Thermal gravimetric (10 °C/min) of HA, Nano-spinel MgAl₂O₄, castable containing 5wt.% of HA and different amounts of HA.*

Because of HDTC low solubility in alkaline environment and the hydrogen bonds, a protective coating on the surface of the magnesia particles is formed that can halt the hydration reaction and simultaneously bonding the castable's matrix particles strongly together. Replacing the calcium alumina cement (CAC) with hydrated alumina (HA) as a binder and nanosized alumina-magnesia spinel addition up to 3 wt.%, result in the great reduction of magnesia hydration and eliminating its effects. In sample H3 the lowest pH value was obtained. Graphs of mass loss versus temperature show that at temperatures below 200 °C large amount of water was removed from the sample and sample encountered with the high mass loss. Additionally, peaks in the range of 15 to 350 emerged due to the presence of hydrated alumina and Nano-spinel. At a temperature of 350 to 600 °C, the presence of 3% Nano-spinel caused minimum decomposition of brucite and reduced the hydration of magnesia. The low pH of this sample reduced the rate of brucite formation due to the less alkaline environment.

*XRD analysis investigation*
Also, X-ray diffraction pattern of samples containing different amount of the MgAl₂O₄ (Figure.6) indicates that increase of MgAl₂O₄ up to 3% causes the enhancement of HDTC formation; therefore, decreased the hydration of magnesia.

*Fig.6: XRD pattern of castables containing hydratable alumina with different amount of Nano-spinel MgAl₂O₄.*

**Physical, phase analysis and microstructure of optimized sample at different temperature (sample H3)**

*Physical investigation of sample H3 at different temperature*
The PLC results suggest that two mechanisms may be involved that are the expansion due to spinel phase formation and/or shrinkage due to sintering process. Based on the opposed mechanism the PLC results showed 2.24 % expansion in sample which fired at 1250 °C

that could be caused from spinel formation, while the sample showed 3% shrinkage by increasing the temperature up to 1400 °C. The sample showed 20% shrinkage, which could be due to solid sintering of sample, by increasing the temperature up to 1700 °C. Also, the bulk density of sample was enhanced by increasing the temperature, which can be the result of good sintering of sample.

*XRD analysis of sample H3 in different temperature*
The phase structure of the sintered H3 at variable temperatures was investigated using the X-ray diffraction technique (Figure 7). The X-ray diffraction pattern of the samples indicates the formation of spinel ($MgAl_2O_4$) and periclase (MgO) phases, which shows increase in intensity with increasing temperature. Very weak corundum peaks ($Al_2O_3$) appeared for H3 sample sintered at 1250°C; This could be attributed to formation of spinel phase in higher temperature.

*Fig.7: XRD patterns of H3 at different temperatures*

According XRD patterns, no wide peak that indicates the formation of amorphous compounds during sintering was observed that could be because of solid state sintering. However, due to the possibility of existence of small amounts of amorphous phases, the samples were examined by SEM electron microscopy.

*Microstructure investigation of sample H3 in different temperature*
The SEM images of samples sintered at 1700 °C (Figure 8) shows that there is direct bond contact between grains, and no liquid phase formation was observed which was determined by XRD analysis confirming the H3 dense structure. The results showed that with increasing the temperature from 1250 to 1700 °C and due to the growth of crystals and also the reduction of voids, the dominant mechanism could be Solid State Sintering. The absence or very low amount of low melting point phases in the composition cannot affect the thermodynamic properties of the castables.

*Fig.8: SEM microstructure of sample H3 fired at 1700 °C.*

**CONCLUSIONS**
Magnesium aluminate spinel has been prepared by Citrate-Nitrate route. In addition, the effect of nanosized $MgAl_2O_4$ spinel on MgO hydration and HA binder was investigated. The XRD and TEM results showed that the $MgAl_2O_4$ phase was formed successfully. The replacement of CAC by hydratable alumina showed distinctive pH results. In fact, the changes of pH value indicated that the effect of Magnesia hydration decreased in the castables prepared using HA as binder and 3 wt.% of nanosized spinel ($MgAl_2O_4$) in the matrix of MgO. It was also found that Magnesia hydration was affected by the generation of hydrotalcite (HDTC) in the surface of castables. The improved hydration properties of magnesium castables can be attributed to the addition of hydrated alumina along with Nano-spinel. This work indicates that the Hydratable Alumina binder has more practical values that CAC.

## ABSTRACT

This study used a novel aqueous dispersion of silanized colloidal silica (SCS), whose particles' surfaces were modified with an epoxysilane–based coupling agent, as liquid medium and binder for $MgO$-$Al_2O_3$-containing suspensions. Fine calcined alumina and magnesia sinter particles were dispersed in CS to form a 65 vol% solids suspension. Silica-free compositions containing calcium aluminate cement and hydratable alumina were also tested. After mixing, the SCS-suspension showed low viscosity and suitable workability. After curing, the formation of a thin protective coating of magnesium silicate hydrate (MSH) prevented MgO hydroxylation and improved bonding strength amongst particles, generating green-dried structures of significant flexural strength (8 MPa). During initial heating, the decomposition of MSH and the softening of amorphous silica particles reduced the expansion of spinel formation. After sintering, the final structure showed high flexural strength (73 MPa) and a microstructure comprised of large and regularly-shaped spinel crystals surrounded by a thin amorphous silica layer.

## INTRODUCTION

*In situ* magnesium spinel ($MgAl_2O_4$)-containing castables are chief materials for steelmaking due to their high refractoriness and corrosion and thermal shock resistance. Despite their technological importance, such materials present two significant drawbacks. Due to the high density of the initial reactants (MgO, 3.5 $g.cm^{-3}$; $Al_2O_3$, 4 $g.cm^{-3}$), the formation of $Mg(OH)_2$ (2.4 $g.cm^{-3}$), during curing and drying, and $MgAl_2O_4$ (3.2 $g.cm^{-3}$), during sintering, can cause significant volumetric expansion and mechanical damages to the structure [1,2]. This study proposes a simultaneous solution for both problems based on the use of a novel grade of colloidal silica whose silanol groups at particles' surfaces were modified with an epoxy silane-based coupling agent (gamma-glycidoxypropyltrimethoxysilane, GPTMS) [3,4]. The epoxy-ring opening reaction that occurred during the surface modification process resulted in a diol functionality at the end of each silane group, providing them with a hydrophilic character and leading to superior steric stabilization, in comparison to conventional unsilanized grades [5]. Therefore, high-solid load suspensions of fine MgO sinter particles can be prepared without instantaneous gelling (Fig. 1a).

Figure 1: a) MS+SCS suspension: remaining fluid after 30 min at 60ºC; b) apparent volumetric expansion test for $MS+H_2O$ or MS+SCS samples (7 days, 60ºC, humid environment) [3].

The reactions between dissolved $MgOH^+$ ions and siloxanes groups of the silanized colloidal silica (SCS) produced a thin protective coating of magnesium silicate hydroxide hydrate ($Mg_5Si_8O_{20}.8H_2O$) at the surfaces of MgO particles [3,4]. Besides hindering further hydroxylation reaction and apparent volumetric expansion (Fig. 1b), it significantly enhanced the flexural strength and rigidity of the structure after thermal treatment from 120ºC up to 1600ºC. During sintering, part of the $SiO_2$ present in the system produced a small portion of $Mg_2SiO_4$, which improved densification and gain of strength. No significant traces of crystalline $SiO_2$ were detected.

In this study, aqueous mixtures of fine calcined alumina and MgO sinter were prepared to produce stoichiometric spinel and bonded with the same volumetric amount of calcium aluminate cement (CA), hydratable alumina (HA), or silanized colloidal silica (SCS). The large fraction of MgO (30 wt%) employed highlights the potential damages caused by the apparent volumetric expansion of MgO hydroxylation and *in situ* formation of spinel. The hydraulic binders were tested as references, whereas CA is widely used in refractory castables due to its versatility and competitive costs, HA is well known as an effective anti-hydroxylation-calcium-free binder for MgO-containing systems [6,7].

## EXPERIMENTAL

Raw materials: fine MgO sinter (MS, High-Purity M30, RHI-Magnesita, Brazil; $D_{50}$ = 8 µm, 98.3 wt% MgO), calcined alumina (AA, E-sy 1000, Almatis, USA; $D_{50}$ = 1.5 µm, 99.7 wt% $\alpha$-$Al_2O_3$), hydratable alumina (HDA, Alphabond 300, Almatis, USA; $D_{50}$ = 7.6 µm, 99.4 wt% $\alpha$-$Al_2O_3$ after calcination 1000ºC); calcium aluminate cement (CAC, EL70, Elfusa GE, Brazil; $D_{50}$ = 2.0 µm, 70 wt% $Al_2O_3$); silanized colloidal silica (SCS, Levasil FX401, Nouryon, Sweden; $D_{50}$ = 11 nm, 40 wt% of solids), dispersant (Castment FS20, BASF, Germany, 0.1 wt% dry-basis), distilled water. Three compositions were prepared with the same equimolar $MgO/Al_2O_3$ ratio and a similar volumetric ratio of water (35 vol%) and solid binder (10 vol.%) (Table 1).

Table 1: Compositions tested.

| Raw materials | Compositions (wt.%/vol.%) | | |
|---|---|---|---|
| | MS_AA_HDA | MS_AA_CAC | MS_AA_SCS |
| MS | 22.17/17/.06 | 22.00/17.26 | 22.31/16.95 |
| AA | 54.63/37.38 | 53.50/37.32 | 56.66/38.29 |
| Binder | 10.23/10.24 | 11.79/10.14 | *8.37/10.72 |
| Water | 12.97/35.32 | 12.71/35.29 | **12.66/34.05 |

*Solid $SiO_2$ particles and **water from SCS

After mixing (paddle mixer, 1000 rpm, 3 min), the samples were cast as 70 mm length × 16 mm diameter cylinders for total porosity and three-point flexural strength tests, 40 mm length × 40 mm diameter cylinders for drying and apparent volumetric expansion (AVE) tests, and 8 mm length × 6 mm diameter cylinders for dilatometric analysis. They remained for 24 h at 60ºC in a closed environment and for 24 h at 60ºC in a ventilated environment before drying at 120ºC overnight and sintering (1ºC.$min^{-1}$ up to 400ºC, 1 h hold, 2ºC.$min^{-1}$ up to 1500ºC, 3 h hold; cooling rate of 5ºC.$min^{-1}$ down to 800ºC and 10ºC.$min^{-1}$ down to room

temperature). The crystalline phases formed were identified by X-ray diffraction and microstructure was observed in fractured samples by scanning electron microscopy. Refer to [1,2,7] for a detailed description of the techniques.

## RESULTS AND DISCUSSION

In comparison to the SCS-free samples, those containing SCS showed suitable flowability and remained fluid for approximately 30 min at 60ºC (Fig. 2a). Differently from the combination with unsilanized anionic colloidal silica, no instantaneous gelling occurred [8-10]. The formation of a negatively charged and protective coating of magnesium silicate hydroxide hydrate at the surface of MgO particles prevented further dissolution and ensured flowability [3].

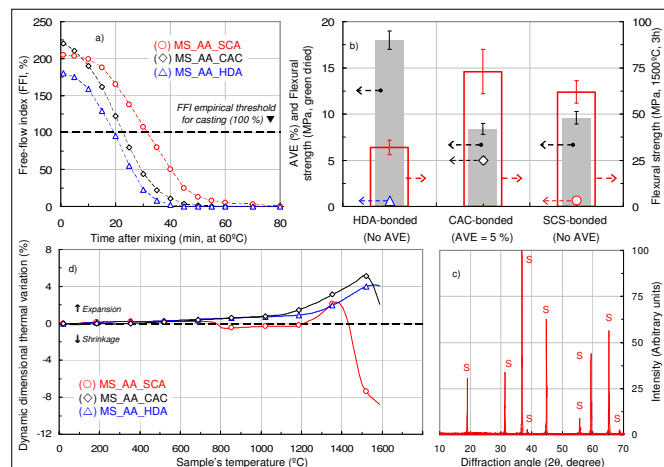

Figure 2: a) Free-flow index, b) flexural strength (green dried; after sintering) and AVE (3 days, 60ºC), c) XRD for MS_AA_SCS after sintering (1500ºC, 3h; S=Spinel, $MgAl_2O_4$), d) dimensional thermal variation for samples containing different binders.

For the same reasons, during the curing and drying steps, no significant apparent volumetric expansion was observed for samples bonded with HDA and SCS, whereas for the CAC-bonded one, severe cracking started after 24 h (Fig. 2b). Similarly to SCS, the combination of MS and HDA is hydroxylation-resistant due to the formation of a protective coating of hydrotalcite $(Mg_6Al_2(CO_3)(OH)_{16}.4H_2O)$ [7]. After sintering, the SCS-bonded ones displayed a microstructure comprised of large crystals of spinel (Fig. 2c) surrounded by a non-crystalline $SiO_2$-based phase (Fig. 3).

Figure 3: SEM/EDX image of fracture cross-section for MS_AA_SCS after sintering (1500ºC, 3h).

The HDA-bonded sample showed a significant volumetric expansion and experienced a strong densification resistance due to the spinel formation, as observed elsewhere (Fig. 2c) [2], whereas the CAC-bonded one exhibited the formation of liquid phases and densification after an initial expansion that followed $CaAl_{12}O_{19}$ reaction [7]. The presence of soft and non-crystalline $SiO_2$-based phases produced three interesting effects. First, it reduced the volumetric expansion of spinel; second, the high mobility of $Mg^{2+}$, $Al^{3+}$, and $O^{2-}$ ions through it favored the densification and construction of large crystals, thus leading to intense porosity reduction. Such aspects, which are technologically interesting regarding thermal shock and corrosion resistance, are currently under investigation in the Authors' research group.

## CONCLUSIONS

The composition comprised of calcined alumina, MgO sinter (MS), and silanized colloidal silica (SCS) showed suitable workability for mixing, casting, and drying. In comparison to the reference samples prepared with calcium aluminate cement (CAC) or hydratable alumina (HDA), those bonded with CS showed similar or higher flexural strength and much lower hydroxylation degree for MgO. Such behavior was associated with the formation of a magnesium silicate hydroxide hydrate at the surface of MgO particles, hindering their hydroxylation and strengthening the structure. After sintering, CA and MS reacted to form spinel. Lower levels of expansion and total porosity were verified in the CS-bonded samples due to the softening action of amorphous $SiO_2$. The final microstructure comprised large and well-built spinel crystals surrounded by a thin layer of non-crystalline $SiO_2$. The low total porosity levels, the compactness of the structure, and the large size of spinel crystals suggest such a composition is highly likely to be corrosion-resistant. This aspect is currently under investigation in the Authors' research group.

# THE *IN-SITU* SPINEL FORMATION IN A MAGNESIA ALUMINA CASTABLE AND THE EFFECT OF SELECTED ADDITIVES ON THE PROPERTIES OF THE CASTABLE

J. Angelkort, M. Cichocki, S. Higgins, Y. Lakotta-Weinhold, N. Fröse, M. Mix
Intocast AG, Westpreußenstr. 30, 47809, Krefeld, Germany
email address: joachim.angelkort@intocast.de

**Short Communication**

Additions of sintering agents in refractory materials can help to promote the in-situ spinel formation. In this comparative study, four sintering agents (namely sodium polyphosphate, microsilica, titania and zirconia) were tested in a magnesia alumina castable to probe their influence on spinelization. It was found that castables containing one of the additives formed a significantly larger amount of spinel than additive-free reference samples burned at the same temperature (1200 °C and 1500 °C, respectively). Among the tested additives, sodium polyphosphate proved to be the most suited agent to enhance the amount of spinel in the castable. Consistently, dilatometric measurements showed that a phosphate addition affects a strong increase of the linear thermal expansion with an onset of the expansion occurring already ~100 °C below the starting temperature of the spinelization in the reference sample. Moreover, phosphate-containing castables experienced during the burning process a much larger volume expansion and a larger weight loss than the reference sample and possessed, in comparison to the latter, a lower mechanical strength after burning. The large swelling and the distinctively larger weight loss of the phosphate-containing samples are regarded as indications for a vaporization of parts of the sodium phosphate on heating.

In the microsilica-containing sample burned at 1500 °C, silicate phases were found to cover the surface of periclase grains. These layers shielded the interior of the MgO grains from a chemical attack and seemingly counteracted the progress of the spinalization.

An addition of 1 wt% of the $TiO_2$-containing additive led to a lowering of the formation temperature of spinel by ~20°C compared to the reference sample. A heat treatment of the $TiO_2$-containing castable at 1500 °C resulted in a strong increase of the mechanical strength of the castable.

The addition of the $ZrO_2$-containing additive was associated with an increase of the thermal stability of the castable. The $ZrO_2$ addition was found to exert a positive impact on the spinel formation at a temperature of ~1200 °C and above. The effect is presumably caused by fine $ZrO_2$ particles, a few micrometers in size, serving as nuclei for the spinel formation.

# A NOVEL APPROACH TO DEVELOP SUSTAINABLE CEMENT-FREE MAGNESIA CASTABLES

Hong Peng

Materials Innovation, Elkem Silicon Products Development, Kristiansand, Norway

*Email: hong.peng@elkem.com

## ABSTRACT

Magnesia (MgO)-rich castables are not commonly used in the steel-making industry due to the reaction between magnesia and water, which forms brucite ($Mg(OH)_2$) during mixing, curing, and drying. This reaction causes volume expansion and cracking, commonly known as "slaking." In this paper, the advantages of using cement-free MgO castables are reviewed from an environmental standpoint. These advantages include: i) easy installation and energy savings compared to MgO bricks, ii) direct reduction in CO2 footprint due to the substitution of the cement binder with microsilica, and iii) easy recycling of the spent MgO castable thanks to the absence of $Ca^{2+}$ from calcium aluminate cement. The focus of the study was on understanding the role of microsilica in MgO castables. Microsilica not only serves as a silica-gel binder ($MgO-SiO_2-H_2O$) to replace calcium aluminate cement, but also functions as a powerful anti-hydration agent to prevent brucite formation. Furthermore, the impact of the dimensions of specimens and drying agents on water removal of industrial-scale samples (up to 80kg) of a selected MgO castable was investigated using a unique macro thermo-balance (macro-TGA). The results indicate that it is possible to develop a close-to-reality drying profile for industrial-scale samples. Perfect 600kg blocks of cement-free MgO castables with enhanced properties have been produced with no cracking after drying. Finally, a novel approach is proposed to produce cement-free MgO castables involving using microsilica-gel as a binder in combination with a proper drying agent and adopting a more accurate drying profile.

## 1 INTRODUCTION

Magnesium-containing refractories, mainly bricks, are commonly used in ladles and tundishes in the steelmaking industry due to their high refractoriness and excellent corrosion resistance to alkaline slag. The continuous improvement of refractory materials is driven by the requirements and needs of many industries, particularly the steel industry, which accounts for approximately 70% of the market as the largest end-user of refractory products. As a result of increasing $CO_2$ emissions and the costs associated with the European Green Deal, industries are facing the pressing challenge of remaining competitive by investing in breakthrough technologies to decarbonize and reduce energy consumption, while continuously improving production efficiency. In refractory technology, the most notable trend in recent years has been the increasing use of amorphous or unshaped products. There is significant potential to convert shaped magnesia refractory materials to magnesia castable due to the advantages of relatively low raw material costs, energy savings, shorter installation times, and easier maintenance.

Refractory castables containing MgO, whether formed in situ or preformed spinel ($MgAl_2O_4$)-containing cement-bonded refractory castables (LCC), have been developed for ladle applications due to their excellent corrosion resistance to basic slag and good thermomechanical properties [1]. Refractories are essential for iron and steel production. However, the

potential for reducing $CO_2$ emissions through the selection of refractory material and design aligned to each application area is often underestimated. Optimal refractory solutions can extend operating times and prevent unscheduled furnace stops. Over the last 40 years, many papers have presented castables based on MgO; however, development seems to be mainly focused on MgO-containing systems and lab-scale results, and magnesia-rich castables are not widely used in steel-making industries. One of the major challenges is that magnesia reacts with water to form brucite ($Mg(OH)_2$) under mixing, curing, and dry-out. The formation of brucite causes volume expansion and subsequent cracking, a phenomenon commonly referred to as "slaking" [2]. Earlier research has demonstrated that the interaction between MgO and microsilica ($SiO_2$) prevents slaking.

In 1989, Elkem started developing a binder system for basic castables based on the reaction between MgO fines, microsilica ($SiO_2$), and water. An important observation was that no slaking occurred at 6% microsilica addition in lab-scale samples [3]. Since then, considerable research has been conducted to understand and solve the hydration problems of MgO in castables [4-7]. Various technologies have been reported to inhibit and/or prevent brucite formation by using microsilica as an anti-hydration agent, fibers as a drying agent to accelerate water evaporation, and optimizing additives and water addition to minimize water available for brucite formation after placing. However, most studies on the hydration of MgO described above are focused on "MgO-containing" castables, such as spinel-magnesia castables with cement. Little work has been done on MgO-rich cement-free castables, and few studies on actual-size MgO castables have been reported.

At ALAFAR 2012, Hong et al. presented preliminary results using an additive package designed to promote the sustainable bond system $MgO-SiO_2-H_2O$ for cement-free MgO castables, and to produce crack-free large pieces [8]. Recently, it has been observed that microsilica not only acts as a gel binder but also suppresses the hydration process of MgO during curing and drying. The types of additives, microsilica content and drying agents have a strong impact on flowability and slaking. Systematic studies based on both lab and industrial-scale specimens confirm that crack-free, cement-free MgO castables using $MgO-SiO_2-H_2O$ can be made. A 3wt% dosage of microsilica is necessary for producing lab-scale specimens, while more microsilica is needed for industrial-scale use. The combination of microsilica (up to 8%) and a specialty product (SIOXX®-Mag, Elkem) and a proper drying agent appears to be an efficient anti-hydration solution for MgO castables [9-14].

Microsilica, also known as condensed silica fume or silica fume, is an amorphous sub-micron silicon dioxide that has a spherical shape. It is produced by collecting and treating the fumes/smoke released during the production of ferrosilicon and silicon metal, as shown in Fig.1. The process involves reducing high purity quartz in electric arc furnaces at temperatures over 2,000 ºC using coal, coke, and wood chips as reduction materials. The smoke is drawn through cooling pipes, a

pre-collector, and a cyclone to remove coarse particles that may have been carried over from the furnace. It is then blown into specially designed baghouse filters where the microsilica is collected. By removing silica fume from smelting furnace smoke, a visible pollution problem is eliminated and the microsilica is turned into a useful product in various fields such as concrete and refractory castables since the 1970's.

*Fig. 1 Schematic drawing of production at a smelter using electric arc furnaces to produce Si-met or ferrosilicon alloy.*

The carbon footprint of microsilica, also known as silica fume, can vary depending on the production process and the source of raw materials used. However, the production of microsilica generates a significant low carbon footprint compared to other cementitious materials, such as Portland cement. Euroalliages advocacy has allocated a zero C-footprint for microsilica. The use of microsilica in various industrial segents, such as concrete and refractory, is one of the most impressive examples of "from pollution to solution," as exemplified in Fig. 2.

*Fig. 2 The forms and its application of microsilica. A) pollution as smoke, b) morphology of microsilica under SEM, and c) refractory castable containing microsilica for steel production.*

Microsilica is an ultrafine powder that primarily consists of spherical amorphous (non-crystalline) silicon dioxide ($SiO_2$) with an average particle size of 150nm (Fig. 2b). When microsilica-gel bonding is used instead of cement bonding, the refractory castable not only exhibits improved hot-properties but also reduces $CO_2$ footprint. Hence, it is worthwhile to explore the use of microsilica-gel as a binder for MgO castables from both technical and environmental perspectives.

There are several solutions to produce sustainable MgO castables, including:

1. Use of cement-free binders: The use of cement-free binders, such as microsilica-gel, can reduce the carbon footprint of MgO castables and enable easy recycling of spent castables.
2. Optimization of drying conditions: The drying conditions of castables need to be optimized to prevent cracking and eventually fast dryout. This can be achieved by adopting a more accurate drying profile and using a proper drying agent [12, 13].
3. Recycling of spent refractories: Spent refractories can be recycled and used as raw materials in the production of new refractories, reducing waste and conserving resources.
4. Development of new technologies: new technologies, such as nanotechnology, can be used to develop sustainable MgO castables with improved properties and reduced environmental impact.
5. Use of renewable energy: The use of renewable energy sources, such as solar or wind power, in the production of MgO castables can reduce the carbon footprint and improve sustainability.

The use of cement-free MgO castables offers several advantages, including improved thermal-shock and slag resistance against basic slag, easy installation, and energy savings compared to MgO bricks. Additionally, the substitution of cement binder with microsilica reduces the direct $CO_2$ footprint. Furthermore, spent MgO castable can be easily recycled thanks to the forsterite from the interaction between MgO and $SiO_2$ and no $Ca^{2+}$ from calcium aluminate cement.

However, producing crack-free large objects of MgO castables is challenging due to brucite formation during the curing and drying process, especially for industrial-scale samples. This paper focuses on understanding the roles of microsilica in MgO castables. The EMMA program was used to design the MgO mixes with different q-values, and the impact of drying agent and specimen dimensions on water removal of industrial-scale samples (up to 80kg) was investigated using a unique macro thermo-balance (macro-TGA).

This work has led to a better understanding of the MgO hydration mechanism and ultimately, a solution to develop microsilica-gel bonded MgO castables. By understanding the roles of microsilica in MgO castables, producers can develop more sustainable castables that are crack-free, environmentally friendly, and energy-saving.

## 2 EXPERIMENTAL
### 2.1 Mix design
Table 1 displays the mix design of magnesia castables with an $MgO$-$SiO_2$-$H_2O$ binder. Castable SF-8 and SF-6 are self-flowing mixes with q-values of 0.24 and 0.25, respectively. The mix with a q-value of 0.28 is a vibration castable labelled VF-6. The main raw materials used are synthetic dead burned MgO of different fractions (Nedmag 99, labelled Synthetic DBM) and microsilica (Elkem Microsilica® 971). SioxX-Mag, designed specifically for magnesia castables, is used as a dispersant at a dosage of 2%, bringing the silica content of the mixes to a total of 6% for SF-6 and VF-6 and 8% for SF-8. To understand their dry behavior and produce industrial-scale blocks, MgO mixes of SF-8 and VF-6 with 0.1% drying agent (EMSIL-DRY®, Elkem, Norway) were also produced. The water dosage remains at 5.5% for all mixes.

Table 1: Mix design of MgO castables.

| | | SF-8 | SF-6 | VF-6 |
|---|---|---|---|---|
| Synthetic DBM | (0-5mm) | 65 | 63 | 71.5 |
| | 100 mesh | 6 | 10 | 11 |
| | 325 mesh | 19.5 | 19.5 | 10 |
| ELKEM MICROSILICA® | 971U | 7.5 | 5.5 | 5.5 |
| SioxX®-Mag | | 2 | 2 | 2 |
| Water | | 5.5 | 5.5 | 5.5 |
| q-value | | 0.24 | 0.25 | 0.28 |

### 2.3 Sample preparation and characterization
The dry components were mixed for 4 minutes in a mixer, and then water was added. The castable was wet mixed for an additional 6 minutes. Self-flow and vibration-flow were measured using the flow-cone described in ASTM C230 (with a height of 50mm, not 80mm as described in EN 1402-4:2003). The self-flow value is the percentage increase of the diameter of the fresh mix measured 90 seconds after removing the cone. The castable was then cast into 40x40x160mm moulds for Cold Crushing Strength (CCS) and Cold Modulus of Rupture (CMOR) measurements. The moulds were kept at 20oC at >90% RH for 24 hours before de-moulding and then dried at

110oC for 24 hours. All lab-scale small prisms were crack-free. To investigate the thermal behavior of 300mm cubes (approximately 80kg), a unique macro thermo-balance capable of measuring industrial-sized samples (Macro-TGA, Elkem, Norway), as shown in Figure 3, was used. The heating schedule was 20 to 450°C at 50°C/hr, and cooling from 450 to 20°C at 50°C/hr. During heating, the 80kg cube was put in a steel net cage to prevent damage to the furnace wall if an explosion occurs. The mass loss of the specimen was recorded

Fig. 3: Schematic drawing of the industrial-scale thermo-balance (Macro-TGA).

Fig. 4: A 300mm cube with embedded thermocouple in the centre of the specimens to monitor the temperature during the heat-up process.

The mass loss, temperature in the centre of the cube and in the furnace is recorded. The drying rate at time $t_i$ is calculated using the derivative of the $W$ (wt%) parameter, which represents the cumulative fraction of water released during the heat-up, according to the expressions:

$$W=100\% \times (M_0 – M)/(M_0 - M_F) \qquad (1)$$

$$(dW/dt)_i = (W_i – W_{i-10})/(t_i – t_{i-10}) \qquad (2)$$

Where $M$ is the instantaneous mass recorded at time $t_i$ during the heating stages of the samples, $M_0$ is the initial mass and $M_F$ is the final (dry) mass of the sample.

## 3 RESULTS AND DISCUSSION
### 3.1 Hydration behaviour of MgO in industrial-scale samples
To investigate the MgO hydration behavior and possible cracking of large blocks, different sizes of MgO castable with 6% and 8% microsilica (no drying agent) were produced.

Small blocks (300x300x150mm) of MgO castable with 6% microsilica were produced first (SF-6 and VF-6, Table 1). After being demolded after one day, all the blocks were found to be perfect, with no cracks observed. After curing for another day in air, all the blocks were dried at 150°C for 12 hours. Figure 5 displays the MgO blocks after drying, and all of the blocks appear to be perfect, with no cracks observed after drying.

Fig. 5: Blocks (~38kgs, 300x300x150mm) after dry-out at 150°C for 12hrs (dry-out profile I): a) SF-6 and b) VF-6. The block of SF-8 was also perfect.

Next, blocks with double the thickness (300mm, ~75kg) were produced (as seen in Figure 6). SF-8 with 8% microsilica did not crack, while the others with 6% microsilica cracked. SF-6 had small cracks, and VF-6 had larger cracks. It is evident that the amount of microsilica and the thickness of the samples have a strong impact on the hydration of MgO and subsequent cracking of the dried larger blocks.

Fig. 6: Cubes (~75kgs, 300mm) after dry-out at 150°C for 12hrs: a) SF-6: 6% microsilica, b) SF-8: 8% microsilica, c) VF-6%: 6% microsilica.

To understand the MgO hydration mechanism, samples from the center of ~75kg blocks of SF-6 and SF-8 were used for a mineralogical phase analysis using XRD and SEM characterization. Figure 7 presents the XRD patterns. The SF-6 with 6wt% microsilica contains mainly periclase (MgO) and small amounts of brucite. In SF-8 with 8wt% microsilica, only periclase is observed, and no brucite phases could be detected. The major difference in composition between SF-6 and SF-8 is the microsilica content; 6% and 8%, respectively. Furthermore, no magnesia silicate hydrate (M-S-H) could be detected in the two samples, indicating that the M-S-H has poor crystallinity.

Fig. 7: XRD patterns of cubes (~75kgs, 300mm) after dry-out at 150°C for 12hrs: a) SF-6: 6% microsilica, b) SF-8: 8% microsilica.

Figures 8 and 9 display the SEM microstructures of the fractured surfaces of SF-6 and SF-8, respectively. In Figure 8, $Mg(OH)_2$ crystals can be observed as fibrous rosettes exhibiting a trigonal crystal system (hexagonal scalenohedral). In this case, 6% microsilica appears to be sufficient to fill all gaps/pores for close packing and good flow. However, this is not enough to cover all the surfaces of MgO. Some MgO fine powder in the matrix will contact water during the placement

process and be hydrated to a certain extent to form brucite. When 8% microsilica was used (Figure 9), all the surface of the magnesia was covered, and hydration of the magnesia was prevented so that brucite was not visible.

Fig. 8: SEM micrographs of fractured surfaces of SF-6 with 6% microsilica after dry-out at 150°C for 12hrs.

Fig. 9: SEM micrographs of fractured surfaces of SF-8 with 8% microsilica after dry-out at 150°C for 12hrs.

Based on the results presented in Figures 7 to 9, a higher dosage of microsilica appears to be an effective way to prevent and/or slow down brucite formation during the curing and drying process. When 6% microsilica is used, MgO hydration is significantly reduced, resulting in crack-free lab-scale prisms and blocks with dimensions of 300x300x150mm, as water evaporates relatively quickly. However, when larger blocks with a thickness of 300mm are produced, cracking may occur during the dry-out process. Increasing the microsilica content (e.g., 8wt%) seems to be a viable alternative.
Fig. 10: Effect of drying agents on self-flow and vibration-flow of castables.

### 3.2 Flowability and mechanical strength
The results from a previous study showed that the flowability of MgO mix is greatly affected by the type of drying agent used [14]. When EMSIL-DRY® (EMD) was used instead of polypropylene fiber (PP-fiber), the self-flow value of VF-6 mix increased from approximately 12% to approximately 44%, while the vibration-flow value remained similar.
In this context, Figure 10 summarizes the results of self-flow and vibration-flow measurements for MgO mixes containing either 6% or 8% microsilica, with and without EMSIL-DRY® (EMD). The introduction of EMD only slightly reduced both

self-flow and vibration-flow values, and the mixes were still able to be easily cast with the same amount of water as the reference mixes.

Fig. 11: Effect of drying agents on mechanical properties after drying at 110°C for 24hrs.

In this section, Figure 11 shows the compressive strength (CCS) and cold modulus of rupture (CMOR) of the samples after being dried at 110°C for 24 hours. The CCS and CMOR values of the SF-6 (q=0.26) series were slightly greater than those of the VF-6 series. Additionally, it was observed that the type of drying agent used did not significantly affect the mechanical strength of the samples after drying.

### 3.3 Mass loss and drying rate evaluation by industrial-scale Macro-TGA
In order to understand how drying agents affect the thermal behavior of large specimens (weighing around 75kg and measuring 300mm cubed) and to improve the drying process, a special macro-thermo-balance (Macro-TGA) was used to measure the percentage of mass loss (%) and the drying rate (dw/dt, %/min) during the heating process. The heating schedule involved a temperature range of 20 to 450°C, with a rate of 40°C per hour.

Fig. 12: Cubes (~75kgs, 300mm) after Macro-TGA: a) SF-8 with 0% EMD, b) SF-8 with 0.1%EMD, c) VF-6 without EMD and d) VF-6 with 0.1% EMD.

Figure 12 displays photographs taken after the Macro-TGA measurement. With 0.1% EMD, both the SF-8 and VF-8 blocks were in perfect condition, while the reference samples without EMD had cracks. Additionally, it was observed that the 75kg SF-8 block was in perfect condition after being dried at 150°C for 12 hours (as shown in Figure 6B). This confirms that the drying process significantly affects water removal and the formation of cracks.
Figures 13a and 13b show the mass loss (%) and drying rate (dw/dt) versus core temperature of the samples, respectively.

Compared to the reference sample without EMD, the samples containing EMD showed faster dewatering and a lower temperature for maximum dewatering rate in the temperature range of 100-300°C. The Macro-TGA results indicate that EMD contributes to faster dewatering in the early stage of the firing process, primarily due to its low melting point. This leads to lower steam inside the block and less water available for brucite formation, subsequently reducing the risk of cracking caused by brucite formation.

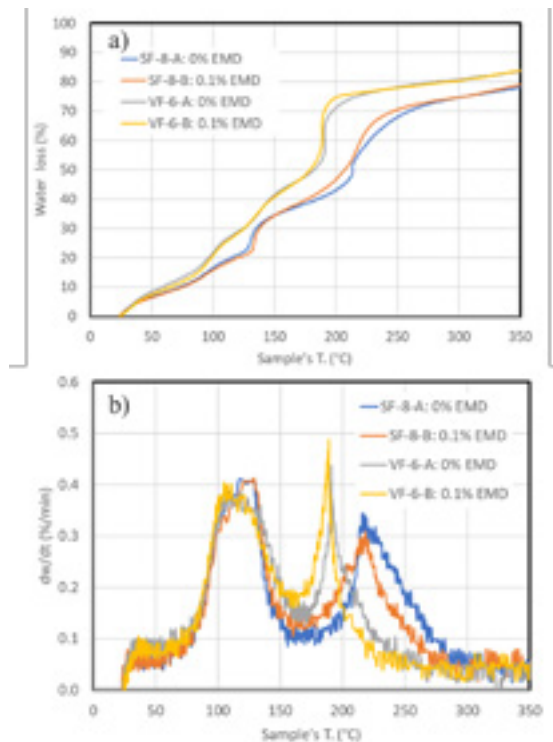

*Fig. 13 Drying behaviour of LCC containing drying agents using Macro-TGA. A) Mass loss, and B) Drying rate (dw/dt).*

The temperature at the center of the blocks was also measured and plotted as a function of the furnace temperature, as shown in Figure 14. Two "plateaus" were observed for all samples, at sample temperatures of approximately 130°C and 200°C, respectively. The corresponding oven temperatures ranged from approximately 220°C to 320°C, respectively. Therefore, the following drying profile is recommended to produce larger blocks of SF-8 and VF-6:

i) Room temperature to 220°C, 30°C/hr, and hold at 220°C for 5 hours.

ii) 20°C to 320°C, 50°C/hr, and hold at 320°C for 8 hours.

iii) Turn off the furnace and allow it to cool.

*Fig. 14 Sample T. in the center of block plotted as a function of furnace temperature under Macro-TGA test.*

By following this drying profile, the risk of cracking caused by brucite formation can be significantly reduced, resulting in less failure of MgO castable.

### 3.4 "Real-size" industrial-scale specimens

To evaluate the effect of microsilica content and drying agent on crack formation, two series of blocks of SF-8 and VF-6, weighing approximately 600kg with dimensions of 900x900x270mm, were cast with varying dosages of EMD. Here, 10% DBM (325mesh) was replaced by calcined alumina (Table 1), based on the request of a customer. The blocks were demolded after one day and air-cured at ambient temperature before the dry-out process began. A thermocouple was embedded in the center of the specimens to monitor the temperature profile. The optimized drying profile recommended above based on Macro-TGA measured input was applied.

Figures 14a to 14d present photos of the blocks of two series of SF-8 and VF-6 with varying dosages of EMD after drying. The typical pattern of crack formation due to brucite formation damage was observed in the SF-8 block without EMD and the VF-6 block with 0.05% EMD. This crack forms around the center of the castable and propagates to the surface. This can be explained as an "autoclave effect" inside the castable. For larger blocks, internal vapor pressure is generated, which favors the formation of brucite in this area. This reaction causes a dramatic expansion of the internal volume of the sample.

*Fig. 14: Blocks (~600kgs, 900x900x270mm) dried at 320°C for 8hrs. a) SF-8, no drying agent, b) SF-8, 0.1% EMD, c) VF-6, 0.05% EMD, and d) VF-6, 0.1% EMD.*

Furthermore, it was observed that cracking in VF-6 containing 6% microsilica + 0.05% EMD was much more severe than in SF-8 containing 8% microsilica and no EMSIL-DRY™. This confirms that for larger industrial samples, more microsilica is required to prevent brucite formation. When EMSIL-DRY® was increased to 0.1%, both the SF-8 and VF-6 samples produced perfect blocks after drying, with no cracks observed. These results demonstrate the effectiveness of using EMSIL-DRY® to prevent brucite formation and subsequent cracking in large industrial-scale MgO castables.

These results demonstrate the importance of using microsilica and drying agents to prevent the formation of brucite and subsequent cracking in industrial-scale MgO castables. By understanding the mechanisms of crack formation, producers can develop more effective drying profiles and refine their formulations to produce high-quality, crack-free industrial-scale MgO castables.

### 4 CONCLUSIONS

The future of refractory technology is focused on developing long-lasting, energy-saving, environmentally-friendly, low-carbon, and functional combinations through research and

innovation. This paper investigates the impact of microsilica dosage (q-value) on the hydration behavior of MgO in industrial-scale blocks using SEM and XRD. Additionally, the drying profile is optimized using Macro-TGA. Microsilica serves not only as a binder ($MgO-SiO_2-H_2O$) but also as a potent anti-hydration agent, preventing the formation of brucite. The result is the production of cement-free magnesia castables with low $CO_2$ footprint bonding (micro-silica-gel bonding) without any issues.

This study also offers a solution for developing crack-free industrial-scale MgO castables using a microsilica-gel binder, controlling MgO hydration, and applying a tailor-made drying profile. However, further research is necessary for continued innovation and advances from both environmental and technological perspectives. Several approaches should be pursued, such as selecting magnesia raw materials with a reduced $CO_2$ footprint, using recycled magnesia material, simultaneously developing refractory formulation, and bonding systems, and collaborating with refractory producers and end-users to develop application-oriented solutions. By pursuing these approaches, the refractory industry can continue to innovate and improve while meeting the demands of a changing world.

# DRY HIGH-PERFORMANCE MATERIALS IN THE CHANGE OF TIME

Bojan Damjanovič, Aleksandra Veličevič
EKW-Kremen d.o.o., Šentjernej, Slovenia

Erik Kurtscheid, Daniel Cölle
EKW GmbH, Eisenberg, Germany

**ABSTRACT**

The so-called dry mixes represent an extremely important species of unshaped refractory ceramics for serving monolithic lining concepts in a wide range of industries that are, however, essentially based on the metallurgical melting process. Even a normative definition of dry material exists according to ISO 1927-1:2012: "These are materials which are specially designed for dry application by vibration, "vibro-compaction" or ramming. The dry mixes achieve maximum densification during installation, making it possible to remove the template either before or after heating. These materials may have a temporary bond, but are ultimately ceramic bonded."

A comprehensive introduction to the "specific world" of dry materials with an historical overview and focus on fundamental, classificatory aspects of raw material geology and mineralogy is presented. The latest regulations within the continuous REACH discussion require a targeted response from the refractory industry and are interpreted as an opportunity to generate progressive approaches to solutions. Dry mixes are also experiencing a modernized design and are characterized by new structural characteristics which are identified and critically discussed on the basis of well-chosen examples.

The article would like to conclude with discussions of a couple of actual metallurgical problems and proposed solutions from exemplary industrial and engineering end-users and at the same time provide an outlook on future problems and approaches to solutions for the integration of dry mixes in modern monolithic refractory linings of industrial systems.

# ASSESSMENT OF THERMAL–MECHANICAL STRESS DAMAGE MECHANISMS OF MONOCARBONATE BONDED ALUMINASPINEL CASTABLES BY HIGH–TEMPERATURE WEDGE SPLITTING TEST

Ning Liao, Wenjing Liu, Yawei Li, Shengli Jin

The Key Laboratory of Refractories and Metallurgy, Wuhan University of Science and Technology, Wuhan, 430081, China

National-Provincial Joint Engineering Research Centre of High-Temperature Materials and Lining Technology, Wuhan, 430081, China

## ABSTRACT

The hydration behavior of calcium aluminate cement (CAC) greatly affects the structures and properties of the CAC bonded alumina-spinel castables, especially the mechanical properties and thermal shock resistance. Therefore, we investigated the specific influences of characteristic hydrates ($CAH_{10}$, $C_2AH_8$, and $C_3AH_6$), the curing, the heating temperatures on the evolutions of nano and micron-sized pore structures of castables through mercury intrusion porosimetry (MIP) combined with micro-CT scanning technology, where the corresponding fractal dimensions were calculated to determine the complexity. Furthermore, more stable hydrates such as $C_4AcH_{11}$, and $Mg_4Al_2(OH)_{16}(CO_3)\cdot 4H_2O$ were elaborately designed based on thermodynamic calculation of hydration (GEMS). Finally, the fracture behaviors were characterized by wedge splitting test (WST) both at room temperature and high temperature to better evaluated the thermal shock resistance of castables in practice.

## 1 INTRODUCTION

Refractory castables are widely used as furnace lining materials owing to their energy efficiency, adaptability, excellent integrity, and high efficiency [1].CAC, as one of the commonly used hydraulic binders for refractory castables, has higher green strength and excellent thermomechanical properties compared to other binders. In fact, the mechanical properties, phase composition, and microstructure evolution of the castables are associated with the early hydration of CAC and the formation of various calcium aluminate phases [2]. Recently, there have been extensive discussions about the effects of CAC hydrates on the properties of castables. It has been widely accepted that there are three kinds of hydrates of CAC, i.e., $CaO\cdot Al_2O_3\cdot 10H_2O$ ($CAH_{10}$), $2CaO\cdot Al_2O_3\cdot 8H_2O$ ($C_2AH_8$), and $3CaO\cdot Al_2O_3\cdot 6H_2O$ ($C_3AH_6$). Our previous study has confirmed that plate-like hydrate $C_2AH_8$ could construct highly homogeneous $CA_6$ after high-temperature treatment, resulting in a more complex and homogeneous pore structure, hence acquiring excellent comprehensive properties [3].

However, metastable phases (C-A-H, C/A$\leq$2) inevitably transform during the conventional curing and drying stages, and the process is accompanied by the increase of pores and the decay of strength (Fig.1) [4]. Therefore, designing stable plate-like hydrates to inhibit hydrates transformation has been a promising solution. Luz [5] et al. added $CaCO_3$ to cement pastes, resulting in improved volume stability and early strength owing to the formation of monocarbonate ($C_3A\cdot CaCO_3\cdot 11H_2O$, $C_4AcH_{11}$) instead of $CAH_{10}/C_2AH_8$. Besides, $C_4AcH_{11}$ was confirmed as a plate-like and stable phase even though sufficient water was available in the hydration system, which distinguished it from $C_2AH_8$. However, it is worth noting that the generation of hydrates with high C/A ratios ($C_2AH_8$, C/A=2 and $C_4AcH_{11}$, C/A=4) was inevitably accompanied by the precipitation of substantial amounts of $AH_3$ [6]. Its stronger pore-filling effect is further deteriorating the permeability of the CAC-bound castables, resulting in an explosion risk. Therefore, the generation of stable plate hydrates together with the consumption of $AH_3$ in the system is the focus of the hydrates design.

Based on the GEMs thermodynamic calculations (Fig.2), MgO was added into the CAC system containing carbonate, and the reaction of $AH_3$ with MgO induced the hydrate hydrotalcite (M-A-H). M-A-H was demonstrated to be a lamellar structure, and its generation not only solved the problem of reduced permeability but also contributed to the improvement of early bonding strength. This paper presents carbonate and MgO to modify and design hydration products and further assess the effect of early hydration on alumina-spinel castables' pore structure and resistance to thermomechanical stress damage.

## 2 MATERIALS AND METHODS

### 2.1 Preparation of hydration samples and alumina-spinel castables.

Nanoscale $CaCO_3$, Mg-Al hydrotalcite, and $MgCO_3$ compounded with MgO were added to the CAC hydration systems, and the detailed preparation procedures can refer to our previous work [3]. The raw materials used for the castables are tabular alumina aggregates, tabular alumina powder, $\alpha$-$Al_2O_3$ powder, spinel powder, CAC binder (Secar 71), and nanoscale $CaCO_3$/ Mg-Al hydrotalcite/ $MgCO_3$ compounded with MgO, the specific compositions and preparation of castables are also referred to previous work [7].

### 2.2 Test and Characterization.

For hydration samples, the phase compositions were identified by powder X-ray diffraction analysis using a Philips X' Pert PRO diffractometer. The microstructures were observed using field-emission scanning electron microscopy. The hydrates and the degree were analyzed using differential scanning calorimetey. The early setting behavior of castables was monitored in real time using ultrasonic velocity testing. The modulus of rupture (CMOR), cold crushing strength (CCS), and apparent porosity (AP) of castable specimens was evaluated. Additionally, the center part of the castables was cut into some cubes with a side length of ~5 mm for mercury intrusion porosimetry. The high-temperature wedge splitting test of specimens pre-fired at 1600 °C was loaded at a rate of 0.5 mm/min for unidirectional compression at 1400 °C, the test procedures and device can refer to the literature [8].

## 3 RESULTS AND DISCUSSION

Fig. 3 indicates that the predominant hydrates of the R sample cured at 25 °C for 1 d were plate $C_2AH_8$ and with tiny amounts of prismatic $CAH_{10}$ and $AH_3$. The NCc sample with nanoscale $CaCO_3$ showed distinct diffraction peaks at $2\theta$ angles of ~12° and ~23°, which matched with the monocarbonate-$C_4AcH_{11}$. SEM results confirmed that the morphology of $C_4AcH_{11}$ was a plate and constituted interlocking structures. For the MAH sample with Mg-Al hydrotalcite, the main hydrates were $C_2AH_8$ and $C_4AcH_{11}$, and the morphology of both hydrates was typical plate structure. While the hydrated sample with $MgCO_3$ and MgO was cured at 40 °C for 12 h and then at 80 °C for 12 h. The results verified the feasibility of the two-step curing, which induced the formation of nanoplate $Mg_4Al_2(OH)_2(CO_3)\cdot 3H_2O$ along with the stable micrometer plate $C_4AcH_{11}$. Both the addition of carbonate-containing additives and the two-step curing led to a significant decrease in the diffraction peaks of the CA and $CA_2$ compared to the R sample, i.e., a significantly increased degree of CAC hydration.

127

*Fig.3 XRD patterns (a) DSC (b), and SEM of hydration samples.*

The early hydration of CAC determines its bonded castables setting behavior and green strength. Fig. 4 indicates that an earlier increase in the velocity was detected in the specimens of castables with the addition of nanoscale $CaCO_3$ and hydrotalcite (earlier setting behavior). This is ascribed to the fact that nanoscale $CaCO_3$ and hydrotalcite provide more nucleation sites to accelerate the CAC hydration. It also confirmed that the plate-like hydrate $C_4AcH_{11}$ played a similar and better reinforcement role as $C_2AH_8$.
Fig. 4 Ultrasonic wave velocity vs. time of castables containing nanoscale CaCO₃ (a) and microscale hydrotalcite (b).

Fig. 5 exhibits that the R sample had larger pores and pore connectivity. Furthermore, more detailed, R sample had larger plate $CA_6$ grains, while for NCc sample, the pore was refined and the morphology of $CA_6$ gradually changed to small and elongated structure, owing to CaO sources being well dispersed and high reactivity (Fig. 5e). Additionally, the similar refinement of the pore structure was verified when the additive of $MgCO_3$ compounded with MgO was added. Furthermore, $CA_6$ encrusted microcrystalline spinel structure was formed in the matrixes (Fig. 5f).

Fig. 5 SEM of castables treated at 1600 °C: (a, d) R sample, (b, e) NCc sample, (c, f) Mc+M sample.

Mercury intrusion porosimetry to assess pore size up to 5 nm~800 μm, as shown in Fig. 6. Obviously, the pores with a diameter range of 1~10 μm were significantly increased with the increase of nanoscale $CaCO_3$, attributed to the pore structure constructed by the interlocking of elongated $CA_6$. Similarly, the addition of Mg-Al hydrotalcite significantly increased the proportion of <10 μm pores along with a reduction of 100~100 μm. Additionally, the addition of $MgCO_3$ compounded with MgO was favorable to increase the pores of 10-100 nm and decreasing the micropores (100~800 μm) after drying and firing.

Fig. 6 Divisions of pores volume of castables treated at 1600 °C based on MIP.

Noteworthily, the high-temperature wedge splitting test presented more interesting fracture behavior at 1400 °C as shown in Fig.7. Distinguished from the room temperature test, all specimens presented nonlinear fracture behavior, and the vertical loads reduced from ~2500 N to ~600 N. Furthermore, the specimens with nanoscale $CaCO_3$ showed larger vertical displacements up to 6~7 mm and exhibited better resistance to crack propagation (with smaller load-dropping rate and larger vertical displacements). It indicated that the CAC-bonded castables exhibited stable crack propagation and excellent toughness fracture characteristics at high temperature. Again, it demonstrated that the addition of nanoscale $CaCO_3$ can play a strengthening and toughening role in castables. Comprehensively, a distinctive feature of the load-displacement curves was that the fracture curves showed high peak loads and narrow ultimate displacements at room temperature, whereas the curves assessed at 1400 °C were dramatically different, lower maximum loads and larger ultimate displacements.
*Fig. 7 Vertical force-displacement curves (b) and of alumina-spinel castables evaluated at 1400 °C.*

Additionally, based on the 2D images scanned by Micro-CT, crack damage identification and evaluation were further performed (Fig.8). The results demonstrated that the crack paths of the specimen R were mainly within the matrixes (69.9%), together with 30.1% through the aggregates. With the addition of nanoscale $CaCO_3$, the cracks were induced through aggregates owing to the reinforcing effects of the elongated network-$CA_6$ in matrixes, and the reducing percentage of cracks through the matrixes was well-verified (~66%). However, there was also the fact that the percentage of cracks through the matrixes of specimen containing 1% nanoscale $CaCO_3$ was rebounded compared to NCc0.5 specimens. The results were related to the increase of total porosity which slightly weakened the matrixes, but it still exhibited matrixes reinforcement.

*Fig. 8 Cross-sections in different directions and 3D photo of samples after high-temperature splitting tests.*

## 4 CONCLUSIONS

The generation of plate-like hydrates ($C_2AH_8$, $C_4AcH_{11}$ and $Mg_4Al_2(OH)_{16}(CO_3)\cdot 4H_2O$) together with proper hydration degree contributed to higher bonding strength after demolding and thereafter heat treatments. Meanwhile, these hydrates were conducive to the construction of multistage porous structures, which facilitated the consume of elastic energy stored in the crack tip and induced crack propagation within the matrixes and along aggregate-matrix interfaces. These works provided a new solution to enhance thermal shock resistance of CAC bonded castables.

# USE OF NOVEL REFRACTORY DESIGN AND INSTALLATION TECHNIQUES FOR IMPROVED ENERGY EFFICIENCY IN IRON AND STEEL AND OTHER ENERGY INTENSIVE INDUSTRIES

James G. Hemrick
Oak Ridge National Laboratory, Oak Ridge, USA

Manoj K. Mahapatra
University of Alabama – Birmingham, Birmingham, USA

## ABSTRACT

This work describes a US Department of Energy funded program which unites key players to develop and deploy new technologies aimed at increasing energy efficiencies while reducing their overall energy and environmental footprint. The research brings together a vertically integrated collaborative team consisting of the end user (US Steel), material producers/suppliers (Allied Mineral Products and Reno Refractories), raw material suppliers (American Metallurgical Services, Minerals Manufacturing), and research organizations (Oak Ridge National Laboratory, National Energy Technology Laboratory and University of Alabama-Birmingham) with the objective of designing and producing new refractory materials. Design and production criteria are based on novel aggregates, improved particle packing, and engineered surface textures. In addition, the recycling and use of spent refractory materials has been investigated resulting in development of a novel installation technique that utilizes additive manufacturing technology and existing refractory shotcrete technology. The combination of these new technologies will improve the energy, environmental, and economic efficiencies of the steel industry while reducing the environmental footprint. The developed technology is potentially applicable to additional energy intensive industries including cement, glass, pulp and paper, and non-ferrous metals processing.

## BACKGROUND

Oak Ridge National Laboratory (ORNL) has a history of being one of two federal laboratories (the other being the National Energy Technology Laboratory (NETL) who is also a partner on this project) actively involved in refractory ceramic research for the improvement of the energy efficiency of energy intensive industrial processes. Successful past projects related to refractory ceramics have been carried out utilizing the unique capabilities and facilities housed at ORNL and have involved both the advanced characterization of existing materials and the development and implementation of new materials for numerous industrial applications including the analysis of fusion cast refractories for more energy efficient oxy-fuel glass furnaces, identification and evaluation of refractory materials for black liquor gasification in the pulp and paper industry, development of multifunctional metallic and refractory molten metal handling materials used in the steel/aluminum/copper/special alloy industries, development of nano-scaled interpenetrating phase composites for industrial and vehicle applications, development and testing of refractories for coal gasification, and the development of novel refractory materials for high alkali and high temperature environments including aluminum, black liquor, coal gasification, and lime kiln environments.

It is the goal of this project to address the estimated 80% of the total energy usage in the steel industry (shown in Tab. 1) which can be directly affected by improved refractory technology by building on previous work to develop and implement improved monolithic refractory ceramic materials with longer lifetimes resulting in an increase in thermal efficiency of key processes in the steel industry and providing an incremental increase in time before refractory lining materials require maintenance. A near-term goal of 2% and a long-term goal of up to 10% overall energy savings due to improved refractory materials is sought relating to over 17 TBtu/Yr (2% goal) and 85 TBtu/Yr (10% goal) in the steel industry, with additional benefits possible if iron foundries are included.

Tab. 1. Energy Savings Possible Through Refractory Improvements

| Industry | NAICS codes | Total TBtu/year* | Usage affected by refractories | | Energy savings goals for improved refractories (TBtu/Yr) | |
|---|---|---|---|---|---|---|
| | | | % | TBtu/Yr | Near-term 2% | Long-term 10% |
| Iron and Steel Mills | 3311111 | 1,065 | 80% | 852 | 17.04 | 85.20 |
| Iron Foundries | 331511 | 48 | 80% | 38 | 0.77 | 3.84 |

## PROJECT FOCUS

This project focuses on the design of refractory ceramic materials used in applications such as blast furnace linings, electric arc furnace (EAF) linings and metal transport vessels (ladles, tundishes, etc.) utilized in the steel industry. Current refractory lining systems for the vessels of interest generally consist of brick or monolithic ceramic materials. In the case of brick, the installation of these materials is highly labor and time intensive. Additionally, the failure of a single region of the lining can lead to widespread failure of the lining as surrounding bricks rely on each other to remain in place, and the many joints between the bricks offer paths for corrosive liquids and vapors to penetrate the lining. Monolithic refractory lining systems (like those being proposed in this project) have the advantage of faster installation methods (casting, gunning, shotcreting) and elimination of the joints between the bricks that offer paths for corrosion. Additionally, monolithic materials are generally installed in continuous panels or complete rings removing the reliance of bricks on their local neighbors for lining integrity. While brick linings have traditionally been favored in many steel applications, monolithic refractories are recently finding use due to improvements and innovations such as no-cement binder systems and improved properties.

Depending on the vessel of interest, refractory lining systems can last for several years (in the case of blast furnaces and EAF) or can be completely replaced as often as weekly or monthly (transfer vessels such as ladles or tundishes). In between complete refractory relines, vessels will be patched as

needed (daily, weekly, or monthly) using monolithic repair material which is gunned, shotcreted, or applied by hand as a coating. In this project we will address primary lining materials, as opposed to repair materials, although the technology being developed could be applied to these repair systems. This project will not only address the energy savings goals above but will also aim to provide an incremental increase in time before the material requires maintenance as shown in Tab. 2 for several example vessels.

Tab. 2. Process Vessel Lifetime Improvement Goals

| Process Vessel | Normal Outage Period for Maintenance | Target Outage Period for Maintenance |
|---|---|---|
| Blast Furnace | 6 months | 12 months (2X) |
| Electric Arc Furnace | 6 months | 12 months (2X) |
| Metal Transfer Ladle | 1 month | 3 months (3X) |
| Tundish | 2 weeks | 6 weeks (3X) |

**PROJECT PROGRESS HIGHLIGHTS**

This project is entering the third and final year. In the first year of the project, the approach taken was to utilize artificial intelligence/machine (AI/ML) learning resources at ORNL, not currently available or widely utilized by the refractory industry, to optimize particle packing and mix composition, along with surface topology, in an effort to produce materials with greater densities (20%), lower permeabilities (10%), and greater chemical inertness resulting in stronger, more corrosion resistant and longer lasting linings. This translates into installed linings being replaced less frequently (reducing process down times, the need to cool and reheat process vessels, and the need to produce and install new refractory materials) and allowing for higher energy efficiency of the process as the insulating value of the lining is maintained as the refractory lining is not degraded as quickly.

Fig. 1: Example ASCENDS data set (input table) and correlation analysis output.

The ASCENDS (Advanced data SCiEnce toolkit for Non-Data Scientists) AI/ML tool developed at ORNL was evaluated for use in educated refractory design. This tool allows the advantage of training of various machine learning models from a spreadsheet-type dataset. Predictions can then be made from trained surrogate models without additional coding. Work under this project was carried out with datasets put together from information previously collected at ORNL and additional data sets provided by refractory partners used as input tables to "train the model". This information was then used to produce correlation tables which were used for model predictions (output tables). Although some information could be gathered from this exercise and the use of this tool (which was used to guide refractory development and design for the remainder of the project), it was determined that larger data sets are needed to fully utilize the capabilities of such AI/ML methods for future refractory design.

Fig. 2: Scanning electron micrographs of new $ZnAl_2O_4$ material.

The primary new material system developed under this project is a zinc aluminate ($ZnAl_2O_4$) system based on funded and co-advised graduate student and undergraduate student research work at the academic partner University of Alabama – Birmingham (UAB). This system appears to be a viable candidate for replacing existing alumina- and spinel-based systems in the current applications of interest. Several papers regarding this material and its application have been published [1][2] along with the associated dissertation work [3]. Advantages of this new material include intimate bonding of the aggregate with traditional monolithic refractory matrices, favorable thermal expansion behavior, and good corrosion resistance to molten metal and slag. Incorporation of this material into relevant industrial refractory formulations is being undertaken by the refractory industrial partners and samples will be prepared for suitable applications and industrial validation during the final year of the project.

Additionally, the use of recycled raw materials was investigated during the first year of the project and continued into the second year as a means to further improve the energy, environmental, and economic efficiency of the produced materials and targeted processes. Recycling has been a topic of consideration in both the steel industry, as they look for ways to dispose of waste materials after a furnace rebuild, and in the refractory industry, as they look for alternative raw material sources and possible cost reductions. It has also been a topic of academic research as nearly 35 million tons per year of raw materials are consumed worldwide for the manufacture of refractory materials for the iron, steel, other non-ferrous metals, cement and glass industries [4]. According to Industrial Mineral Forums and Research "Mineral Market Matrix", refractories rank 10th out of the 26 leading markets for industrial minerals, consuming 24 different industrial minerals. The economic viability, along with feasibility of

131

using such materials has been problematic in the past due to issues regarding material sorting, material purity, material cost, and material supply [5]. Technical issues include contamination by metal inclusions and corrosive species of the refractory material being processed, comingling of individual refractory raw materials, and the cost of recycled materials relative to equivalent primary raw materials.

*Fig. 3: Recycled raw material from a steel delta.*

The use of recycled refractory materials has taken two paths under this project. The first is led by industrial partner American Metallurgy Services regarding investigations into possible waste streams from the steel industry and their use as raw material streams to produce new refractory materials. It has been estimated from current work that the processed recycled materials being produced could be as much as 50% cheaper when substituted for virgin raw materials. Currently, about 1,500 pounds of crushed calcined bauxite from used steel deltas and several hundred pounds of tabular alumina from other sources has been processed. Opportunities to try this material in industrial refractory mixes are currently being investigated and trialed. A new industrial process is currently being patented from this work as well.

*Fig. 4: UAB senior design project.*

In conjunction with the above work, a senior design project was funded at academic partner University of Alabama – Birmingham (UAB) to investigate low-cost mechanical separation of salvaged refractory material from steel slag and waste after tear out. This project resulted in the development of a simple apparatus utilizing grit blasting and rotary separation techniques that successfully demonstrated separation of refractory waste streams from metal inclusions and waste.

The second recycled material pathway involves the development of recycled alumina and magnesia/alumina spinel aggregate materials sutiable for use in the steel industry by a new industrial partner Evergreen Alumina [6]. The production of this aggregate is based on a new recycled raw material source from the aluminum industry previously not utilized (currently 100% landfilled). Preliminary characterization efforts have been undertaken on this recycled raw material and the processed material which will potentially be used for aggregate production. It is also being introduced to the refractory producers for testing in monolithic refractory mix formulations and is hoped to be trialed in industrial trials later in the project.

*Fig. 5: Examples of shotcrete and novel installation geometries.*

In the second year of the project efforts also focused on the development of a novel installation technique that takes advantage of additive manufacturing technologies currently under development at ORNL's Manufacturing Demonstration Facility (MDF) for ceramic and metallic systems and extending the use to refractory ceramic systems (large aggregate, pumpable mixes) based on knowledge of commercial scale refractory shotcrete technology. Such a method is hoped to increase the rate of installation of these refractory materials, reduce the manpower required for installation of these materials, increase the accuracy of the installation, and allow for novel installation geometries not possible by traditional installation techniques.

Advances in additive concrete manufacturing techniques are relevant here, along with large scale additive processes developed and implemented by the ORNL MDF [7][8]. These techniques can be married with existing industrial technology for the shotcreting of refractory ceramic systems currently being employed and widely utilized by the project industrial partners. One example of advances that can be introduced through the use of AM is graded structuring. This would allow for having different conditions at the free surface/slag line, in the freeboard above the liquid and in the liquid containment space of a steel containing vessel or furnace. Conceptually, one might print a cellular insulating lightweight structure from recycled materials in the freeboard, then at the slag line print a dense corrosion resistant engineered refractory and in the liquid contact area a combination of high density at the hot face with low density insulating material behind it.

*Fig. 6: ORNL SKYBAAM system.*

The ORNL MDF staff identified two possible platforms for this application. The first is the ORNL SKYBAAM (Sky Big Area Additive Manufacturing) cable-hoisted construction 3D printing technology designed for concrete installation, but which could possibly be modified to accommodate refractory gunning or shotcrete mixes. This system utilizes a gantry system to introduce a large print head for computer-controlled application of cementitious materials on a large scale.

*Fig. 7: ORNL OCILOW system.*

The second and preferred platform is the ORNL OCILOW (Off-Centered In-Line Omni-directional Wheels) omnidirectional vehicle which is a programmable steerable platform with up to 10,000-pound payload on which a standard shotcrete or gunning hose assembly could be mounted for computer controlled refractory installation. This system is currently being retrofitted to meet our project needs. It is currently planned to modify this platform for use in a demonstration in conjunction with the project refractory partner Reno Refractories to shoot a test vessel surface or panel when they are in the area servicing a local client with the demonstration either being performed at the ORNL MDF or at the local customer site.

The third year of the project will focus on further refining and characterizing the materials and processes developed during the first two years and validating commercially produced (by our refractory industrial partners) samples of these materials and methods through industrial trials of at partner locations. Operational trials of up to six months are hoped for, along with acerated laboratory trials.

## CONCLUSION

The successful completion of the project will result in new materials and technologies not only appropriate for improving the productivity and energy efficiency of the iron and steel industry, but also multiple other energy intensive industries such as non-ferrous metals, cement, glass, and pulp and paper. Not only will the lifecycle energy of the produced products in these industries be improved, but environmental benefits will also be seen through reduced fuel usage and the use of recycled raw materials and advanced technology and research methods only available at national laboratories and universities will be leveraged into industrial settings.

# INFLUENCE OF THE TYPE OF PHOSPHATE ADDITIVE ON THE SETTING KINETICS OF CA CEMENT BONDED REFRACTORY CASTABLES WITH SPECIAL REGARD TO THE RESULTING PH VALUE

J. Kasper, M. Bastian, C. Dannert

Forschungsgemeinschaft Feuerfest e. V. at the European Centre for Refractories, Höhr-Grenzhausen, Germany

## INTRODUCTION/RESEARCH APPROACH

A recent study showed that an increased S-(T)PP concentration (sodium (tri)polyphosphate) as dispersing agent in a refractory castable resulted in a distinctly earlier onset of the main hydration of CA cement (which corresponds to a shorter dormant period) [1] and the specific reasons for this behaviour were questioned. One recent theory comprises that the dormant period results from the formation of an Al-O-H passivation layer on CA cement particles by the depletion of $Ca^{2+}$ [2-4]. This Al-O-H-rich passivation layer then has to go through an aging process [2, 3] to enable a further dissolution of CA cement and thus the overall hydration reaction of CA cement. Kasper put up for discussion that differences of the pH value during the dormant period reasonably explain the length of the dormant period: an increased pH value increases solubility and probably also the rate of solution of the Al-O-H passivation layer in the pore water. Therefore, the subsequent main hydration, which causes the final and major increase in green strength, will be accelerated or decelerated, depending on the pH value. At neutral pH values, the solubility of the passivation layer is low and a retarded aging of the passivation layer on CA cement particles is present. At higher pH values, the solubility of the passivation layer is being increased and an accelerated aging of the passivation layer on CA cement particles is present. The acceleration resp. retardation of the aging of the passivation layer corresponds to a change of the hydration velocity of refractory castables [5-6, 7].

Since the phosphate component becomes ineffective by its complexation with $Ca^{2+}$ [8, 9] during coagulation of the matrix suspension, one could argue that the remaining part of S-(T)PP in solution, the $Na^+$ ions, may provoke the accelerating behaviour if the S-(T)PP concentration is being increased. Especially, since pure phosphoric acid results in a strong retardation of the hydration reaction of CA cement [10]. The amount of $Na^+$ introduced by S-(T)PP may be varied by two measures: Firstly, the chain length of the phosphate influences the concentration of $Na^+$ in solution at a constant S-(T)PP concentration. Secondly, the concentration of $Na^+$ can be varied by the S-(T)PP concentration itself. It is assumed that these changes of the $Na^+$ concentration may be responsible for provoking the changes of the length of the dormant period of the CA cement hydration in the presence of S-(T)PP, by changing the pH value and the corresponding dissolution kinetic of the Al-O-H passivation layer.

The aim of this study was to investigate how the pH value during the dormant period of the CA cement hydration changes, and how this pH value shortens or prolongs the dormant period in dependence of the $Na^+$ concentration. Subsequently, the theory of a pH dependent solubility of the Al-O-H passivation layer shall be confirmed and the influence of the concentration of $Na^+$, as a measure for the shift towards dissolved NaOH by the complexation of phosphate by $Ca^{2+}$, shall be determined.

## MATERIALS AND METHODS

Setting experiments were conducted on alumina-based model refractory castables (coarse grains up to 3 mm, all alumina raw materials supplied by Almatis). CA cement (Secar71, imerys) was used as binder. Different types of S-(T)PP (Chemische Fabriken Budenheim) and citric acid were used as dispersing agents, retarder and accelerator respectively. The water content was chosen to achieve a flow value between 210 and 250 mm (medium to good flow at a water content of 6 wt.-%, vibration according to ISO 1927-4). Only with a high concentration of S-TPP of 0.2 wt.-%, a higher water content of 6.3 wt.-% was needed to achieve a sufficient flow of 190 mm.

The refractory castables were mixed in batches of 3.5 kg using a compulsory mixer (kitchen aid professional) for 3.5 min (0.5 min dry and 3 min wet).

The setting kinetics were investigated using pH value measurements and gave information about the pH value of the pore solution of the refractory castables during setting in a direct comparison to the events which were identified by measuring the sonic velocity, especially about the pH value during the dormant period. Sonic velocity (data presented in Open Ceramics peer review paper) was measured to correlate pH value increases with the period of main hydration of CA cement within the refractory castables.

## RESULTS

The pH value of the pore solution of the refractory castables during setting due to differing chain lengths of the phosphate molecule and differing concentration of S-(T)PP is displayed in Fig. 1. The correlation between the pH during the periods of constant pH and the time when the pH value starts to increase is displayed in Fig. 2. The following observations could be made:

- The pH value was found to increase in distinct steps: A low S-(T)PP concentration (0.1 wt.-%) results in a three-parted increase of the pH value for all phosphate chain lengths with two intermediate periods of constant pH value. The third increase of the pH value corresponds to the main hydration. At high S-(T)PP concentration (0.2 wt.-%), the pH value increases in two steps with one intermediate period of constant pH value. The second increase of the pH value corresponds to the main hydration.

- General speaking, at low S-(T)PP concentrations the pH value increases less compared to high S-(T)PP concentrations. This results in a retarded aging of the passivation layer (lower solubility) at a low S-(T)PP concentration and in an accelerated aging of the passivation layer (higher solubility) at a high S-(T)PP concentration. The chain length of the S-(T)PP plays a less important role.

*Fig. 1 pH value of the CA cement bonded refractory castables during setting, differing concentration of S-(T)PP (0.1 and 0.2 wt.-%) and chain length (3, 7, 28 and 30 P-O units) resp. $Na^+$ concentration, grey boxes indicate time intervall of main hydration.*

- The final increase of pH value is linearly correlated to the final increase of sonic velocity (main hydration, data presented in Open Ceramics peer review paper). This implies that the final increase of the pH value is indirectly related to the increase of strength by the precipitation of hydrate phases.
- The periods of constant pH value can be differentiated into two regions (Fig. 2, grey background and white background): The pH value stays below 12.2 and no hydration of CA cement takes place after this period and the pH value exceeds 12.4 and hydration takes place directly after this period ended. The differentiation supports the assumption of Kasper et al. of a pH-dependant solubility of the Al-O-H passivation layer on CA cement particles as the reason for the dormant period [6, 11]. Nevertheless, additional effects seem to be present which influence the length of the dormant period of the CA cement hydration beyond the pH value: Above pH of 12.4, there is no clear correlation between the pH value directly before the occurrence of the main hydration and the time when main hydration takes place (final increase of the pH value and final increase of sonic velocity).
- Only the higher $Na^+$ concentrations of 0.15 to 0.22 (resulting from 0.2 wt.-% S-(T)PP) result in a direct hydration of CA cement between 8-11 h. At the lower $Na^+$ concentrations between 0.08 and 0.12 (resulting from 0.1 wt.-% S-(T)PP), a further final increase of the pH value, additional to the slight increase of the pH value at 10/11 h, has to take place between 18-22 h to provoke the immediate hydration of CA cement.

Fig. 2 pH value during the 1st/2nd period of constant pH value vs. time of increasing pH value of the pore solution of the refractory castables during setting, parameter S-(T)PP concentration, grey - region no hydration of CA cement, white - region hydration of CA cement.

**CONCLUSION**

Finally, there is a noticeable correlation between an increasing $Na^+$ concentration from S-(T)PP and the time where the pH value finally increases and the main hydration takes place. The initial assumption that the remaining free $Na^+$ ions provoke an increased pH value resulting in a faster dissolution of the Al-O-H passivation layer, a corresponding shorter dormant period and accelerated main hydration of the CA cement seems reasonable. Nevertheless, the connection of setting kinetics with the $Na^+$ concentration could be better. This implies that there are effects like remaining free phosphate molecules or the ionic strength of the pore solution which may influence the hydration reaction of CA cement further. However, the theory of a pH-dependent solubility of the Al-O-H

passivation layer as the reason for the length of the dormant theory is strengthened [6, 11].

## ABSTRACT
Until now the mechanism and conditions of growth and decomposition of calcium aluminate cement hydrate phases (CAH-phases) that determine the drying behaviour of calcium-aluminate bonded castables are not sufficiently understood. This paper focuses on the influence of different deflocculants (polyphosphate, acrylate, polycarboxylate ether) on the formation of hydrate-phases and their impact on the development of the technological properties of Medium Cement Castables during first heating. To improve the understanding on the hydrate phases CAH-phase formation and decomposition, the investigation of the technical properties (flexural strength and open porosity) of the castables at various temperatures during first heating was combined with high resolution SEM, XRD phase analysis and pore size analysis. Flexural strength was found to develop differently with increasing temperature depending on the type of the used dispersing agent. Considerable influence of the deflocculants on the pore sizes was detected. SEM imaging reveals the differences in shape and size of the formed hydrate CAH phases.

## INTRODUCTION
During the first heating of a castable spalling may occur when the internal pore pressure exceeds the material strength. Studies conducted on cement limes or simplified castable mixes already stated which hydrate phases are formed under defined ambient conditions and at which temperatures hydrate phases are thermally decomposed [1,2,3]. However, said findings do not incorporate the entire composition and microstructure of castables. Deflocculants significantly influence the forming of CAH-phases as discussed in this paper. They also affect the thermal evolution of the pore structure and consequently the permeability of the castable. Low permeability leads to increasing pore pressure during the first heating of the castable and the boiling point of water shifts to higher temperature. It has to be considered that the resulting hydrothermal conditions may stabilize cement hydrate-phases to higher temperatures.

## MATERIALS AND METHODS
For the evaluation of the temperature dependent changes of technological properties of CAC-bonded castables, three modifications of a model MCC containing 90 wt.-% alumina and 10 wt-% CAC were developed using three different types of deflocculants: Each deflocculant affects the workability of the castable in a specific way, requiring different amounts of deflocculant and water. These were adapted accordingly for the following types of castable mixes:

**(a) MCC-P+C:**    0.15 wt.-% sodium polyphosphate (Budit 4H) [1]
0.02 wt.-% citric acid [1],
6.50 wt.-% deionized water

**(b) MCC-A:**    0.30 wt.-% acrylate (KX2314) [2],
6.50 wt.-% deionized water,

**(c) MCC-PCE:**    0.06 wt.-% polycarboxylate ether (Castament FS60, BASF, Germany),
4.8 wt.-% deionized water,

[3] BASF SE, Germany

Thermal analysis by the Method of Monotonic Heating (MMH) [4] and Thermal Gravimetric (TG) analysis were conducted after a curing period of 48 h at 20 °C and 95 % relative humidity. Flexural strength of freeze-dried prismatic test pieces was tested after curing and after subsequent heating up to 5 temperature levels that were selected to frame temperature ranges in which mineral phase changes were detected by MMH and TG. The halved prisms and fragments thereof were used to determine open porosity (water absorption method), pore size distribution (mercury intrusion porosimeter), size and habitus of the developed hydrate phases (FE-SEM) and mineral phase composition (XRD-Analysis).

## RESULTS AND DISKUSSION
### MMH and TGA
The signals detected in MMH and TGA indicate the ebullition of water and the thermal decomposition of hydrate phases under hydrothermal conditions, similar to those described by Simmat et al. for LC castables. These were investigated using the same test procedure as described here for the MC castables [5]. Exothermic signals at ~100 °C were attributed to the thermally induced rapid hydration of relict CAC remaining after the curing process. Endothermic reactions above ~130 °C are related to the thermal decomposition of different hydrate phases: $CAH_{10}$, dicalcium aluminate hydrate ($C_2AH_x$), katoite ($C_3AH_6$), gibbsite ($AH_3$) and boehmite (AH). The correlation of the endothermic signals in the MMH curves with the thermal decomposition of discrete hydrate phases in the castables has already been described in [5]. The assignment of the signals in MMH was carried out based on plausibility under consideration of known hydrate phases and their temperatures of thermal decomposition as documented in the literature [6]. The relation of these dehydration temperatures to the signals in the MMH-curves is not straightforward, because the stated temperatures have been determined on cement limes, but not on full-scale castables. The low permeability of the dense castables allows the formation of high vapour pressure in the pore structure during the initial heating. The high vapour pressure can stabilise hydrate phases to higher temperatures.

Distinct signals in the form of sharply increasing curves of $a_{eff.}$ were interpreted as the end of the ebullition of free water. At the temperature at which this endothermic process was completed, the heating rate in the sample immediately increased, causing an increase in $a_{eff.}$. This temperature was found to be higher than 150 °C in all samples, indicating hydrothermal conditions prevailing in the pores of the castables.

The temperatures of MMH signals related to the decomposition of hydrate phases for each type of MC-castable are given in table 1.

Tab. 1: Temperatures of MMH-signals attributed to the decomposition of hydrate phases for different types of MCC.

| decomposing hydrate phase | MCC-A Temp. [°C] | MCC-P+C Temp. [°C] | MCC-PCE Temp [°C] |
|---|---|---|---|
| $AH_3$ | 270 | [1] | 290 [2] |
| $CAH_{10}$ | [1] | 130 | [1] |
| $C_2AH_x$ | 155 | 170 | 175 |
| $C_3AH_6$ | 320 | 320 | 320 |
| AH | [1] | 530 | 530 |

1) not detected 2) origin of signal not yet clarified, provisionally interpreted as the decomposition of gibbsite

**Mineral phase Analysis (XRD)**

Significant differences in the mineral phase composition of castables prepared with varying deflocculants are detected after curing. All types of MCC show an increased hydrate phase content after heating to 130 °C but the mineral phase composition develops differently:

**MCC-A**: Only a small amount of hydrate phases ($CAH_{10}$ and $AH_3$) is detected after curing. $CAH_{10}$ is no longer detected at 130 °C but considerable amounts of $AH_3$ and $C_3AH_6$ are evident. The $AH_3$ proportion gradually decreases in the following temperature levels, whereas the $C_3AH_6$ proportion remains stable up to 250 °C but is extinct at 300 °C.

**MCC-P+C:** After curing the gibbsite content is higher than in MCC-A and additionally some $C_3AH_6$ is found. At 130°C $C_3AH_6$ and $AH_3$ are the predominating hydrate phases with traces of $CAH_{10}$ and $AH$. The $C_3AH_6$ content increases with rising temperature up to 250 °C, whereas $AH_3$ is reduced. Instead $AH$ forms a growing part of the hydrate phases. The increasing weight share of the summarized hydrate phases gives evidence of an ongoing hydration process up to 250 °C. At 355 °C $C_3AH_6$ is no longer detected in MCC-P+C.

**MCC-PCE:** After curing the hydrate phase composition is similar to MCC-P+C but with a higher content of $C_3AH_6$. After heating to 130 °C $C_3AH_6$ and $AH_3$ are the prevalent hydrate phases. Compared to MCC-P+C a higher amount of $AH_3$ is detected. The transformation of $AH_3$ to $AH$ occurs later than in MCC-P+C, whereas $C_3AH_6$ decomposes at lower temperature, resulting in $AH$ as the predominant hydrate phase at 300 °C.

**Technical properties**

After curing the examined types of MCCs show widely deviating open porosity (OP), ranging from 2.4 % (MCC-PCE) to 14.6 % (MCC-A). During first heating of the castables a similar increase of OP is observed for all MCCs. MCCs prepared with varying types of deflocculant show specific patterns in pore size distribution. After curing the median pore diameter in MCC-A (~0.2 µm)=is larger than in the other types of MCC (~0.1 µm) examined in this study and increases during first heating. Opposed to this, pores in MCC-P+C and MCC-PCE remain small throughout the heating process.

As depicted in *Fig. 1* the tested MCC modifications show different levels of flexural strength after curing. This can be attributed in part to the detrimental effect of high open porosity on the tensile strength. Differing curve progression with rising temperature substantiates an additional influence due to the differing strength of the hydraulic bond developing within the castable.

*Fig. 1: Modulus of Rupture (MoR) for each type of MCC after 48 h curing at 20 °C and after subsequent short-time heating to the indicated temperature, followed by freeze drying. Depending on the type of dispersant MoR develops differently with increasing temperature above 180 °C*

**Microscopy**

Depending on the used deflocculant high resolution microscopy revealed considerable differences in the shape and size of the hydrate phases formed during the curing step and their evolution at different temperature steps. After curing mainly clusters of long prismatic crystal shapes and very few tabular crystals are visible in MCC-A. MCC-P+C shows prismatic and tabular crystals and a matrix partly compacted by a gel-like phase. In MCC-PCE very small prismatic crystals are visible only at higher resolution. After the first heating step (130 °C) a complete change in the hydrate phase habitus can be observed. In MCC-A the granular matrix is now interspersed with some tabular hydrate phases. In MCC-P+C and MCC-PCE densely packed large prismatic crystal shapes are prevalent at 130 °C. Through the 180 ° and 250 °C heating steps these prismatic crystals are replaced by a network of intergrown tabular crystals.

**Conclusion**

The results show that deflocculants have significant influence on the formation and decomposition of hydrate phases during the first heating and consequently on the drying behaviour. These results only apply to the liquefiers used in combination with the specific corundum refractory concrete and are not to be standardised.

Using the method of monotonic heating different decomposition temperatures of hydrate phases have been observed. The signal in the range from 150 – 180 °C related to the decomposition of $C_2AH_x$ is shifted to higher temperature in castables with low open porosity. This is attributed to the prevailing hydrothermal conditions. The observed dehydration temperature of $C_3AH_6$ at ~320 °C is not affected by differences in porosity.

XRD analysis confirmed deviations in the mineral phase composition after curing and at five preselected temperature steps depending on the used deflocculant. Heating of the castables leads to a thermally induced rapid hydration of relict clinker phases forming predominantly katoite and gibbsite in all examined castable modifications. The liquefier has a significant effect on the pore structure of the castable, thus affects the thermal decomposition of the hydrate phases. Only in castables with low open porosity the transformation of gibbsite to boehmite is observed.

Flexural strength is typically used to indicate the resistance of castables against spalling. In CAC-bonded castables, this is determined firstly by the quality of the interparticle bonds, which are strengthened by the growth of interlocking hydrate phases, and secondly by the influence of porosity. Both aspects are strongly affected by the type of dispersing agent utilized in the preparation of deflocculated castables.

# IMPACT OF NANO ADDITIVES ON THE PERFORMANCE OF LOW CEMENT REFRACTORY CASTABLE

R. Boris*, V. Antonovič, J. Malaiškienė, R. Stonys

Laboratory of Composite Materials, Vilnius Gediminas Technical University, Lithuania

**ABSTRACT.**

The use of nano additives has attracted great interest due to the impact on the hydration of calcium aluminate cement (CAC) and possibilities to change the properties of refractories.

In this work, the properties of low cement castable (LCC) with 0; 0.3; 0.5 and 0.8% of nano-silica (NS) and combined superplasticizer (0.2%) with the CAC content of 7.0 wt% were investigated. The physical, mechanical, and thermal properties of the castables after thermal treatment (105, 800, 950, 1100 and 1200°C) were determined. The SEM results obtained show a positive effect of NS on the formation of the structure during its hardening. Modification of the binder with nano-additives results in a more densified structure, as a result, a lower total porosity and a higher amount of the smallest pores in the microstructure formation of the LCC. NS was found to increase density, cold crushing strength and thermal shock resistance of LCC; reduces shrinkage, and the optimal NS content was found to be 0.5 wt%.

**Keywords:** low cement castable, nano-silica, microstructure, properties.

## INTRODUCTION

The global production of refractories was estimated to total approximately 45-50 million tons per year. Furthermore, it is expected that the prospects of market's growth will further extend and increase the use of refractory materials [1]. It is important to create and investigate refractory castables, because of their increasing applications and the requirements for the quality of them. A substantial increase in the quality of the new generation of refractory castables can be achieved by reducing the cement content, adding nano and micro additives, and applying effective deffloculants [2]. Nanotechnology plays an important role in the development of cementitious materials [3]. Due to investigations the use of nanomaterials in refractory castables have a great interest in the following aspects: obtaining more unique properties by suppressing the conversion of hydrates [4], improving the bonding, densification, durability of materials (better thermal shock resistance), higher cold crushing strength, control of cracks, etc. depend on the formation of nano and microstructure [5,6]. Studies of nanostructures in refractory materials, in which CAC is used, have not been studied as widely as has been done in the case of Portland cement systems [7,8]. In particular, only a small amount of adding nano-silica mitigated the conversion from metastable phases to stable phases, improving early age strength, durability and decreasing compressive strength loss [4]. Therefore, adding nano particles could improve the castable properties, as long as the nano agglomeration problem is kept under control. There is still an interesting field for investigating the influence of nano additives on the behaviour of properties and microstructure of CAC-based LCC. Furthermore, these castables have valuable properties, such as high density and strength and lower shrinkage [9,10]. Recently, the use of nanosized particles has increased in many refractory-related ceramic applications with the aim of filling even the void space between the micrometre-sized particles and improving the formation of a more densified structure, which is the most important parameter in the function of high performance castable.

The aim of this work was to determine the effect of nano-silica on the structure formation, physical, mechanical and thermal properties of the low cement castable. According to our knowledge, the influence of nano-silica as an admixture has been studied to a small extent on the impact on the CAC hydration and conversion processes and the modification of the properties of castables. This work is the first step in comparative investigations of the possibilities of using these admixtures in refractory castable.

## MATERIALS AND METHODS

The following materials were used to make the samples:

Calcium aluminate cement Gorkal-70 (G70) (chemical composition, mass %: $Al_2O_3$—71.0; CaO—28.0; $SiO_2$—0.5, and $Fe_2O_3$—0.4. Blaine surface area 450 $m^2$/kg) manufactured by Górka Cement Sp. zo.o. (Poland). Microsilica (MC) RW-Fuller (chemical composition, mass %: $SiO_2$—96.06, $Al_2O_3$—0.2, $Fe_2O_3$—0.05, C—0.6, CaO—0.25, MgO—0.4, $K_2O$—1.2, $Na_2O$—0.1, and $SO_3$—0.35) manufactured by RW Silicium GmbH (Germany). Reactive alumina (RA) CTC 20 (chemical composition, mass %: $Al_2O_3$—99.7; $Na_2O$—0.12; $Fe_2O_3$—0.03; $SiO_2$—0.03; and CaO—0.02. Blaine surface area 2100 $m^2$/kg) manufactured by Almatis (Germany).

Bauxite filler (BF; chemical composition, mass %: $Al_2O_3$—81.7; $SiO_2$—10.0; $TiO_2$—4.4; $Fe_2O_3$—2.4; CaO—0.5; $P_2O_5$—0.3; $K_2O$—0.3; MgO—0.2; $ZrO_2$—0.2; $Na_2O$—0.04; and $SO_3$—0.02) of 0-1; 1-3mm was used as a filler (Stanchem, Poland).

The compositions were prepared using the two mixed superplasticizers. Nano-silica (NS) properties: purity 99.8%, particle surface area 202 $m^2$/g, size of grains: 10–30 nm (Sigma-Aldrich Chemie GmbH, Germany) [11,12].

Low cement castables according to the guide recipe given in Table 1 have been prepared by mixing all dry components in a Hobart mixer for five minutes. The NS particles were dispersed in water for 5 min at 400 W, 22 kHz (in an ultrasonic dispergator UZDN-2 T). Furthermore, the resulting suspension was cooled to a temperature 21±1∘C; and the prepared suspension was poured into the castable, after the addition of water, the mixing was continued for another five minutes.

**Table 1.** Compositions (mass %) of the castables tested.

| The mark of composition | G70 (%) | MC+RA (%) | BF (%) | NS* (%) | Superplasticizers* (%) | Water* (%) |
|---|---|---|---|---|---|---|
| LC0 | 7 | 29 | 64 | 0 | 0.2 | 6.5 |
| LCNS1 | 7 | 29 | 64 | 0.3 | 0.2 | 6.5 |
| LCNS2 | 7 | 29 | 64 | 0.5 | 0.2 | 6.5 |
| LCNS3 | 7 | 29 | 64 | 0.8 | 0.2 | 6.5 |

* — above 100%, calculated according mass of dry materials.

The samples for the physical and mechanical properties tests according to LST EN ISO 1927-(5-6):2013 were fired at 105, 1100 and 1200°C. The ultrasonic pulse velocity (UPW) of the castable was established using „Pundit 7" (Germany).

The porosity of the samples was investigated by a mercury intrusion porosimetry (MIP) Quantachrome Poremaster 33/60 (USA).

The samples for thermal shock resistance (TSR) tests were fired at 800°C and 950°C. The destruction of the material was estimated by means of changes of ultrasonic pulse velocity and compressive strength.

The microstructure analysis of the materials was performed with a SEM JEOL SEM-7600F scanning electron microscope (Japan).

## RESULTS AND DISCUSSION

The effect of nano-silica on the density, UPW and CCS of bauxite based LCC were tested. Investigations show that NS has slight effect on the density of castables after drying at 100 °C (~2650 kg/m$^3$), and after thermal treatment at different temperatures (at 1100 °C – ~2620 kg/m$^3$ and at 1200 °C – ~2600 kg/m$^3$) (Fig. 1, a). The difference in the average density values compared to the control sample exceeds 1 to 2%. However, it was found that the UPWs of the castable samples with 0.5% of NS are higher. Considerably UPW values exceeds 7 to 10% compared to the control sample (Fig. 1, b).

a)                                                                          b)
**Fig. 1.** The density (a) and ultrasonic pulse velocity (b) of castable samples after thermal treatment

The results of mechanical testing showed (Fig. 2) that a NS dosage of 0.5% had a significant effect on the CCS of the castable samples (LCNS2). The cold crushing strength strength of LCNS2 was the highest (213 MPa and 205 MPa) compared to the castable control specimen LC0 (185 MPa and 164 MPa). It was found that depending on the addition of 0.5% of NS after firing at 1100°C and 1200°C, the CCS increased by 15-25%, compared to the CCS of the control sample. It was found [13] that the total content of high activated of nanometres and micrometres SiO$_2$ can promote the sintering between the particles, reinforcing the structure of the castable and, as a result, creating an improvement in strength after thermal treatment. In practice the higher CCS leads to the higher erosion resistance of castable and prolonged life time. The tendency of decreasing in CCS up to 1200°C for tested castables may occur due to the dehydration of CAC.

**Fig. 2.** Cold crushing strength and shrinkage of the castable samples after thermal treatment

The microstructure of the CAC-based control matrix and containing nano-silica after firing at 1100 °C is shown in Figure 3. The microstructure analysis of the characteristic matrix with NS (Fig. 3 c, d) reveal the formation of a more compaction structure and microstructurally smaller pores are visible after thermal treatment. A more porous structure of the control binder was observed (Fig. 3 a, b). Different sorts of the investigations refractories with nano additives suggested that NS influences the hydration behaviour of CAC by facilitating the growth of hydration products, has structure modification properties, the microstructure is more stable and providing the nucleation site [12,13]. The samples shrinkage tests after firing at temperatures of 1100°C range from 0.15 to 0.31%.

139
**Fig. 3.** The microstructure of the a, b - LC0; c, d – LCNS2 sample after thermal treatment at 1100ºC

Measurements of the pore size distribution (Fig. 4) in characteristic castable samples (LC0 and LCNS2) were performed. The pore volume of ~0.1µm size was higher in the samples containing NS (0.5 %), which involves an increase in the pore volume by ~1.5 times. The more pronounced number of smaller pores (~0.1µm size pores) in the samples modified with NS agrees with the results of the SEM analysis (Fig. 3 c, d). The results of both analyses show that the samples with NS have more small pores than the reference sample (LC0). These microstructural results are consistent with the literature [13], which can be attributed to dehydration after firing which produces porosity with smaller pores.

**Fig. 4.** Results of the pore size distribution of LC0 and LCNS2 (0.5% of nano silica)

The thermal shock resistance of the castable samples was evaluated by cyclic firing of the samples at a temperature of 800°C (1st methodology) and subsequent cooling between two metal plates cooled by water and according to the 2nd – firing at a temperature of 950°C and cooling in water. After 7 heating and cooling cycles, the residual bending and cold crushing strengths were determined (Fig. 5, a). The drop in UPW after firing is typical for refractory castables: the discontinuity of the microstructure increases as a result of thermal cycling. The curves of ultrasonic pulse velocity in the castable samples tested during thermal cycling are shown in Figure 5 (b). The bigger decrease in the velocity of the ultrasonic pulse corresponds to a larger number of microcracks and other discontinuities developed in the material during thermal cycling and, respectively, a lower material capacity to withstand thermal shocks. The highest residual CCS values (more than 1.5 times) and the lower decrease in UPW were obtained in castable LCNS2 with 0.5% of NS admixture compared to the control sample.

a)                                                                                      b)
**Fig. 5.** Thermal shock resistance of castable samples: a - variation of CCS and bending strength after 7 heating-cooling cycles at 800°C, b - variation of ultrasonic pulse velocity after thermal cycling at 950°C

As clearly indicated by the above results, the castable with nano-silica addition exhibit higher residual strength, UPW, and as a result better thermal shock resistance. This may be attributed to the nano- and micro-particles that fill the gaps and pores in the matrix forming an optimum packing mode and can also react with $Al_2O_3$ that forms an in situ mullite ceramic bonding phase, improves the strength of the castables after thermal treatment [14]. Therefore, adding NS to refractory castable which improve better mechanical, thermal properties, and exhibited higher amount of the smallest pores, in general, could extend the service life. Some statements require experimental confirmation and such castables will be the subject of research in the future.

**CONCLUSIONS**

In the present work, the effect of nano-silica on the microstructure, physical, mechanical properties, and thermal shock resistance behaviour of low-cement refractory castable with bauxite filler was studied. The following conclusions were drawn from the results of the experimental research described in this paper:

1. It was found that nano-silica influence more compacted matrix formation, which was observed during microstructural analysis, and, in terms of material matrix continuity, can be considered as a formation of smaller uniformly distributed cavities of regular shape.
2. The tested castable exhibits a sufficient strength, with more small pores which results in a good thermal shock resistance. This study showed that even a small quantity of certain additives might significantly modify their mechanical properties through different mechanisms, such as densified structure and smaller pores formation. Because the nano-silica has the most significant influence on the mechanical behaviour, further studies will treat this type of additives in more detail.

## ABSTRACT

Changing the refractory lining concept for any high-temperature equipment is not a straightforward task. It involves many steps, including materials' selection, design adjustments, new procurement specifications, contractor application training, and so on. This work illustrates how this process took place for a circulating fluidized bed boiler in an alumina refinery, aiming to reduce the total overhaul time by decreasing the curing and drying time. This objective was attained by replacing cement-bonded castable by phosphate-based ones. Firstly, the selected materials were tested in lab conditions, to guarantee that the change would not affect the lining performance and equipment reliability. After that, pilot trials were conducted in selected boiler areas to evaluate the materials' behavior under operating conditions. Later, during the next overhaul, the new materials were applied in the whole maintenance selected regions, ensuring a reduction from the original 64h to 48h in the dry out curve. The benefits of this modification were various: higher productivity (additional 16h of steam production), lower need to use an external contractor to manage the drying step, shorter curing time (5h for the phosphate-bonded castable versus 24h for the cement containing ones), increase in the products' shelf life (from 6 to 18 months), lower amount of product's types (2 instead of 4) and financial savings. Because of this systemic approach, it is not only expected shorter overhauls but also greater intervals between two consecutive maintenance halts, pointing out the advantages of a suitable materials' selection.

## INTRODUCTION

Circulating fluidized bed boilers (CFB's) are used for steam and power generation, covering nearly all types of solid fuels, such as coal and biomass. The combustion technology delivers high efficiency and reliability, allowing almost complete combustion with lowest emissions ($CO_2$, unburned carbon in ash, $SO_2$ and $NO_2$). The coque particles are suspended in a hot, bubbling fluidity bed of ash and other particle materials (sand, limestone, etc.). The system requires jets of air, which are blown to provide the oxygen for combustion. The fuel is burnt at temperatures ranging from 750 to 1000°C. Fig. 1 presents a schematic representation of the CFB operating mode [1], in which high pressure air lifts the bed material and keeps it in suspension. For circulation, the particles of coal, ash and bed materials are carried to the upper areas and into the cyclone, where the separation of the heavier particles from the gas takes place, returning later to the furnace for recirculation. Meanwhile, the hot gases go out of the boiler.

Due to the high speed of the particles' circulation, the refractory lining is mainly subjected to erosion. In this case, the refractory wear occurs due to the impact of the particles on the material, causing its surface removal. Parameters such as the particles' size, density, hardness, and speed, as well as the castables' microstructure (sort of aggregates, binder, etc.) and toughness affect the degree of damage that is generated [2, 3]. Typical lining damage profiles observed in the boiler vessels (lower and upper furnace regions) are shown in Fig. 2.

Fig. 1: Schematic view of a CFB boiler operating conditions.

Fig. 2: Erosion wear in (a) the lower and (b) the upper furnace areas.

Besides erosion, the furnace region is submitted to temperature changes, generating thermal stresses mainly in the lower region, where the burners are located. For this sort of refractory damage, crack branching, cracked corners with a 45° degree and structural spalling are usually detected. The thermo-mechanical stresses are caused by the differential expansion or shrinkage along the refractory lining thickness, caused by thermal gradients. During cooling, the lining surface cools down faster than the inner part, leading to a tensile state. Conversely, during heating, the surface expands to a

greater extension than the inner region, resulting in a compressive state [4]. Fig. 3 illustrates the cracking profile and the lining wear caused by thermal shock in the CFB furnace area.

*Fig. 3: Refractory lining spalling due to thermal shock damage.*

Typical CFB projects involve the use of conventional refractory products, such as high alumina bricks, high alumina (chamotte, mullite, bauxite) cement-bonded castables, and lightweight insulation. Different installation methods are used (ramming, gunning, casting) depending on the area geometry, available room for application and required properties. In this concept, the dry out process is a slow and lengthy process. Therefore, if an unexpected halt takes place and the same material is used, resuming the operations takes longer. Furthermore, usual shut-down intervals are of 12 months and the period of downtime is limited (between 2 and 4 weeks). To fulfill this requirement of restarting the process as soon as possible, phosphate-bonded castables are an interesting alternative. This sort of material can ensure easy placing, fast setting and heat up, coupled with suitable erosion and thermal shock resistances [5].

Taking these aspects into account, this work focused on replacing typical castables bonded with calcium aluminate cement by phosphate-bonded materials. A holistic approach, involving initial lab evaluation, followed by pilot trials and then final implementation involves a longer but trustful procedure, to ensure that the changes would not impart a negative effect on equipment operations. In the end, positive results in terms of reducing the shut-down time and increasing the CFB boiler productivity were attained, indicating that the technical and management decisions were worthy.

**METHODOLOGY**

Four steps were conducted before the full lining replacement:

1. Materials selection and testing in lab scale: the current cement-bonded castables (CAC - vibratable - VB, self-flowing - SF and ramming - RAM) had their erosion and thermal shock resistances evaluated in the lab, following the ASTM C704-15 and C1171 standards, respectfully. The vibratable and self-flowing castables are high alumina products (72 wt% $Al_2O_3$, containing tabular alumina and mullite in their composition, 1.4 wt% CaO, density of 2.65 g/cm$^3$, Calderys). The ramming castable has higher alumina content (85 wt% $Al_2O_3$, containing calcined bauxite, and 2.3 wt% CaO, density of 2.9 g/cm$^3$, Morgan Thermal Ceramics). The phos-bond (PHOS) options (Thermbond, Alkegen) were also tested in the lab. The vibratable (VB) castable is a high alumina product (85 wt% $Al_2O_3$ and 4 wt% $P_2O_5$, density of 2.8 g/cm$^3$). The self-flowing (SF) material has less alumina (61 wt% $Al_2O_3$, 1.80 wt% CaO and 0.05 wt% $P_2O_5$, density of 2.5 g/cm$^3$) and is cast with water. Even though,

it was developed to provide fast setting and dryout as typical phos-bond composition. The ramming (RAM) phos-bond composition is also high alumina (80 wt% $Al_2O_3$ and 4 wt% $P_2O_5$, density of 2.9 g/cm$^3$). For the erosion resistance, the samples were fired at typical boiler operating temperatures (600, 800 or 1000°C for 5 hours) and evaluated at room temperature. The thermal shock tests were conducted on samples fired at 1000°C for 5 hours and submitted to thermal cycles of 15 minutes (cooling and heating) under a thermal gradient of 975°C. The ramming castables were only evaluated for the erosion resistance as they are applied in a specific region of the boiler, at the upper furnace region, where erosion is the only predominant wear mechanism.

2. Technical discussions among Engineering, Operations and Manufacturer teams: after approving the materials in the lab, some meetings took place to raise the operational issues and limitations and decide on the new dry out curve.

3. Field trial tests: the new castables were installed in pilot panels in different boiler regions (upper and lower furnace, close to the burners) to evaluate the performance under operational conditions.

4. Final assessment and decision: after evaluating the behavior in the field and other important parameters such as castables' shelf-life, cost-benefit, and potential savings.

**RESULTS AND DISCUSSION**

Fig. 4 presents the erosion results of the CAC-bonded castables and the alternative PHOS-bond options. For all the material types (vibratable - VB, self-flowing - SF and ramming - RAM), the phos-bond castables showed a relevant improvement in the erosion resistance (lower eroded volume) when increasing the firing temperature. Conversely, the CAC-containing options did not change too much this property as a function of the temperature, as the calcium aluminate phases require temperatures above 1000°C to be generated and provide ceramic bonding. At typical boiler operating temperatures (800 to 1000°C), all phos-bond options showed excellent erosion resistance and, thus, were approved for the field testing.

*Fig. 4: Erosion resistance for CAC or PHOS-bonded castables, after firing at distinct temperatures.*

Regarding the thermal shock resistance, the phos-bond castables also had a better behavior (Fig. 5). Both materials presented higher absolute elastic modulus coupled with lower percentual loss as function of the number of thermal cycles. The relative elastic modulus (% loss) indicates the degree of thermal shock damage caused by cracking formation. The higher the loss, the greater the number of defects that are generated during the thermal cycling. Due to the suitable lab results, the materials were approved for pilot tests in the boiler.

143
*Fig. 5: (a) Absolute and (b) relative elastic modulus for CAC or PHOS-bonded castables, after 8 cycles of thermal shock under a thermal gradient of 975°C.*

While waiting for the plant trial, the technical team had several discussions with the processing area and the manufacturer to figure out the best way to conduct the heat up curve, based on the lining thickness and overall amount of applied material in a typical boiler maintenance shutdown. It is well known that controlling the heat up of a CFB boiler, without using external burners provided by external contractors, is not an easy task due to its size and design. Nevertheless, as phos-bond castables can withstand higher heating rates, it was confirmed that the procedure could be managed by the processing team, using the boiler burners and the typical heat up process. The proposed dry out curve (Fig. 6) was shorter than the one typically used for the CAC-containing castables, leading to a faster return to operations (reduction of 16 hours).

The approved materials were then applied in different sections of the boiler to evaluate its performance under the operating conditions. The ramming version (PHOS RAM) was installed in a typical area where erosion is severe (kick-out section, upper furnace), during an emergency shutdown (with no dryout curve) and as a patching material as well, for partial repairing of a burner (lower furnace region). Fig. 7 shows the details of these applications. The self-flowing version (PHOS SF) was also analyzed in a plant trial (Fig. 8), in two different areas: next to the burners and close to the second air nozzles. It is worth mentioning that this SF castable can also be shaped using vibration by decreasing the water content. Considering this aspect, it was then selected instead of the vibratable version (PHOS VB) originally evaluated in the lab. This would reduce the number of materials to be purchased for the boilers overhaul, easing the acquisition and transportation logistics (no need to use phosphoric acid liquid for this case - mixed with water).

*Fig. 6: Reduction of the dry out / heat up curve time when changing CAC-bonded castables by PHOS-bond ones.*

*Fig. 7: Applications of the ramming phos-bond castable: (a) on the kick out area (high erosion wear), (b) during an emergency shutdown and (c) as patching material (partial burner repair).*

*Fig. 8: Applications of the self-flowing phos-bond castable: next to the burners (lower furnace) and close to second air nozzles.*

After four months of operations, the boiler had an emergency halt, and it was possible to evaluate the performance of the PHOS SF material (Fig. 9). The panels applied below the burner (to assess the thermal shock resistance) and near the second air nozzles (to assess the erosion resistance) presented no signs of degradation, pointing out the suitable performance during its use in the boiler. The ramming castable (PHOS RAM) was applied in different opportunities during emergency halts as it could also be used as a patching option. During these evaluations, it has also been approved for the major boiler overhaul.

Taking these results into account, it was decided to move forward with the refractory lining concept change, which resulted in various benefits:

- Decrease in the dry out curve from 64 to 48 hours;

- Reduction in the castables' curing time (5 hours for the PHOS-bond versus 24 hours for the CAC-containing);

- Increase in the products' shelf life (18-24 months for the PHOS-bond versus 6 months for the CAC-containing);

- Cost reduction with gas purchasing due to shorter boiler offline time;

- No need of an external contractor to conduct the first part of the dry out curve (100% managed by the operations);

- Decrease in the number of castables required for the overhaul (4 types for the CAC castables, there was another one used in low volume for some specific areas that was not evaluated in the lab, versus 2 types for the PHOS-bond compositions);

- The PHOS-bond castables are available in Brazil, making the logistics easier in case of emergencies. The CAC-containing castables are imported;

- The high performance observed in the lab and in the plant for the selected materials also indicates the possibility of increasing the lining working life, minimizing the need for maintenance and associated costs.

*Fig. 9: No relevant wear was identified in the refractory lining (extensive cracks or thickness reduction), after a campaign time of 4 months.*

## FINAL REMARKS

Proper refractory selection is key for maintenance and operational advances. Changing calcium aluminate cement castables by phosphate-based ones, although increasing the purchasing costs, led to outstanding achievements: faster curing and drying, faster return to operations and cost reductions. The holistic approach ensured a safe and well-designed development, enhancing the boiler reliability and productivity.

## ABSTRACT

A few decades ago, no cement castables (NCCs) were a real novelty with increasing papers published on the so-called sol/gel bonded castables for now to be stablished industrially. In the present study, among other things, the effect of the remaining pore water on the development of green strength was investigated and is put up for discussion. An important part of the work was the comparison of new $SiO_2$-free sol biding systems with the established silica sol binding system. The different binding systems are compared concerning their workability using different rheological tests like the flow cone test and regarding the hardening of these NCCs, ultrasonic velocity measurements were used.

## 1. INTRODUCTION

To overcome the drawbacks related to calcium aluminate cements, colloidal silica has been recently used as bonding agent. In addition to the faster drying and the improvement to the thermomechanical resistance, especially in acidic environment compared with materials containing calcium aluminate cements, they also present an increase in thermomechanical resistance at elevated temperatures (750°C-1500°C) due to possible formation of mullite when micro-silica is adding in the starting mixture [1-4]. However, in basic environment such as numerous steel process, the increase in micro-silica content or the presence of amorphous silica from the silica binder decreases the corrosion resistance. It is because of micro-silica or amorphous colloidal silica binder which can react with CaO or MgO contained in the slags or dust by forming low melting point or glassy phases [5]. To avoid such issues other colloidal binders for refractory castables were tested in the literature such as alumina, spinel, mullite and boehmite sols. The results of these studies have indicated similar or even higher thermomechanical and thermochemical properties for castables bonded with alternative colloidal binders [6]. In this context, this study investigates the effect of the use of different sintering additives in high alumina vibrating refractory castables on early age mullite formation and the effect of the use of different alternative high solids colloidal binders compared to those described in the literature on high temperature properties.

## 2. MATERIAL AND METHOD

### 2.1 Materials

Two different base compositions were used in this study, a fine variant (F) and a coarse variant (C) and an industrial reference (IN). The fine version was evaluated using commercial silica sol and different additives (0,1%): $TiO_2$ (FT), boehmite powder (FB) and $MgF_2$ (FM). Furthermore, the behaviour of this variant without any binding agent (FN) was analysed. To evaluate the effect of the different colloidal suspensions, the coarse variant was used.
To improve the workability time showed by the composition containing boehmite sol, it was decided to produce a composition without spinel (since Mg present may lead to a more basic value of pH producing the collapse of the nanoparticles). In this new composition (CBS2) all matrix components were substituted by tabular alumina with a particle size of 0-0,045 mm.

### 2.2 Methods

The mixing procedure was conducted with an intensive mixer (R05, Maschinenfabrik Gustav Eirich) and a stand mixer (KitchenAid 5KSM7990XESL 325 W). The fine compositions were mixed using the intensive mixer with 1-minute dry mixing at the lowest rpm possible and 3-minute wet mixing at 450 rpm. For the coarser compositions the stand mixer with lower mixing energy was used.
After mixing, the slump flow was determined using a metal conical mould for vibratable castables (according to DIN 1927-4). The mould was filled within an interval of 30 seconds, afterwards the mould was lifted and the castable was vibrated for 60 seconds. At the end the diameter of the slump was recorded. The setting process was analysed using a ultrasound measuring system. (Tester IP-8, Ultratest GmbH).
The castables were casted in bar moulds with measurements of 40x40x160 mm. The samples were left to cure in open air conditions for 24 hours and then left to dry at 110°C for 24 hours. Then they were sintered at different temperatures. The burned samples were milled and their mineralogical composition was investigated with X-ray diffraction technique.
Cold modulus of rupture tests (CMoR) were conducted after demoulding (green state), drying (110°C for 24 hours) and burning/sintering the samples at 800 °C, 1000 °C, 1100 °C, 1200 °C, 1400 °C and 1600 °C using a three-point bending measuring

146

device from Franz Wohl & Partner Prüfmaschinen GmbH. The microstructural characteristics of one of the samples presenting a higher value of CMoR were evaluated using field emission scanning electron microscopy (JEOL JSM-7200F).

To analyse the pore water effect, bar samples were stored at 25 °C with a relative humidity of 60% for five days. The test was conducted by measuring the CMoR after 5, 24, 36 and 72 hours, then weighing the samples and then again after drying at 110 °C for 24 hours to calculate the rest water.

## 3. RESULTS AND DISCUSSION

### 3.1 Effect of additives on fine composition

*Fig. 1: Two-dimensional slump flow values at 0, 15 and 30 minutes after mixing.*

The different additives showed no significant effect on the workability of the fine composition, meaning that with time no significant change in consistency was observed within the 30 minutes after mixing (see left diagram from fig. 1).

*Fig. 2: CMoR values after different sintering temperatures with a dwell time of 1 hr. Fine composition with different sintering additives (left); comparison different bonding agents (right).*

Tab. 3: CMoR values (MPa) after sintering samples at different temperatures.

| T(°C) | F | FN | FB | FT | FM | IN | C | CBS |
|-------|-----|-----|------|------|------|-----|-----|-----|
| 1100 | 7,8 | 0,3 | 6,9 | 7,7 | 7,3 | 6,4 | 6,5 | 0,8 |
| 1200 | 9,0 | 0,5 | 10,7 | 8,4 | 7,5 | 6,8 | 7,2 | 0,4 |
| 1400 | 8,1 | 2,5 | 10,0 | 9,0 | 9,1 | 6,0 | 8,3 | 1,6 |
| 1600 | 9,2 | 7,4 | 9,3 | 12,1 | 11,4 | 5,4 | 7,1 | 2,1 |

The results of the CMoR measurements are reported in Figure 2. In order to make a better comparison, a formulation without silica sol (FN) and a silica sol bonded commercial castable (IN) were

subjected to the test. With the drying and sintering temperatures 110 °C and 800°C respectively, no significant difference between the modulus of rupture values of the compositions with different additives can be noted. After burning the samples at 1000 °C, the MgF$_2$, containing castables (FM) shows a higher strength value. It has been previously found that MgF$_2$ promotes densification and grain growth in certain types of ceramics which may be the cause for this behaviour at this temperature [7]. At the sintering temperature of 1200 °C a peak corresponding to the composition with 0,1% boehmite (FB) can be observed. Similar behaviour has been already reported in the literature [8]. At the temperature of 1600 °C the highest modulus of rupture value corresponds to the composition with TiO$_2$ (FT), which can be explained by the fact that TiO$_2$ favours an abundant liquid phase during sintering, leading to a higher degree of densification of the sample [9].

*Fig. 3: XRD Diagrams of (from top to bottom) compositions FT, FB and FM after sintering at 1100 °C for 1 hr (left) and 1200 °C for 5 hrs (right).*

The investigations with X-Ray diffraction were conducted on the samples that were fired at 1200 °C with a dwell time of one hour. In the composition containing TiO$_2$, it is clearly showed that gibbsite and mullite are present in the samples. Concerning the composition with MgF$_2$, it can be observed that spinel is present in the composition. The latter can explain the higher cold modulus of rupture reported previously in this firing temperature range (Fig. 2 left diagram). Figure 3 shows the X-ray diffraction diagrams corresponding to the same compositions, but after sintering at 1200 °C with a dwell time of 5 hours. In all of three of them, a small amount (between 7 and 8%) of spinel can be found. For this reason, the composition containing titania was evaluated with FE-SEM (Fig. 4). Besides the presence of beta alumina, no evidence of spinel could be found with this technique.

*Fig. 4: FE-SEM images of a sample of the composition with TiO$_2$ after sintering at 1200 °C for 1 hr.*

### 3.2 Effect of different sol suspensions on coarse version (C)

The slump flow test was performed right after mixing, and after 15 and 30 minutes to determine the workability time of this variations of the castables. The results are shown in Fig. 1 (right diagram).

The commercial silica sol and the spinel sol with 30% solids, produce similar values due to the similar pH (10 and 9 respectively) and equal solid content. The spinel sol with 20% solids, produce no

change in the slump flow value as time increased, which may indicate longer periods of time for the samples to be ready to demould. This can be endorsed with the results from the in Figure 8. The results show that the composition with commercial silica sol develops enough placement properties after 24 hours after being casted, whereas for the samples containing spinel sol 20% solids it takes more than 48 hours to develop enough strength to be demoulded.

*Fig. 4: Setting process diagram comparing the coarse composition with commercial silica sol (30 % solids, pH 10), spinel sol (20% solids, pH 9) and boehmite sol (20% solids, pH 3).*

The ultrasound diagrams (Fig. 4) show that, compared to silica sol, both boehmite and spinel sol containing castables require a longer time (more than 24 hours) to show good setting properties. This may be due to the lower solid content of this castables. Samples corresponding to the composition CBS showed to have better demoulding properties than those of CBS2, so within the workable timeframe, further samples with the composition CBS were casted for further investigations.

The pore water investigation (Fig. 5) shows a slight increase in green strength of the samples containing 0,1% of MgO. This may indicate that MgO is promoting the setting mechanism of silica nanoparticles, as stated in the literature [10], by favouring the generation of $Mg(OH)_2$, generating a higher green strength.

*Fig. 5: Diagram of CMoR against pore water content (%w) comparing E2C composition, with and without 0,1% MgO (dead burned magnesia).*

Fig. 2 (right diagram) compares the cold modulus of rupture of the compositions with different sol suspensions against the fine version, an industrial reference and the coarse version. At temperatures below 1600 °C the compositions containing silica sol (F and C) present higher CMoR values, even than the industrial

reference. The composition containing spinel sol with 20% solids show very low values at the temperatures of 1100 and 1200 °C, similar to the composition containing pseudo-boehmite sol (20% solids). This may be due to the lower solid content of the castables.

## CONCLUSIONS

The sintering additives have no significant effect on the cold modulus of rupture of the fine version of the castable after the analysed burning temperatures below 1600 °C, only at this last temperature an important difference can be noted. Nevertheless, when comparing the variation of the castable with no binder, meaning no silica sol, show lower values of CMoR. The silica sol thus leads to a densification of the structure because of liquid phase sintering, which leads to higher cold compressive strengths. It was confirmed that for these specific formulations the pH value has a very important role on the workability of the castables, meaning that for the coarse composition a basic sol suspension with at least 30% of solid content produces a workability time of at least 30 minutes and good placement properties.

## INTRODUCTION

The high demand for carbon black on the world market is due to its unique ability to increase the strength and wear resistance of synthetic rubber. The most effective in this capacity are active grades of carbon black, for the production of which it is necessary to increase the temperature in the combustion chamber of reactors for carbon black production to 1900 ºC and above, meanwhile the higher temperature the higher percentage of quality products [1]. In the JSC "URIR named after A.S. Berezhnoy" a technology of ramming masses based on zirconia stabilized by $Y_2O_3$, CaO or combined stabilizing additives CaO and MgO on a phosphate bond, which provide the service temperature up to 2450, 2350 and 2250 ºC, respectively, has been developed and their production has been mastered [2–5]. These refractory materials are successfully used in the combustion chambers lining of industrial carbon black reactors and other high-temperature equipments with oxidizing gas environment.

In the reaction zone of reactor with operating temperature up to 1850 ºC and reducing atmosphere, the refractories containing ~ 99 % $Al_2O_3$ or alumina with addition of 5–12 % $Cr_2O_3$, which are developed and produced in JSC "URIR named after A.S. Berezhnoy", are used [6].

Considering the above, as well as the service conditions at the boundary of combustion and reaction zones of the carbon black reactors - erosion wear and corrosion from high-speed gas flows and droplets of sprayed process feedstock, a variable oxidizing to reducing gas environments, and aggressive effects of alkaline additives introduced into the process feedstock to regulate the quality of produced carbon black - it was advisable to carry out research to develop a special zirconia-alumina ramming mass for this area of the reactor lining.

## EXPERIMENTAL PART

The initial materials for research were fused stabilised zirconia containing 94.0 % $ZrO_2$ and 5.80 % CaO (hereafter stabilised zirconia), monoclinic zirconia containing 98.52 % $ZrO_2$ and alumina containing 99.65 % $Al_2O_3$ (α-$Al_2O_3$ ~ 98 %).

To study the influence of alumina additive amount on the main properties of ramming mass samples based on zirconia stabilized by calcium oxide on a phosphate bond, four compositions were made. The basic composition is zirconia ramming mass, in which the coarse aggregate is represented by stabilized zirconia with a maximum grain size of 5 mm, matrix — vibro-milled zirconia (stabilized and monoclinic). The next batch compositions differed from the basic composition by fact that they contained in matrix vibro-milled alumina in the amount of 5 %, 10 % and 15 % instead of vibro-milled zirconia. The batches were moistened with orthophosphoric acid with a density of 1.7 $g/cm^3$, taken in the amount of 4.2 % (2.6 % $P_2O_5$).

The studied samples were formed on a hydraulic press at a pressure of 100 $N/mm^2$. Determination of the main properties was carried out on samples-cylinders with diameter 36 and height 36 mm (CCS) and 50 mm. Drying of the samples was carried out at 110 ºC in a desiccator. Heat treatment of the samples was carried out at 200, 800, 1200, 1400, 1600, 1700, 2000, 2100 ºC with keeping at each of these temperatures within 2 hours.

The physical and chemical properties of the samples were determined by standard methods. Open porosity, apparent density of the heat-treated samples were determined according to DSTU ISO 5017:2014, CCS — according to DSTU ISO 10059-1:2018, thermal shock resistance (1300 ºC – water) — according to GOST 7875.0-2018. Chemical composition of the initial materials was determined by the chemical analysis method according to acting standards.

Analysis of phase composition was carried out on diffractometer DRON-2.5 in radiation Cu-Kα (with Ni-filter)[1].

## RESULTS AND DISCUSSION

The study of main properties dependence of the ramming mass samples based on stabilized zirconia on the alumina additive amount showed that with increasing of this additive content from 5 to 15 % CCS of the samples regardless of their heat treatment temperature is ~ 1.5 times higher than that of the samples without additive, while an apparent density of the samples with additive somewhat decreases and their open porosity slightly increases compared with the samples without additive. Thermal shock resistance of the samples practically does not change with the alumina introduction (amounts to 5 and 6 heat changes of 1300 ºC – water without and with alumina additive, respectively).

Taking into account of the obtained results, the samples containing 10 % of alumina additive are optimal in terms of properties after firing at 1600 ºC: open porosity — 15.9 %, CCS — 62 $N/mm^2$, linear dimensions change — 1 %. Further tests were carried out on the samples of this composition.

Due to the fact that the carbon black reactor is put into operation within 9–12 days after the refractory lining has been made, the change of main properties (Figure) and phase formation in the developed zirconia-alumina lining material depending on heat-treatment temperature in the range of 200—2100 ºC was studies.

Analysis of the data presented in the Figure shows that the studied samples properties change as the heat treatment temperature increases, as follows:

*Fig.* The main properties dependence of the ramming mass samples based on stabilized zirconia with 10 % alumina additive on the heat treatment temperature

– at 200 ºC — the samples have quite high strength (42 $N/mm^2$) and the lowest values of open porosity and relatively high apparent density (13.4 % and 4.38 $g/cm^3$);

– 200–800 ºC — the samples strength increases significantly and amounts to 67 $N/mm^2$, their open porosity increases from 13.4 % to 16.5 %, and apparent density decreases from 4.38 $g/cm^3$ to 4.32 $g/cm^3$;

– 1200–1400 ºC — CCS of the samples decreases to 35–44 $N/mm^2$, open porosity increases and apparent density decreases (accordingly 18.1–20.0 % and 4.28–4.19 $g/cm^3$);

– 1400–1700 ºC — CCS of the samples increases to 53 $N/mm^2$ and their open porosity changes and makes up 18.2 % against 18.1 and 20.0 % for the samples fired at 1200 and 1400 ºC accordingly, and their apparent density — 4.28 $g/cm^3$ against 4.28–4.19 $g/cm^3$;

– 1700–2000 ºC — hardening of the samples (CCS – 95 $N/mm^2$), as well as decreasing of open porosity and increasing of apparent density in comparison with the analogous characteristics of the

---

[1] Carried out by V.V. Varganov.

samples fired at temperature 1700 ºC, namely from 18.2 to 17.2 % and from 4.28 to 4.30 g/cm$^3$, respectively, are observed;

– 2000–2100 ºC — decrease in the samples strength (to 64 N/mm$^2$), as well as an increase in their open porosity from 17.2 to 19.5 % and a decrease in apparent density from 4.30 to 4.23 g/cm$^3$ are observed, compared to these properties of the samples fired at 2000 ºC. A slight melting of the sample surface is also observed.

At the same time, the samples strength after firing in the temperature range of 200–2000 ºC remains high enough to ensure the structural strength of a lining.

The phase composition dependence of the zirconia-alumina ramming mass samples on the heat treatment temperature in the range 200–2100 °C was also studied. This study showed the change of $ZrO_2$ phases during heat treatment in the presence of $Al_2O_3$ and $P_2O_5$ and the effect of these processes on the ramming mass properties. It was found that phase composition of samples after heat treatment at 200 and 800 °C is represented by cubic and monoclinic $ZrO_2$ (accordingly ~ 68–70 % and ~ 18—20 %), as well as glass phase and zirconium, calcium and aluminium phosphates (~ 8–10 %) formed by the interaction of $P_2O_5$ with components of the sample batch. These phosphates act as bond and harden the samples structure. The most complete interaction of $P_2O_5$ with cubic $ZrO_2$ occurs in the temperature range 1200–1400 ºC, which appears in a significant destabilization of cubic $ZrO_2$ phase (whose amount varies from 70 to ~ 35 %). At that time, monoclinic $ZrO_2$ amount increases to ~ 51–53 % and total content of glass phase, zirconium, calcium and aluminium phosphates and the resulting calcium aluminates increases to ~ 11–13 %. It is accompanied by a decrease of the samples strength (CCS varies from 62–72 to 35–44 N/mm$^2$), which remains sufficient to maintain the structural strength of a lining. The destabilization process of cubic $ZrO_2$ phase ends at 1700 ºC (content, %: cubic $ZrO_2$ ~ 28–30; monoclinic $ZrO_2$ ~ 58–60; glass phase, the above phosphates and aluminates ~ 11–13). Increasing of heat treated temperature of the samples from 1700 to 2000 ºC causes the decomposition of aluminium, calcium and zirconium phosphates and leads to the $ZrO_2$ re-stabilization with the cubic $ZrO_2$ phase formation (which amount increases to ~ 33–35 %). The above processes contribute to densification and hardening of the samples structure. Further increasing of temperature from 2000 to 2100 ºC results in the melting of sample surface due to $Al_2O_3$ melting at 2050–2070 ºC.

As a result of this research it has been established that the maximum service temperature of a lining made of the developed zirconia-alumina ramming mass should not exceed 2000 ºC. During phase formation in the temperature range of 200–2000 ºC, the ramming mass strength is high enough to ensure structural strength of the lining in service.

The developed zirconia-alumina ramming mass has been successfully applied at one of the carbon black plants for the lining making on the boundary of combustion chamber and reaction zone of industrial carbon black reactors.

## CONCLUSIONS

The influence of alumina additive amount on the main properties of ramming mass samples based on zirconia stabilized by calcium oxide on a phosphate bond has been studied. It was shown the samples containing 10 % of alumina additive are optimal in terms of properties: content, wt. %: $ZrO_2$ + $HfO_2$ — 83.52, CaO — 3.86; porosity — 15.9 %, CCS — 62 N/mm$^2$, linear dimensions change — 1 %; thermal shock resistance (1300 ºC – water) — 6 heat changes.

The phase formation processes and main properties of the zirconia-alumina ramming mass samples based on a phosphate bond heat-treated in the temperature range 200—2100 ºC have been studied. The changes of $ZrO_2$ phases during heat treatment in the presence of $Al_2O_3$ and $P_2O_5$ and the effect of these processes on the ramming mass properties were shown. It was found that the most complete interaction of $P_2O_5$ with cubic $ZrO_2$ occurs in the temperature range 1200—1400 ºC, it is appeared in a significant destabilization of cubic $ZrO_2$ phase and accompanied by a decline in the samples strength. The destabilization process of cubic $ZrO_2$ phase ends at 1700 ºC. Increasing of heat treated temperature of the samples from 1700 to 2000 ºC causes the decomposition of aluminium, calcium and zirconium phosphates and leads to the $ZrO_2$ re-stabilisation. These processes contribute to densification and hardening of the samples structure. Further increase of temperature from 2000 to 2100 ºC leads to some melting of sample surface.

It is found that during phase formation in the temperature range of 200—2000 ºC, the lining strength made of the zirconia-alumina ramming mass is high enough to ensure its structural strength in service. In view of the above, the maximum service temperature of the lining made of the developed zirconia-alumina ramming mass must not exceed 2000 ºC.

The developed ramming mass has been successfully applied at one of the carbon black plants for the lining making on the boundary of combustion chamber and reaction zone of industrial carbon black reactors.

# DEVELOPMENT OF CEMENT FREE DRY-GUNNING MIX AND ITS APPLICATION TO ACTUAL FURNACES

Shiho Takeuchi *, Shuto Azukizawa, Kazushige Watanabe, and Yasutaka Yoshimi

MINO CERAMIC CO.,LTD., Nagoya, Japan

## 1. INTRODUCTION

### 1-1. Cement free dry-gunning mix

Castables have such advantages as they can be installed relatively easily without the need for skilled techniques and also installed even in complex shapes compared to shaped refractories. The castable installation generally include pouring installation and gunning construction in terms of its method. Compared to pouring installation, gunning installation does not require formwork and has the advantage of higher installation efficiency. Gunning installation can be roughly divided into dry-gunning installation and wet-gunning installation. In the installation setup, dry-gunning installation is superior in terms of ease of workability, while wet-gunning installation is superior in terms of quality of installation body.

With regards to binders for castables, alumina cement is generally used but the calcia component in its binder reacts with foreign components such as alkali components and acid gases derived from treated materials and fuels. Furthermore, castables containing a certain amount of alumina cement are inferior in denseness and strength compared to fired bricks. Therefore, in the 1970s, low cement castables with reduced alumina cement content were developed by using the dispersion and agglomeration of fillers with particle sizes ranging from a few microns to submicrons as a method of strength development.

However, these low cement castables have the disadvantage that they are dense and lack the air permeability, making them prone to explosion when heated. Generally, it is possible to prevent explosion by slowing down the temperature rise rate and lengthening the drying time, but there will be issues with longer installation period and increased use of burner fuel. As this situation requires castables with high air permeability that can be dried in a short period of time, various cement free castables have been developed with improved air permeability in recent years.

This paper presents a cement free dry-gunning mix using silica sol as a binder. We have investigated the effects of types of silica sol and amount of clay raw material added on the air permeability, the strength, and workability of the cement free dry gunning mix and also reported the result after a service in an actual furnace.

### 1-2. Mechanism of explosion

In the drying process, dry of castables starts from the heating of the sample surface. After that, as the surface temperature rises, the inside temperature gradually rises due to heat conduction, and the water in the castables evaporates. Water vapor diffuses through pores, but vapor pressure inside the castables increases due to ventilation resistance if water vapor is hard to flow. If water vapor pressure inside the castables becomes greater than the strength of construction body, it occurs crack and explosion.

### 1-3. Improvement of explosion resistance using silica sol

The silica fine particles in the silica sol are negatively charged and dispersed, but when mixed with the powder in refractory materials, they gelatinize and aggregate under the influence of counter ions derived from the powder, resulting in bonding. On that occasion, microcracks are created, which provide an escape route for water vapor during drying of castables, thereby improving the air permeability. Additionally, cement free dry-gunning mixes using silica sol as a binder have the advantage of being less likely to explode due to the low crystalline water content.

## 2. EXAMINATION OF SILICA SOL

The properties of cement free dry-gunning mixes using silica sol are considered to be greatly influenced by the types of silica sol, such as pH, the average particle size, and the solid concentration.

### 2-1. Evaluation method

Table 1 shows the composition of the samples used in the evaluation. Samples were prepared in a bench scale test and the amount of silica sol added was adjusted to achieve the same degree of softness in each sample. Evaluated were the air permeability, the bending strength at room temperature, and the workability. The samples for air permeability measurement were casted in $\varphi 50mm \times 50mm$ mold, cured for more than 24 hours at room temperature and demolded. The air permeability was measured for the cured samples and the samples heated at 110 ºC $\times$ 24 hours. The samples for bending strength measurement were casted in 160 mm $\times$ 40 mm $\times$ 40 mm mold, cured for more than 24 hours at room temperature and demolded. The bending strength at room temperature was measured for the cured samples and the samples heated at 110 ºC $\times$ 24 hours by the 3-point bending test. In addition, dry-gunning tests were conducted using dry gunning equipment (Sika's Aliva-237), assuming a ceiling section. Figure 1 shows the appearance of the dry-gunning test. Figure 2 shows a schematic view of the dry-gunning test assuming a sidewall section. Dry powder materials are generally conveyed with pressurized air, mixed with pressurized silica sol by a separate system at the nozzle tip, and installed by spraying. The workability was evaluated in terms of moisture range, and dust generation, etc. The moisture range refers to the range of the amount of silica sol that can be mixed with the material at the nozzle tip during dry-gunning, and the wider it is, the better the workability.

Table 1 Details of samples used in the evaluation

| | | | DG1 | DG2 | DG3 |
|---|---|---|---|---|---|

Fig.2 Schematic view of dry-gunning test.

## 2-2. Results and discussion

### 2-2-1. Solid concentration of silica sol

Figure 3(a) and 3(b) show the results of the air permeability and the bending strength at room temperature respectively when the solid concentration of silica sol is varied. The results are shown as an index with the measured value after curing of DG2 being 100. As seen in the graph, the air permeability was greater at higher the solid concentrations of silica sol. This would be due to the higher amount of silica particles derived from the silica sol in the sample, which increased the amount of microcracks generated during gelation. Additionally, the bending strength at room temperature was greater at higher solid concentration of the silica sol. This can indicate that the silica particles in the silica sol act as a filler to fill the spaces between the aggregates of the castables, thereby improving the filling properties of the samples and increasing their strength.

(a) Air permeability

(b) Bending strength at room temperature
Fig.3 Results of the air permeability and the bending strength at room temperature when the solid concentration of silica sol is varied

### 2-2-2. Average particle size of silica sol

Figure 4(a) and 4(b) show the results of the air permeability and the bending strength at room temperature respectively when the average particle size of silica sol is varied. The results are shown as an index with the measured value after curing of DG2 being 100. As

seen in the graph, the air permeability was greater for the smaller the average particle size. When silica sol with the same solid concentration is used, it is considered that the smaller average particle size has a larger specific surface area, resulting in a larger volume shrinkage associated with gelation and more microcracks. In addition, the bending strength at room temperature was smaller for the smaller average particle size. As mentioned earlier, this would be due to the greater volume shrinkage caused by the smaller average particle size and the spread of microcracks.

(a) Air permeability

(b) Bending strength at room temperature
Fig.4 Results of the air permeability and the bending strength at room temperature when the average particle size of silica sol is varied.

### 2-2-3. Workability

Table 2 shows the results of the dry-gunning test with different types of silica sols. The workability in dry-gunning test demonstrated good results, but nozzle clogging occurred in DG1 using silica sol with 40 mass% solid concentration. Because silica sols with higher solid concentrations are more viscous, DG1 was considered more viscous in its mixture with the powder than DG2 and DG3.

## 3. EXAMINATION OF THE AMOUNT OF CLAY RAW MATERIAL

Since the application of clay raw materials is essential for adhesion with dry-gunning mixes, the effect of the amount of clay raw material A added on the air permeability was investigated.

## 3-1. Evaluation method

Table 3 shows the composition of the samples used in the evaluation. The total amount of fines less than 75 µm in each sample was kept constant, and the amount of silica sol added was adjusted to achieve the same degree of softness in each sample. The same procedure as in the Section 2 was used to measure the air permeability, the bending strength at room temperature, and to conduct the dry-gunning test evaluate the workability.

Table 3 Details of samples used in the evaluation

| | | | DG4 | DG5 | DG6 | DG7 |
|---|---|---|---|---|---|---|
| Raw materials | Chemical composition / mass% | $Al_2O_3$ | 72 | | | |
| | | $SiO_2$ | 23 | | | |

| Silica sol | Solid concentration / mass% | | 30 | | | |
| | Average particle size / nm | | α | | | |
| | Amount of addition / mass% | | 14.7 | 14.9 | 15.4 | 15.7 |

## 3-2. Results and discussion

### 3-2-1. Amount of clay raw material

Figure 5 shows the results of the air permeability as an index with the measured value after curing of DG4 being 100. The air permeability of DG6 and DG7 was comparable, but the air permeability tended to increase with the addition of a larger amount of clay raw material A. Additionally, a tendency for the amount of silica sol added to increase with an increase in clay raw material A was observed. Considering clay raw materials have high water retention properties, the increase in the amount of silica sol added could be due to the water retention properties of clay raw material A. The increase in the amount of silica sol added is considered to have increased the amount of silica particles that contributes to gelation and improved the air permeability. Figure 6 shows the results of the bending strength at room temperature for DG6 and DG7, which had comparable air permeability, expressed as an index with the measured value after curing of DG6 being 100. The bending strength at room temperature was higher for DG6 with a smaller amount of clay raw material A than for DG7, which could be caused by the increased water content derived from the silica sol in DG7.

Fig.5 Results of the air permeability measurement after curing at room temperature in the study of clay raw materials for varying amounts of clay raw material A added.

Fig.6 Results of the bending strength at room temperature after curing at room temperature and after drying at 110°C for varying amounts of clay raw material A added.

### 3-2-2. Workability

Table 4 shows the results of the dry-gunning tests for DG6 and DG7. DG6 had a narrow moisture range and dust generation was observed, while DG7 had a sufficient moisture range, no dust generation or nozzle clogging was observed, and the workability was good. DG7 is considered to have a sufficient moisture range due to the large amount of clay raw material A with water retention properties.

Table 4 Results of dry-gunning test with different amounts of clay raw material A added

| | DG6 | DG7 |

| Amount of clay raw material A added / mass% | 3 | 4 |
| Adhesiveness | ○ | ○ |
| Dust generation | △ | ○ |
| Nozzle clogging | ○ | ○ |
| Moisture range | △ | ○ |

## 4. CEMENT FREE DRY-GUNNING MIX PROPERTIES

Based on the above considerations, a cement free dry-gunning mix based on DG7 was developed. Since the developed dry-gunning mix is expected to have improved explosion resistance and alkali resistance, we evaluated its explosion resistance and alkali resistance. We also inspected the conditions for installation and drying, and performance in an actual furnace.

### 4-1. Explosion resistance

The test method
· Sample size 60×60×60mm with thermocouple at the center.
· Casting in cast mold.
· Curing for 24 hours.
· The sample into the electric furnace was maintained at 400 °C.
· The temperature inside the sample was measured.
· The temperature change inside the sample is shown in Fig. 7.

The evaluation method
· The surface temperature of the sample into the electric furnace maintained at 400 °C rises. After that, the internal temperature of the sample rises because heat is gradually transferred from the surface to the inside (Fig. 7, section ①)
· Heat energy is used as latent heat to change water to vapor. The internal temperature of the sample rises gradually. (Fig. 7, section②)
· The evaporation of water is completed. Heat energy is used to only heat the sample. The sample is heated up faster. (Fig. 7, section ③)
· $t$ °C is a temperature at the inflection point that moves from section ② to section ③. E MPa (Saturated water vapor pressure) is calculated by the following formula (1).

$$E(t) = 6.11 \times 10^{\frac{7.5t}{237+t}} \times 10^{-4} \qquad (1)$$

Assuming that the vapor in the sample was saturated at temperature ($t$), the maximum vapor pressure in the sample was evaluated as $E(t)$.

Table 5 shows the calculated vapor pressure inside the sample. The inside vapor pressure of the developed dry-gunning mix was 0.18 MPa, which was smaller than that of the low cement dry-gunning mix (0.73 MPa), confirming the improved explosion resistance.

153
Fig.7 Example of temperature change inside a sample due to heating.

Table 5 Results of internal vapor pressure test

| | Temperature at inflection point / ℃ | Saturation vapor pressure / MPa |
|---|---|---|
| Developed dry-gunning mix | 117 | 0.18 |
| Low cement dry-gunning mix | 165 | 0.73 |

**4-2. Alkali resistance**

Dry-gunning mixes are generally applied in incinerators. Since the main damage factor is structural spalling caused by alkali attack from foreign components, the alkali resistance of the developed dry-gunning mix was evaluated.

Figure 8 shows a schematic view of the sample used in the alkali resistance evaluation. The samples prepared in the bench scale test were heated at 1000 °C or 1100 °C and filled with sodium carbonate and potassium sulfate as reactants in the space inside the samples. Samples filled with sodium carbonate were heated at 1000 °C × 10 hours, and potassium sulfate samples were heated at 1100 °C × 10 hours. The evaluation was based on the change in appearance of the cut surface of the samples after the test. Table 6 shows the infiltrated area of the reactants in the developed dry-gunning mix, expressed as an index with the measured value of the alumina cement dry-gunning mix as 100. The amount of alkali infiltration in case of both sodium carbonate and potassium sulfate was reduced compared to the conventional alumina cement dry-gunning mixes, confirming improved alkali resistance. The developed dry-gunning mix is considered to have excellent alkali resistance because it does not contain CaO derived from alumina cement.

Fig.8 Schematic view of sample for alkali resistance test.

Table 6 Results of alkali resistance test

| | | Developed dry-gunning mix | Alumina cement dry-gunning mix |
|---|---|---|---|
| Infiltration index | Sodium carbonate | 39 | 100 |
| | Potassium sulfate | 98 | 100 |

**4-3. Actual furnace result**

Figure 9 shows the developed dry-gunning mix applied to the side walls of the secondary combustion chamber of an incinerator. There were no problems with the workability including dust generation and moisture range, and the same equipment and procedures as conventional dry-gunning mixes was used by only replacing the water with silica sol. In addition, it was possible to dry without exploding in less than half the time of conventional dry-gunning mixes. No damage was observed that would interfere with furnace operation after approximately six months of use, indicating stable service life.

(a) Before installation      (b) During installation

(c) After installation
Fig.9 Appearances of actual furnace installation.

**5. CONCLUSION**

In this study, a cement free dry-gunning mix using silica sol as a binder was developed, and its explosion resistance was confirmed to be improved from that of conventional low cement dry-gunning mixes. It was confirmed that the developed dry-gunning mix can be installed in actual furnaces using the same equipment and procedures as conventional dry-gunning mixes, and that the drying time can be reduced.

Shortening the drying time not only shortens the construction period and improves the operating efficiency of the furnace, but also reduces the amount of burner fuel used in the drying process. Since cement is not used, it is expected to contribute to the SDGs by reducing $CO_2$ emissions generated in the cement manufacturing process.

**ABSTRACT**
Numerous, sometimes contradicting factors which influence the rheological properties of refractory castables are listed as state of the art. Some authors report a predominant influence of the rheology of the matrix suspension, while others mention an exclusive correlation between the aggregate composition and the rheology of refractory castables. Again others describe that all the raw materials of a refractory castable together determine the rheology of it. As a result, improving the rheological properties of refractory castables is not as straightforward as it could be.
To gain new knowledge, the matrix suspensions, the aggregates and the overall compositions of refractory castables were modified and the resulting changes of their rheological properties were determined. This was done by measuring the shear rate dependent viscosity of these castables, using a novel lifting sphere viscometer. It was shown that the matrix composition and the aggregates are responsible for the rheology of refractory castables. The rheology of refractory castables is much more complex than assumed and depends on all the raw materials used and their properties. It is demonstrated that negative rheological effects like strong dilatancy or high viscosity can be suppressed by changing the matrix composition, the aggregates, or both. Consequently, there is a large toolbox available to improve the rheological properties of refractory castables.

**INTRODUCTION**
The rheological properties of refractory castables define their behaviour in processing like mixing, pumping, casting and levelling. These in turn are responsible for the quality of the lining or prefabricated part made from the castable. Since there are specific shear rates present at each processing, it is necessary to evaluate the rheological properties like the dynamic viscosity in dependence of the shear rate. A rheogram can be generated as a result, which allows the prediction of the behaviour in processing. If the rheological properties are unsuitable or maladjusted for the processing, the castables are not easily processable and defects in the dried castable may occur that reduce their service life.

Therefore, it is necessary to understand how specific components of the composition of refractory castables influence their rheological properties during processing. **INFLUENCING FACTORS OF THE RHEOLOGY OF CASTABLES**
How and how intense the components of castables influence their rheological properties has not been described uniformly. Some studies indicate that only the matrix components influence the rheological properties of castables, while others highlight the influence of the aggregates. Again others showed that both the matrix and the aggregate composition, respectively the whole composition, is responsible for the rheology of the castables. Some authors advise to change the composition and the fraction of the matrix to adjust the rheological properties of the castable. A finer particle size distribution was reported to lead to an optimisation of flowability and mixability [1]. A more multimodal composition of the matrix components was also reported to reduce the dynamic viscosity of a slurry made of the matrix components of a castable. This reduction directly effects the flowability of the castable, which is increasing with decreasing viscosity [2], [3]. A coarsening of the particle size distribution or an increasing amount of the fine materials was reported to result in castables with a stronger dilatancy [4] [5]. Others describe a strong influence of the rheological properties of a refractory castable from the overall composition of the aggregates of the castable. They describe that the particle size distribution of the aggregate fraction has an optimum in regard to the rheology. That implies that the rheological properties can be adjusted by changes in the aggregate fraction [6]. However, all the studies on castables were carried out with measuring methods that do not allow the description of the rheological fundamentals, like spread flow, or error prone methods like impeller rheometers.
So far, it is not fully understood how the overall composition of self-flowing refractory castables influences their rheological properties.

**MATERIALS AND METHODS**
**Materials**
*Castables for the rheological investigations*
Nine different refractory castables were used (table 1).

Tab. 1: Variation of the raw materials in the castables (in wt.-%). The variations in the raw materials in relation to the base materials V1, V2 and V3 are highlighted in italics.

| Description | medium fine matrix castables | | | coarse matrix castables | | | fine matrix castables | | |

The castables vary in the coarse fraction, in the matrix composition or in their overall composition. The three base materials V1, V2 and V3 contained the same amounts of different tabular aluminas T60 (from 6 mm to 45 µm), while the calcined (CT 9 FG and CT 800 FG, Almatis, Germany) and reactive alumina products (NO 725-10 and NO 713-10 RF, Nabaltec, Germany) were varied in terms of type and concentration/content. The castables specific surface areas were V2 >> V1> V3, so the castables based on V2 were the coarsest.

In these three base materials V1, V2 and V3 (abbreviated "VX"), the overall content of the tabular alumina aggregate fraction (all Almatis, Germany) was kept constant for the variationVX-2, but the amount of the sand fraction was increased, and of the coarse fraction (> 1 mm) was decreased. As a result, the particle size distribution was only varied in the aggregate fraction.

In the castables variations VX-3, the content of the aggregate fraction was raised, while the content of the matrix composition was decreased.

The contents of water (5 wt.-%) and superplasticizer (0,1 wt.-%) (Castament FS 60, BASF, Germany) were kept constant.

*Castables for the manipulation of the dilatancy by adaption of the aggregates*

Since only the castables based on V2 showed a pronounced dilatancy, the dilatancy was manipulated only for these castables. For that reason, the matrix was kept constant to V2, while the aggregate particle size distribution was changed. Therefore 4 wt.-% of the finer sand fraction (0-0,5 mm) was substituted by the coarser one (0,5-1 mm). In the coarse grain fraction, 4 wt.-% of the finer material (1-3 mm) were also substituted by the coarser one (3-6 mm). The contents of water (5 wt.-%) and superplasticizer (0,1 wt.-%) (Castament FS 60, BASF, Germany) were kept constant.

**Methods**
*Rheological investigations*
The rheological measurements were carried out with a novel lifting sphere viscometer. This novel viscometer is able to determine the fundamental rheological value of dynamic viscosity of refractory castables <u>in dependence of the shear rate</u> [7]. Commonly, the consistency of refractory castables is determined by spread flow. For the comparison of the rheological fundamental units with a, in the refractory research and industry well known method, the flowability was investigated by spread flow according to DIN EN 1402-4. Both measurements were done directly after the mixing process.

*Cold crushing strength - CCS*
The CCS was characterized based on the standard DIN EN 1402-6. The castables were stored in a climate cabinet at 20 °C for 24 h. The relative humidity was greater than 90 %. The CCS was determined immediately after the 24 h in the climate cabinet.

**RESULTS**
**Rheological investigations**
The rheological properties of the nine different refractory castables are presented in figure 1. On the left, the results from investigating the medium fine matrix castables V1/V1-2/V1-3 are depicted. The basic material V1 shows a relatively low dynamic viscosity at low shear rates, that decreases at first and then raises again with an increasing shear rate. The castable with the higher amount of the sand fraction (V1-2) shows, for the medium fine matrix castables, the highest dynamic viscosity at low shear rates, which is nearly 50 % higher than that of the basic material. As the shear rate increases, the dynamic viscosity drops sharply and increases again. Except for the viscosity at low shear rates, the dynamic viscosity of this castable (V1-2) is nearly similar to the standard castable V1. The dynamic viscosity of castable V1-3 (lower matrix content) at the lowest shear rate is rated between V1 and V1-2. With increasing shear rate, the dynamic viscosity is initially nearly constant, then increases linearly. The coarse matrix castables (V2/V2-2/V2-3) all show at first a drop, then an exponential increase of the dynamic viscosity with increasing shear rates (figure 1, middle). The basic material V2 shows the lowest dynamic viscosity, the castable with the higher sand content (V2-2) a higher and the castable with the lower matrix content (V2-3) the highest dynamic viscosity. All of these three castables exhibit qualitatively a very similar progression of the shear rate dependant dynamic viscosity. The exponential increase of the dynamic viscosity at high shear rates indicates a high dilatancy.

On the ride side of figure 1, the shear rate dependant dynamic viscosity of the fine matrix materials (V3/V3-2/V3-3) is shown. The progression of the dynamic viscosity of the basic castable (V3) and the castable with the higher amount of sand (V3-2) is nearly identical. The dynamic viscosity is decreasing first, then linearly increasing with increasing shear rates. The dynamic viscosity of the castable with the lower amount of matrix (V3-3) behaves almost like the two others, but the initial decrease of the dynamic viscosity is more pronounced. In this minimum, the dynamic viscosity is similar to those of the other castables (V3, V3-2), while lower or higher shear rates result in a higher dynamic viscosity compared to V3 and V3-2.

Fig. 1: Dynamic viscosity of the castables in dependence of the shear rate. Left: Medium fine matrix castables. Middle: Coarse matrix castables. Right: Fine matrix castables.

The results of the rheological studies represent the dependency of the rheological behaviour from the matrix, the aggregates and the overall composition of the castables. Looking at different castable matrix compositions shows a strong influence on the dynamic viscosity (V1 compared to V2 compared to V3). Changes in the composition of the aggregates (V1-2 compared to V2-2 compared to V3-2) lead to different influencing intensities on the dynamic viscosity, depending on the matrix components. A change in the overall composition (reduced matrix content / V1-3 compared to V2-3 compared to V3-3) generally results in the highest dynamic viscosity of all castables, except the dynamic viscosity at the lowest shear rate (0.013965 1/s) of castable V1-2. These results indicate a very complex rheology which depends on all components and can be influenced by variations in the aggregates, in the matrix or both.

Figure 2 illustrates the dynamic viscosity in dependence of the shear rate of the castables with the coarse matrix. The graph demonstrates that the dynamic viscosity at high shear rates is nearly identical for the basic material V2 and the castable with the higher sand content (V2-2), although the dynamic viscosity of castable V2-2 is higher at medium shear rates. The dynamic viscosity of the castable with the lower matrix content (V2-3) rises significantly stronger with increasing shear rate and takes on values more than twice as high at the highest shear rate. This means a significantly higher degree of dilatancy. Since the shear rate while pumping a refractory castable during installation is high, all of these castables should display a low or impossible pumpability. This means that such castables cannot be processed on customer construction sites.

*Fig. 2: Dynamic viscosity of the castables in dependence of the shear rate of the coarse matrix castables V2/V2-2/V2-3.*

Figure 3 illustrates the dependency of the spread flow of the castables in dependency of the dynamic viscosity at the lowest measured shear rate (0.013965 1/s). Since the viscosity at low shear rates is connected to the yield stress, the spread flow is directly connected to the dynamic viscosity at 0.013965 1/s. With increasing dynamic viscosity, the spread flow decreases linearly. The coefficient of determination of a potential linear regression is sufficient but not extraordinary. One reason is the high error of the determination of the spread flow (approximately ± 10 mm). Additionally, the connection between those two values will only exist if a castable reaches his final spread within two minutes. If the castable did not reach its final spread, the measured data would be faulty.

*Fig. 3: Spread flow in dependence of the shear rate dependant dynamic viscosity of the castables.*

**Manipulation of the dilatancy by adaption of the aggregates**

Figure 4 shows the shear rate dependant dynamic viscosity of two castables with a coarse matrix. While V2 exhibits an extraordinary dilatancy, the dilatancy of V2 mod is mostly supressed. The difference between those two castables is only the particle size distribution in the aggregate fraction. V2 mod had a coarsened sand and coarse grain fraction. This means that the dilatancy of refractory castables can also be manipulated by changing the aggregate fraction of the castable, while keeping the matrix composition constant. This in turn opens the possibility to manipulate the rheological behaviour by changing only the matrix composition, only the aggregate composition or the overall composition. The dynamic viscosity in low shear rate areas is nearly identical for both castables, which should lead to similar material properties like strength and porosity caused by similar flowability and compactability.

157

*Fig. 4: Shear rate dependant dynamic viscosity of the coarse matrix castables with focus on the dilatancy.*

The CCS of the two castables was determined to prove whether the change in the composition of the sand and coarse grain fraction influences the CCS of the castable (figure 5). The variation of the composition in the sand fraction and the coarse grain fraction has no influence on the CCS after 24 hours curing in the climate cabinet at a temperature of 20 °C and a relative humidity greater than 90 %.

*Fig. 5: CCS of the basic coarse matrix castable V2 (left) and the castable "V2 mod" with coarsened sand and coarse grain fraction (right).*

The evaluation of the CCS of these two castables demonstrate that the dilatancy of the castables can be changed without influencing material properties like green strength. This in turn allows to make a castable pumpable without negatively affecting the important green properties.

## CONCLUSIONS

Nine refractory castables with varying composition of the matrix, the aggregate fraction or both were rheologically investigated using a novel lifting sphere viscometer and by measuring the spread flow. It has been shown that:

1.  The matrix composition has a major influence on the shear rate dependant viscosity of the refractory castables.
2.  The aggregate composition also has a significant influence on the shear rate dependant viscosity of the refractory castables.
3.  The intensity of these influences of the rheological properties by the aggregate composition depends on the matrix composition and vice versa.

As a result, the shear rate dependant dynamic viscosity of the castables depends on the overall composition of the castable and each component influences the rheological properties in its own way. This means that there are several opportunities to adjust the rheological properties of refractory castables as required.

Since the influence of variations in the composition of the castables cannot be predicted, one must evaluate it with a suitable method like the novel lifting sphere rheometer. Otherwise, it is not possible to describe the rheological properties and predict the behaviour of the castable in processes like flowing, levelling, pumping and mixing.

The castables with the coarse matrix showed a strong dilatancy, thus the dynamic viscosity exponentially increased with an increasing shear rate. These castables are not pumpable and the mixing process may result in a higher wear of the mixing tool. It was demonstrated that a change in the matrix components from coarse to a medium fine or a fine matrix results in a castable without dilatancy. In many cases the matrix is adjusted to the final use of the refractory castables at high temperatures. Therefore it should be investigated, whether the dilatancy can be supressed by changing the aggregate components.

A coarsening of the sand fraction and the coarse grains leads to a massive reduction of the dilatancy. Despite the change in the composition of the aggregate fraction, the green strength of the castable was unchanged. Such changes create a refractory castable with much improved rheological properties in point of dilatancy, without exerting a negative effect on the green properties like CCS.

All in all, every component in the refractory castables defines its shear rate dependant dynamic viscosity. It is possible to change the rheological behaviour of refractory castables by varying the matrix composition, the aggregate composition or both. Therefore, many possibilities are present with which the rheological properties can be adjusted to the requirements while processing.

# DEVELOPMENT OF A PRINTABLE ALUMINA−BASED COMPOSITION OF REFRACTORY CASTABLE FOR 3D PRINTING PRESHAPED PARTS

Sandra Abdelouhab

BCRC-INISMa, Belgian Ceramic Research Center, Mons, Belgium

## ABSTRACT

Thanks to its high versatility, additive manufacturing is used in many fields such as powder metallurgy, polymers, ceramics and recently in the field of civil engineering.

In the field of refractories, this shaping approach, based mainly on material extrusion, has not yet been adopted whereas it has a significant potential. Indeed, it offers the possibility of producing parts with complex geometries which are difficult to achieve by conventional techniques while avoiding the use of formworks/moulds whose costs from a few hundred to several thousand euros. In addition, a reduction in production costs, environmental and societal impacts can be considered via the reduction of labour and waste, controlled consumption of raw materials via the topological optimisation of parts as well as the reduction of risks on site.

To allow the emergence of this approach in this field, key scientific barriers have to be overcome, especially in the formulation, implementation, and characterization of these materials. This is the purpose of this current study by developing a printable formulation of an alumina based refractory castable. This tailored formulation must have pumpability, extrudability and buildability properties, mandatory for the printability characteristics of such materials. The parts produced by material extrusion will be characterised in terms of thermomechanical performance after printing and firing at high temperature and compared to similar parts obtained by conventional techniques.

## INTRODUCTION

Since the invention of the first 3D printer in 1983, the development of this additive manufacturing technology has been very fast and is currently widely used in several fields, including biomedical applications, jewellery, automotive or aerospace [1].

More recently, the material extrusion technology has been implemented in the building sector as now it is possible to print an entire building with this technique. In the field of refractory materials, this 3D printing technique has not yet been widespread. However, with making a parallel with civil engineering concretes, the use of this technology applied to refractory precast products suggests the same benefits as those in the field of building sector, namely [2]:

- Economic, with a lower time and cost production: usually castable shaping is done with formworks. For refractory pre-shaped parts, formworks can cost from a few hundred to several thousand euros when they are not standardised;
- Environmental, with the reduction of raw material consumption: the 3D-printing process allows a better control of the required material amount for the part construction. This contributes to the waste reduction in addition with the formwork-free construction and less dust generation compared to traditional methods;
- Social, by the reduction of arduous human labour and risk on site through the process automation.

Moreover, this 3D printing technology allows the generation of complex shape designs at a better cost than current casting methods. To print a pre-shaped part, a digital model is firstly created either with a CAD like modelling software or by a 3D scanning of the object. Next, this digital model is sliced by a dedicated software. Finally, a digitally controlled device builds the object slice-by-slice. For the 3D concrete printing (3DCP), the most common used technique is the layered material extrusion [3] even though selective powder binding method have also been reported [4].

For the extrusion method, typically a well-designed cementitious mixture is pumped through a nozzle mounted either on cartesian system or a robotic arm. Based on the 3D digital model, the printing head moves in order to extrude various filament shapes depending on nozzle shape with a printing speed of 50-500 mm/s. To produce refractory pre-shaped parts with the use of 3D extrusion printer, the refractory mix has to meet specific rheological requirements. Indeed, as for printable civil engineering formulations, printability characteristics are prerequisites:

- Pumpability, which is the ability of the cementitious ink at "fresh" state to be conveyed from the wet material tank to the extrusion nozzle via a pipe under the pump action;
- Extrudability, which means the ability of the cementitious ink to be extruded easily under the form of a continuous filament without clogging or segregation during this phase;
- And finally, buildability, which represents the ability of the printed cementitious ink to support the weight of the upper layers without excessive creep of the lower layers or printed element.

When the formulation combines these 3 properties, the cementitious ink is considered printable. However, these rheological characteristics remain antagonistic. While stiffness and cohesiveness are requested for buildability to support the weight of subsequent layers and limit the deformation of the printed layers, a high flowability is requested for pumpability and extrudability [5]. This highlights the whole issue of the composition and formulation of such printable materials, for which an optimum has to be found between flowability and stiffness/cohesion in order to simultaneously satisfy the properties of pumpability, extrudability and buildability.

In this context, the goal of this study was to develop a refractory cementitious ink formulation gathering the printable characteristics. To reach out this goal, this formulation development has been considered through mainly:

- the characterisation of 3D commercial cementitious inks printable with a large-scale 3D printing device without stiffness additives at the printing nozzle;
- a literature review on refractory gunning mixes.

## MATERIALS AND METHODS

### Materials

*Commercial cementitious inks:* For the development of refractory cementitious ink, two commercial civil engineering cementitious inks have been characterised: 704 CLAVEX + HP mortar (704 CL+HP) and SIKACRETE – 751 3D (751 SI-3D). These commercial inks are printable with a cartesian large-scale 3D printing system (Mini Printer Pro supplied by CONSTRUCTION 3D society). The buildability of 704 CL+HP material is limited as it can quickly present an excessive part deformation or a structural collapse. The second one, 751 SI-3D presents a higher buildability. The table 1 reports the main characteristics of both commercial cementitious inks indicated in the product data sheet.

Tab. 1: Main characteristics of commercial cementitious inks.

| Sample reference | 704 CL+HP | 751 SI-3D |
|---|---|---|
| Maximum grain size | 0 - 2 mm | 0 - 1 mm |
| Density (g/cm³) | 2.2 | 2.14 |
| Water content for a plastic consistency | 11% | 18% |
| Setting times at 20 °C | 6 h – 7 h | 45 min – 60 min |
| Practical use life after extrusion (start of the fresh material stiffness) | 60 min | 15 min |
| CCS (MPa) at 28 days | 60 | 50 |
| MOR (MPa) at 28 days | 12 | 10 |

159

*Material selection for the refractory cementitious ink (3D-RCI):* The following raw materials have been used for the formulation of the refractory cementitious ink: tabular alumina (3 – 1 mm, 1 – 0.5 mm, 0.5 – 0 mm, 0.6 – 0.2 mm, 0.2 – 0 mm - ≤ 0.045 mm; Almatis), reactive alumina (RG4000, Almatis) and calcium aluminate cement (Secar 71, Imerys).

As the 3D printing equipment considered to further print the 3D-RCI material, does not allow the addition of a stiffness agent directly after the extrusion at the printing nozzle, the dry refractory mix has to contain a stiffness agent to ensure an early age stiffness development. It will ensure the refractory ink buildability. However, the stiffness development has to be slow enough to avoid pipeline clogging and short enough to avoid a structural deformation or collapsing. The stiffness agent used in this study was a BASF additive.

A water reducing agent was also used to optimise the start of the stiffness development and the water content in the starting mixture. Indeed, due to its plasticizer effect, it allows to decrease the water content required for a good flowability and in the meantime, it influences the early age of the stiffening development as it has retarding properties. A BASF plasticizer was used in this study as a water reducing agent.

*Experimental procedure for the fresh material preparation:* The commercial cementitious inks were prepared according to the recommendations of the technical data sheets.

For the developed refractory cementitious ink, a dry mixing of the raw material was performed for 2 minutes then the required water content was added to mixture and the mixing was carried out for a further 3 minutes. An Eirich mixer, R02/E type, with a star rotor was used with a rpm range between 450 for the dry mixing and 750 for the wet mixing.

## Characterisation methods

*Bulk Density (BD) and Apparent Porosity (AP):* The bulk density and the apparent porosity of the castable samples were measured according to Archimedes' principle in relation with the standard EN ISO 1927-6.

*Flow-cone test:* The pumpable consistency was characterised by means of a flow-cone test. The fresh wet mix was placed in a cone shape mould with standard dimensions (Hagerman cone). After the flow of the material under its own weight, the largest diameter (D1) and the diameter perpendicular to it (D2) were measured. The flow value (F) is given by the following relationship:

$$F\ (\%) = \frac{\left(\frac{D_1 + D_2}{2}\right) - D_{inf}}{D_{inf}} \times 100 \qquad \text{Equation 1}$$

Where $D_{inf}$ is the lower diameter of the cone, which is 100 mm. The upper diameter is 70 mm and height 60 mm.

*Gun test:* As there are no actual standards for extrudability testing, a manual gun device with a 20 mm circular nozzle diameter was used to assess the extrudability of cementitious inks at laboratory scale. The material was defined as extrudable when it squeezed out of the printing nozzle in a continuous manner while maintaining the required dimensional accuracy and layer quality without causing any clogging or segregation. The manual gun used in this study is shown on figure 1.

*Fig. 1: Picture of the device used for manual gun tests*

*Ultrasonic wave transmission measurements:* The material buildability can be assessed through the characterisation of the setting properties determined by ultrasonic wave velocity evolution. Indeed, the increase of the ultrasonic velocity indicates the increase of the stiffness or the mechanical resistance of the material [6]. In this study, the setting properties of all cementitious inks were characterised by using ultrasonic wave transmission measurements performed with a FreshCon system developed at the University of Stuttgart [7]. The FreshCon system consists in a specific mould (for castable or mortar) equipped with two piezoelectric transducers (one transmitter and one receiver). A computer equipped with a data acquisition card is linked to a piezoelectric high voltage pulser to generate a high voltage short rectangular wave (typically 800 V with a pulse width between 2.5 and 5 μs). A wide band ultrasonic (mechanical) wave is generated and picked up by the receiver of which the signal is amplified after traveling through the material. The software automatically computes the travelling time from the transmitter to the receiver and deduces the velocity of the wave. More detailed information on this device can be found in [7].

*Mechanical test:* Format D samples, according the standard EN ISO 1927-6, have been casted with the 3D-RCI composition, cured during 48 h and dried 24 h at 110°C. Cold modulus of rupture (CMOR) and cold crushing strength (CCS) tests have then been performed with samples thus prepared. For each mechanical trial, three samples have been tested.

## RESULTS

### Formulation of the 3D printing refractory mix

For the formulation development of a refractory cementitious ink, the first targeted, among the three characteristics needed to obtain a printable mix, has been the pumpability. For that, a literature review on shotcreting refractory castables has been carried out, focusing especially on the relationship between the castable ability to be pumped and their particle size distribution. This review revealed that to enhance the pumping ability of the shotcreting castable, the ratio between the coarse grains and fine particles has to be optimised. If the mix presents an excess of aggregates, collisions between particles and friction forces will be enhanced, resulting in an increase of the pumping pressure. The mix will also have low cohesion or a greater tendency to segregate during the transport in the pipeline. At the contrary, if the mix presents an excess of fine particles, the mixture will become less fluid during pumping, which will lead to the clogging of the pumping pipe [8].

To determine the optimum ratio between fine and coarse grains to obtain good pumping properties, authors [9] first formulated three compositions of refractory castables according to the Andreasen's model [10] with q coefficients 0.21, 0.26 and 0.31. The rheological behaviour of these three refractory castables was characterised by measuring the torque as a function of the rotation speed of their mixing tool. Tests have been carried out with and without volume restriction, the latter simulating the flow in a pipe during pumping. The results indicated that the rheological behaviour of castable compositions with q values 0.21 and 0.31 was dilatant for tests without volume restriction then became Newtonian for tests with volume restriction. For the composition, with a q value 0.26, exhibited a pseudo-plastic or a rheo-fluidifying rheological behaviour for tests with or without volume restriction [9].

This pseudo-plastic of rheo-fluidifying behaviour is required when a fluid is subjected to an increase in a shear stress, as it is the case during pumping. Indeed, the resistance of the fluid flow tends to stabilise or even decrease with increasing stress for a rheo-fluidifying rheological behaviour. The pseudo-plastic behaviour for castable compositions with q value 0.26 has been confirmed by authors for the use of different maximum grain size [11].

Based on the literature results, a 3D printing refractory mix was designed according to the Andreasen's model with a q value 0.26. The table 2 reports the cementitious ink composition with the different proportions of each component in weight percentage.

Tab. 2: Refractory ink composition (wt %)

| Tabular alumina | T 60 (1-3) mm | 25 |
|---|---|---|
| | T 60 (0.5-1) mm | 5 |
| | T 60 (0.2-0.6) mm | 10 |
| | T 60 (0-0.5) mm | 15 |
| | T 60 (0-0.2) mm | 15 |
| | T 60 (0-0.045) mm | 13 |
| Reactive Alumina | RG4000 | 10 |
| CAC | SECAR 71 | 5 |

This 3D refractory printing mix designed corresponds to a LCC castable according to the CaO content in the composition. (1.5 wt%). A BASF stiffness agent (0.1 wt%) has been added to the dry mixture.

**Flow-cone test results**
After the cementitious ink design, the water content has been determined thanks to the flow-cone test to obtain a pumpable formulation: obtention of a plastic consistency. Firstly, the flow-cone tests have been performed on commercial cementitious inks to establish a flow value range for a plastic consistency. Table 3 reports pictures of commercial materials obtained after adding the mixing water content recommended by the supplier for a plastic consistency and their flow under their own weight after the cone removal. The test results indicate a flow value of 35% and 45% respectively for 751 SI-3D and 704 CL+HP. To obtain approximately the same flow value for the 3D refractory cementitious ink (3D-RCI), a water content close to 8% was needed. This water content led to a flow value of 40% for the 3D-RCI material. A picture after the flow-cone test is also reported on table 3 for the 3D-RCI ink.

Tab. 3: Flow-cone test results

| Sample | Water content (%) | F (%) | Picture |
|---|---|---|---|
| 704 CL+HP | 10 | 45 | |
| 751 SI-3D | 18 | 35 | |
| 3D-RCI | 8 | 40 | |

**Results of ultrasonic wave transmission measurements**
To go further on the development of the refractory cementitious ink formulation, characterisation of the setting properties has been performed to determine the elapsed time between the mixing water addition in the dry mix and the time when the system began to stiffen. The knowledge of this elapsed time is extremely important for the 3D printer as there is no addition possibility of a stiffness accelerator at the printing nozzle. If this elapsed time is too short, there is a risk that the material will stiffen in the pipe during transport, causing the clogging pipe. If the time interval is too long, the material may not be suitable for buildability, with the lower layers collapsing under upper layers.
To suitable adjust the stiffness development of the 3D-RCI material, firstly those of commercial materials, has been determined by using ultrasonic wave transmission measurements and then compared to the developed ink.
The Figure 2 reports the ultrasonic wave velocity evolution through the materials 704 CL+HP, 751 SI-3D and 3D-RCI. During experiment, the temperature profile of each material was also recorded as it allows the setting time detection.

Fig. 2: Ultrasonic wave velocity and temperature over time

For both commercial materials, the ultrasonic wave signal is detected about 20 or 25 minutes after the water addition in the dry mixture whereas it is about 10 minutes for 3D-RCI material. It corresponds to the beginning of a first increase of the ultrasonic wave velocity. Then a second increase of the wave velocity can be defined corresponding to the material setting. The beginning of this second increase is related to the start of the temperature rise inside the material, and the end of the increase of the wave velocity to the exothermic peak. The first increase of the wave velocity is then defined as the material stiffness. For both commercial inks, the setting material occurs just after the stiffness whereas it is not the case for the developed ink. Its setting occurs few hours later.
Comparing both commercial inks, their velocity curves indicate a higher acceleration of the wave velocity at early age for 751 SI-3D than for 704 CL+HP. As the wave velocity value can be related to the mechanical resistance of the materials [6], at early age it signifies, 751 SI-3D material has a higher mechanical resistance than 704 CL+HP explaining its higher buildability. The 3D-RCI material exhibits the same behaviour at early age as those of 751 SI-3D. However, as the wave velocity signal of 3D-RCI ink appears about 10 minutes after the water addition, this result highlights the fact that its stiffness appears too fast and could induce a clogging of the pipe before its extrusion.
To delay the beginning of 3D-RCI ink stiffness, the content of the stiffness agent has been firstly decreased. It induced only an early age of the setting period but not a delay of the stiffness one. Therefore, a water reducing agent has been added to the dry mixture also acting as stiffness retardant. An optimum ratio between the water reducing agent and the stiffness agent had to be found to obtain an appropriate setting curve corresponding to a ratio of 0.75. Moreover, as the water reducing agent is a plasticizer, its addition in the mixture has decreased the mixing water content down to 7% without a degradation of the flow properties at early age. The flow value of the optimised composition was the same as those of the first formulation: 40%. The ultrasonic wave velocity and temperature over time of the optimised formulation are presented on figure 3.

Fig. 3: Ultrasonic wave velocity and temperature over time for 3D-RCI, 3D-RCI optimised, 704 CL+HP and 751 SI-3D

The setting behaviour of the optimised 3D-RCI optimised ink is close to 751 SI-3D ink. Indeed, the stiffness starts approximately at the same time, about 20 minutes after the mixing water addition.

Moreover, the evolution of the wave velocity during the stiffness phase is the same for both materials signifying the same buildability if the consistency is mastered during the 3D printing at large scale.

**Gun tests**

The gun test has been used to assess the material extrudability at lab scale. In the meantime, the buildability has been also evaluated by manually printing 4 or 5 stacked layers. Both commercial inks have been tested with also the optimised 3D-RCI material. Pictures of the manually printed parts are shown on table 4.

Tab. 4: Pictures of the manually printing parts

| Sample reference | Picture during printing | Picture of the parts after printing |
|---|---|---|
| 704 CL+HP |  |  |
| 751 SI-3D |  |  |
| 3D-RCI |  |  |

These manual tests have indicated that the developed refractory ink is extrudable and buildable at lab scale: it was possible to squeeze out of the gun nozzle filaments and to stack several layers without a flow of the lower layers.

**Physical and mechanical characterisation of the developed ink**

As the printable refractory composition thus developed seems to be promising for a large-scale printing test, firstly, 4/4/16 samples were produced according to refractory standards to determine the apparent porosity (AP), the bulk density (BD) and the MOR and CCS of 3D-RCI material after a drying at 110°C. The average results of each test are reported on table 5.

Tab. 5: Physical and mechanical characteristics of 3D-RCI materials

| Sample reference | BD (g/cm³) | AP (%) | MOR (MPa) | CCS (MPa) |
|---|---|---|---|---|
| 3D-RCI | 2.88 | 19.7 | 8.10 | 34.57 |
| 3D-RCI optimised | 2.94 | 17.9 | 10.36 | 40.7 |
| 6S71B [12] | / | 8 | 24 | / |

The AP and BD results of 3D-RCI materials show an improvement of the density, porosity, and green mechanical properties for the optimised formulation. It is probably due to the use of the water reducing agent allowing a decrease of the water addition from 8% down 7% without a deterioration of flow properties at early age. The MOR average value is lower and the average AP value higher than those found in the literature for a high alumina LCC castable composed from Andreasen's model with a q value of 0.26 [12], maybe due to no vibration applied on 3D-RCI samples.

**CONCLUSIONS**

In this study, a 3D printable refractory cementitious ink has been formulated. To reach out a such goal, the strategy adopted was firstly to design a pumpable mix according to the literature review on shotcreting castables. Then, the contents of the mixing water, the stiffness additive and water reducing agent have been optimised to obtain suitable extrudability and buildability properties according to the 3D concrete equipment which will be further used to print the refractory ink. These last optimisations have been achieved through manual gun tests and ultrasonic wave velocity measurements. The developed mix corresponds to a classical LCC castable according to the CAC content.

Although such a 3D printable mix has been developed and its printability has been demonstrated at lab scale, large-scale printing tests need to be carried out. In addition, a great deal of works remains to be done. One of them concerns a deeper rheological characterisation of the printing castable with also the mechanical characterisation at the green state and at high temperature of samples collected from printed parts. The influence of the printing parameters also needs to be studied: nozzle speed, pump flow, slice thickness, …

Upcoming future investigations will be undertaken along these guidelines. An upgrade of the composition by using larger coarse grains (up to 6 mm) or the adding of viscosity modifying agent (VMA) to improve the thixotropic behaviour, may also be of a great interest.

# ADAPTATION OF THE CONTOUR–CRAFTING PROCESS TO REFRACTORIES AND INVESTIGATION OF MATERIAL PROPERTIES AFTER THE 3D PRINTING PROCESS

Florian Holleyn*, Lee Klein, Sinje Zimmer, Olaf Krause

Hochschule Koblenz, Höhr-Grenzhausen, Germany

## ABSTRACT

Traditional casting of refractory materials requires the use of complex and costly moulds. Years ago, the construction industry took first steps to develop Additive Manufacturing (AM) of building concrete, also known as 3D printing. It became clear very quickly that AM offers new degrees of freedom in geometric complexity and abilities of adjustment. So far, however, 3D printing processes are not yet state of the art regarding refractory monolithics.

It was necessary to develop a suitable printing technology as it is not yet available. A further challenge was to develop printable refractory castables, whereby pumpability and the volume stability after printing (stiffening, setting, hardening) are key issues. A major challenge in the future is to provide a system that is easy to use and wins over with regard to its cost-efficient and rapid processing.

We report on our state of the art as we have achieved it within the framework of the foundation of the competence centre, 3D-Keramik in Höhr-Grenzhausen.

The paper shows first steps towards implementation of AM in the refractory industry. Test pieces of printable castables that were successfully developed could be manufactured with a 3D printing device, that was also developed in the project.

Material properties like strength and open porosity are examined. It also will be worked out how the internal structure in contour crafted specimen influence the isotropic technological properties.

In further, it will be figured out that the homogeneity of pre-shaped monolithics could be optimized by optimizing the printing paths.

## INTRODUCTION

Years ago, the construction industry in civil engineering undertook first efforts to develop construction concretes that enables Additive Manufacturing (AM) of large three-dimensional shapes. Components now can even be designed using hollow structures to save raw materials in comparison to traditional monolithic fabrication. Additionally, those hollow structures can be used, for example, to install water tubes, cooling channels or electrical wires [1]. It was successfully proved that AM offers new degrees of freedom in geometric complexity and abilities of adjustment compared to traditional methods. When using Contour-Crafting (CC) time and money can be saved, because AM virtually works without time consuming and therefore expensive formworks. It appears straight forward that AM should be also applied in the refractory industry. Especially in the field of large, prefabricated members like electric arc furnace lids or tundishes AM has a high potential to overcome complex mould production and allows very easily customized design adoption.

At the first glance, AM in civil engineering already has been proved as a feasible technique that allows printing of entire buildings [2, 3], however, meets its limits, because till now solely mortar like concretes with no coarse grains are processed. Thus, from this state of art it can be concluded that concretes can be toughen for AM, but the progress that was made for civil engineering concrete could not be transferred to refractory castables. This is due to the fact, that the nature of refractory castables is entirely different in terms of water addition (approx. 5 wt.-% instead of 20 to 25 wt.-%), a much higher density of the raw material with approximately 3,6 g/cm³ and a much lower content of cement (only 5 % wt.-% in case of LCC). Therefore, for AM of refractory castables material development needs an entirely re-thinking where the shotcreting process can be seen as a good starting point in this development. To enable the refractory industry to build large, prefabricated members, the authors applied successfully for the Establishment of a competence centre for additive manufacturing of inorganic-non-metallic materials that is founded by the Rhineland-Palatinate Ministry of Economic Affairs (MWVLW) and the European Fund for Regional Development (EFRE).

Due to the described characteristics of refractory concrete, the 3D printers used in the construction industry cannot be used. As a result, the structure of a large-scale CC setup had to be rethought.

For the material properties clear targets are defined. The castables must be pumpable. A dimensional stability after extrusion for a distinct and rigid layer formation is inevitable when several layers of refractory concrete must be printed to produce complex component geometries. Hence the castables rheology must be adjusted precisely using different process additives and combinations thereof. In particular, dispersing agents and gelling agents are used, because they allow to gain plastic properties. A long working time is inevitable. This makes on the other hand setting agents as accelerators necessary that are added immediately at the tip of the printing head to achieve a sufficient volume stability of the printing strands.

From technological side, different parameters must be considered when building a large-scale 3D-printer setup and which special features play an important role in the actual printing process. To produce true to size members all variations of the printing process, especially the printing path must be coordinated.

This paper follows on from our work that we presented and published at a previous conference [4,5] and is a scale-up of the results presented at that time. It reports on our state of the art as we have achieved it within the framework of the foundation of the competence centre, 3D-Keramik in Höhr-Grenzhausen. First steps are shown towards implementation of AM in the refractory industry. Test pieces of printable castables that were successfully developed could be manufactured with a large-scale 3D printing device, that was also developed in the project.

Material properties like strength and open porosity are examined. It is also worked out how the internal structure in contour crafted specimen influence the isotropic technological properties.

In further, it is figured out that the homogeneity of pre-shaped monolithics could be optimized by optimizing the printing paths.

### Printable castables with clear focus on targets of material properties

Exact material property targets for printable refractory castables were defined within this project and still published [5]. A key issue for the execution of CC is the pumpability of the castable. The layer wise printing of refractory castables needs a perfect adjustment of the particle size distribution and the right combination of additives. The interplay of all components enables pumpability, a low tendency for particle segregation, also under pressure, dimensional accuracy after printing, a sufficient working time and green strength. In further, accelerators can be used as setting agents and could be added immediately after the extrudate leaves the printing nozzle.

### Large-scale 3D printer

The development and evaluation of the large-scale printer used for this investigation (Fig. 1) was part of the project [4]. In order to produce the components in a sufficient size using the CC process, a robotic arm from ABB Robotics was installed as a manipulator to move the print head in an area of approx. 2.5 x 2.5 x 2 m (l x w x h). Due to the high specific density of the raw materials,

"dry-mix" systems as already established on the market and optimized for the CC of concrete do not work properly and therefore cannot be used. The printer set-up was configured based on solitary components where the mixing and pumping devices are already in use for refractory castables. An 80 l EIRICH mixer (Maschinenfabrik Gustav Eirich GmbH) was used as mixing device, as this type of mixer allows degrees of freedom in terms of a distinct adjustment of mixing power that is inevitable to adjust the rheological properties of the printable castables. In addition, this device allows reproducible results and is already used for a long time in smaller dimensions within the working group. After the mixing process, a pump unit (Mader GmbH) transports the material to the print head, which could be moved in a three-dimensional space in the dimensions mentioned above. The pump unit was chosen because it belongs already to the state of art for the processing of shotcrete material. Both the hose and the nozzle were chosen to be as small as possible (hose inner diameter 35 mm, nozzle opening 15 mm). This dimensional set-up allows the printing of refractory castables with a maximum grain size of 3 mm.

However, printing jobs can be carried out in a continuous process. While the first batch is being printed, another batch can already be homogenized in the mixer and then added to the pump unit and printing process can be continued without interruption.

*Fig. 1: Process chain of Contour-Crafting (from r. to l.): After homogenization by using an intensive mixer, a concrete pump transports the material to the manipulator to create components weighing up to 400 kg in a three-dimensional space.*

**Motion control**

The entire CC process is subject to a large number of factors which can significantly influence the printing result. Extrusion speed, layer thickness, traversing speed and finally also the way in which the individual layers are built up influence the shape and thus also the technical properties of the printed component. Since the large printer is an experimental setup, the individual components (casting agent and additive pump, robot arm, intensive mixer) are not yet coordinated with each other, or the controls cannot yet be combined to implement the process via a central control system. A software update from ABB has recently made it possible to convert CAD files, i.e. the basic information about the appearance of the files to be printed, via a slicing program into machine code that the robot arm understands. Of course, certain geometric details can also be defined in this way, such as the thickness of the individual print layers or the structure of the component itself. This greatly simplifies the programming of the robot arm movements, but the integration of pump control and the addition of additives, as described above, is still missing. To achieve full automation and take full advantage of the ABB software, it must be possible, for example, to stop or, at best, even reverse the material feed if the position of the print nozzle changes during a print job so that the material does not run out. Of course, the output files of a slicer program do not take into account that the system is not yet fully automated, so the print files must be designed with CAD in such a way that the slicer program has no option but to define the print path in the desired way.

For example, to contour a cuboid, the program would suggest solid outer layers with a defined fill pattern. However, this would require the print head to stop at one point and start printing at another. To avoid this, the print path is defined in CAD using the above criteria to create an endless print path, as shown in Fig. 2 with an alignment of the subsequent layers at 180° angles. Other print schemes could represent subsequent layers at 90° or 45° angles. Layer thickness, traverse and extrusion speed, and the overall structure of the CC part must be coordinated to avoid layer formation and defects and to produce a part that is as homogeneous as possible.

To achieve this target, the extrusion speed and thus also the pump pressure, the traverse speed and the layer thickness must be synchronised, always considering the viscosity of the castable and the current printer setup (pump head and hose diameter as well as nozzle diameter). Defects and layer formation can be counteracted by over-extrusion, i.e. forced extrusion of the extrudate into one another by increasing the extrusion speed while maintaining the same travel speed or by slowing down the travel speed while maintaining the same extrusion speed, or by varying the layer thickness.

*Fig. 2: CAD design of five layers of a cuboid (350 mm x 290 mm). Endless print path without any stoppage of material flow, carried out with a printing path by alignment of the subsequent layers in a 180° angle.*

**EXPERIMENTAL PROCEDURE**
**Castable preparation**
For the experiments high-alumina cement bonded castables with a maximum grain size of 3 mm was developed (Tab. 1). The workability of this castable was proven by experiments with two different laboratory 3D printing devices [5]. As a bonding phase 5 wt.-% CA-cement (70 wt.-% $Al_2O_3$) from Imerys S.A., Oberhausen, Germany is added, therefore the castables can be addressed as LCC. A polycarboxylate ether (PCE) (BASF SE, Ludwigshafen, Germany) was used as dispersant. The different alumina fractions were provided by Almatis GmbH, Ludwigshafen, Germany.

Multifil-fibers (< 6 mm) from Elkem, Oslo, Norway were used to improve the volume stability of the castable and to enable a faster dry-out after printing and setting. Methyl cellulose as rheological stiffening agent was used to reduce the castables viscosity and to provoke a kind of plastic behaviour. An interlayer adherence agent from BASF SE, Ludwigshafen, Germany was used in all mixes to accomplish a good interlocking of the printed layers. $Li_2CO_3$ from Carl Roth GmbH & Co. KG, Karlsruhe, Gemany was used as an accelerator for a faster setting in case of cement bonded castables. The castables were mixed in an 80 l intensive mixer (Eirich GmbH & Co. KG, Hardheim, Germany). A star agitator in co-current flow for all experiments was used. Castables were mixed 1 min dry with a rotation speed of 44 rpm and 7 min wet with a rotation speed of 177 rpm. The mixing vessel rotates with 16 rpm. The water demand was set to 7,3 wt.-%.

**Test piece manufacturing and treatment**

A cuboid with a dimension of 350 mm x 290 mm was built by layer-on-layer construction (10 layers in x-, y-axis and 5 layers in z-axis) with the large-scale printer (Fig. 1) after the scheme shown in Fig. 2. The manufacturing was carried out with a printing path by alignment of the subsequent layers in a 180° angle. The real printing process can be seen in Fig. 3. 60 kg of raw material was homogenized and then added into the pump unit to be delivered to the print head. The actual printing process was started manually on both the pump and the ABB robot, and the print path was also programmed manually. $Li_2CO_3$ as setting accelerator was added directly added at the tip of the nozzle using an additive pump.

Test pieces for CMoR according to ISO 1927-5 (160x40x40 mm) Format D prisms were cut out. The sampling positions are marked in Fig. 4. Four test pieces were manufactured in print direction (180° angle) and another four test pieces were prepared at a 65° angle to get clues about the influence of a diagonal offset.

The cuboid was cured at room temperature, after cutting the test pieces were dried at 110 °C for 48 h and sintered at 1500°C with a dwell-time of 2 h.

| Interlayer adherence agent | 0.05 |

**Experimental setup**

CMoR of two test pieces each was measured after drying at 110°C and after sintering at 1500 °C (dwell = 2 h). Open porosity was measured according to Archimedes by water buoyancy weighing.

**RESULTS AND DISCUSSION**

As shown on a smaller scale in former investigations [5] it was possible to upscale the experiments and print a true to size cuboid with the dimensions of 350 mm x 290 mm by layer-on-layer construction (10 layers in x-, y-axis and 5 layers in z-axis) with the self-developed castable CAC 3 mm in combination with $Li_2CO_3$ as an accelerator with the also self-developed large-scale printer.

The printed cuboid cut into two halves is envisaged in Fig. 5. The inner structure of the built layer on layer construction against print direction can be seen. Strands can be obtained that still own their extrusion shape with large casting cavities in between. The printing path could be changed to close those gaps mechanically by using a narrower path of the nozzle in x-, y- and z-direction and thus pressing the extruded strands more into each other. The single strands of the extrudate indicate that the viscosity of these castable is adequate to build out discrete strands. The castable is stable enough to withstand the weight of the subsequent layers and a discrete layer on layer formation can be manufactured. The printed member contains coarse grains of tabular alumina up to 3 mm and it is visible that these coarse grains are homogenously dispersed within the member as well as in every single strand.

Fig. 3: Printing process of a cuboid with a dimension of 350 mm x 290 mm by layer-on-layer construction (10 layers in x-, y-axis and 5 layers in z-axis) with the large-scale printer after the scheme shown in Fig. 2. $Li_2CO_3$ was used as setting accelerator and directly added after nozzle exit.

Fig. 4: Schematic top view and sampling positions within the cuboid (Fig. 3) of four test pieces, manufactured in print direction (180° angle) and another four test pieces at a 65° angle to get clues about the influence of a diagonal offset.

A cut test piece (180° angle), to show the inner structure of built layer on layer construction in print direction can be seen in Fig. 6 (l.). Here individual layers could not be identified. The grains and particles seem homogeneously dispersed and no big pores or cavities are evident to observe. A low tendency for segregation is obvious that can lead to prefabricated members with a high homogeneity.

Fig. 6 (r.) represents the fracture surface of the same test piece after measuring the bending strength. The sample section shows partially separate not well interlocked strands that still own their extrusion shape with large casting cavities in between. $Li_2CO_3$ leads to a volume stability, but acceleration has must be adjusted to enable a cavity free prefabricated member. Also, a more perfect inner structure could be achieved by optimising the printing path.

Fig. 7 shows the evolution of the CMoR and open porosity of CAC 3 mm. Test pieces 180° and 65° angle are pretreated at different temperatures (110 °C and 1500 °C). CAC 3 mm prepared at an angle of 180° delivers a strengths value of 4.5 MPa and an open porosity of 12.6 % at 110 °C. Sintered at 1500 °C the CMoR is 21.1 MPa and the porosity is 29.4 %. The same castable prepared at an angle of 65° shows a CMoR of 4.4 MPa at 110 °C and a porosity of 14.4 %. The strength is 15.8 MPa if sintered at 1500 °C and the porosity is 29.6%. The sampling with regard to orientation in the cuboid and the print path (180° and 65° angle) should be considered. Dried at 110 °C CMoR and open porosity do not seem to be significantly affected in these studies presented. If sintered at 1500 °C, 180° angle samples show a slightly higher strengths than those prepared at 65°. An explanation could be given by a slightly higher tendency for delamination of the layers due to the skew. In

general, the values of CMoR are lower and those of the open porosity are higher compared to conventionally produced members by moulding technique. Further material development could be necessary depending on the application of the manufactured components. However, the open porosity values are likely to be not only real porosity but also cavities due to the printing process. The values could therefore possibly be corrected downwards.

Fig. 5: Cut cuboid, to show the inner structure of built layer on layer construction against print direction.

Fig. 6: Cut test piece (180° angle), to show the inner structure of built layer on layer construction in print direction (l.) and fracture surface of cut test piece (180° angle), to show the inner structure of built layer on layer construction (r.).

Considering the images of the cut cuboid in Fig. 5 and the test piece prepared therefrom in Fig. 6 and the results of the measurement of CMoR in Fig. 7 it can be concluded that the additives must be adjusted more carefully, to achieve a homogenous material that is stable enough to keep its volume stability. Although stable layer formation is desirable, discrete strands will not allow homogeneously printed parts with the desired dimension. In general, the test pieces show lower values of strength compared to conventionally produced ones by moulding technique. This can be explained by more defects like cavities caused due to quite discrete strands standing on top of each other. However, this can be counteracted with a better printer setup when the individual layers were printed more into one another during the printing process by reducing the traverse path of the printer nozzle in x-, y- and z-axis (over-extrusion). A more homogeneous inner structure without cavities could be achieved and less defects in their inner structure could lead to higher values of strengths.

Fig. 7: CMoR and open porosity of castable CAC 3 mm (65° angle and 180° angle test pieces), dried at 110°C and sintered at 1500°C for 2h.

## CONCLUSIONS

In this contribution we envisaged first success in the development of castables that are suitable for CC as well as development of a large-scale 3D printer. It was possible to upscale former experiments [4,5] and print a true to size cuboid.

We figured out, that pumpable castables must be adjusted precisely regarding their grain size and particle size distribution, water demand and additive system and thus their rheology. The use of suitable additives in a precisely adjusted concentration is inevitable to gain the wanted properties of printable castables. Stiffening agents in a defined concentration are necessary to achieve shear thinning rheological behavior that allows a good pumpability but also an increasing viscosity after leaving the printing nozzle to achieve a sufficient volume stability and to produce near net shape members. Accelerator agents are mandatory to achieve a rapid setting of the concrete. The strength evolution must be high enough to withstand the weight of the subsequent layers. However, the right dosage must be still be optimized.

Another very important point is the printing process itself, especially the printing path and the movement of the printing head and thus the nozzle in x-, y- and z-direction. This influences the material properties CMoR and open porosity. Gaps and printing cavities provoke higher open porosities and lead to defects that lower the strengths. In order to produce homogeneous parts, the extrusion speed and thus also the pump pressure, the traverse speed and the layer thickness must be synchronised, always taking into account the viscosity of the castable and the current printer setup Defects and layer formation could be counteracted by over-extrusion, i.e. forced extrusion of the extrudate into one another.

It can be concluded in general that the end-shape printing of large members with a smooth surface and homogeneous material properties like those that are obtained by the conventional moulding technique is a complex interplay of both materials properties and printing process.

In further investigations other printing schemes should be tested, where the application of the layers is changed. Possible variations represent an alignment of the subsequent layers not carried out as in this version at an 180° angle, but at a 90° or 45° angle. The influence on resulting materials properties should be considered.

Microscopic as well as computer tomographic investigations should be carried out to to examine the inner structure and layer formation in more detail.

# EFFECT OF FIRING TEMPERATURE ON THERMO-MECHANICAL PROPERTIES OF LOW CEMENT CASTABLES

Sougata Roy, Subhadeep Chatterjee, Minakshi Dash, Arup Kumar Samanta, Yoshihiro Mizuma, Sunanda Sengupta, P. B. Panda
TRL Krosaki Refractories Limited, Belpahar-768218, Odisha (India)

## ABSTRACT

Due to several advantages of Monolithics, particularly castables, its consumption is increasing day-by-day in different applications replacing bricks. In castables, cement is responsible for developing strength after installation followed by curing and firing. However, the presence of CaO coming from cement restricts the thermo-mechanical properties of castables, specially for low cement castables having microsilica in matrix. Several works have been conducted to improve the thermo-mechanical properties while reducing the cement content or introducing different binders replacing cement. In different applications, some of the items are too complicated and larger in shape which is quite difficult to manufacture in pressed route. In addition, to avoid additional activities and unable to maintain proper pre-firing schedule at application sites, most of the users prefer to use precast and pre-fired (PCPF) items for critical applications which not only provide quick installation but also give consistent performance. Due to criticality and larger in shape, it is not always possible to pre-fire the items at high temperatures to develop required thermo-mechanical properties which are important from the viewpoint of application.

In the present work, two types of castable have been considered where one is designed with microsilica in matrix and other is without microsilica. Different thermo-mechanical properties like HMOR, PLC, RUL etc. are measured after firing the samples at different temperatures. The relation of thermo-mechanical properties with firing temperatures is explained while development of different mineralogical phases as well as changes in microstructure through different techniques e.g., XRD, SEM, EDAX etc.

## INTRODUCTION

Refractory castables as a kind of high-temperature composite, have the several advantages like easy installation, enery savings, suitable for partial repairing and to make monolithic structure. One of the essential component for castables is calcium aluminate binder which gives good workability at the time of application. However, the high-temperature mechanical properties like HMOR[1] of castables depends upon the formation of different mineralogical phases specially $CA_6$. The degree of $CA_6$ formation, its shape and location of formation are also responsible for high-temperature properties. Presence of matrix components and the formation of other liquidus phases strongly affect the high temperature properties. Basically, there are two types of castable. One is with microsilica in matrix and other without microsilica. In both the cases there is formation of $CA_6$ phase[2] but its shape is different and ultimately affect the mechanical properties.

Pre-firing temperature also plays a vital role as different mineralogical phases are formed during pre-firing which contribute better high-temperature thermo-mechanical properties.

## EXPERIMENTAL

Two types of castable are designed in this study having $\sim$ 90% $Al_2O_3$. One is having microsilica in matrix and other is without microsilica. The base raw materials are WTA, sillimanite. Two different kinds of dispersing agents were used for two types of castable. Samples were fired at 1200, 1400 & 1600$^0$C to measure the CCS. To understand the effect of pre-firing temperature on HMOR, samples were pre-fired at 300, 600, 900, 1200, 1300, 1400, 1500 and 1600$^0$C before measuring HMOR at 1450$^0$C. HMOR was also measured for those samples just after drying at 110$^0$C for 24 hours. To identify the formation of mineralogical phases after firing at different temperatures, XRD was done. Development of microstructure was carried out by SEM along with EDAX. RUL of all samples was measured after firing at different temperatures to understand the effect of pre-firing temperature on RUL.

## RESULTS & DISCUSSION

In Table-1, batch formulation for two types of castables is shown. "SF90" batch doesn't have microsilica whereas "LC90" batch is having microsilica in matrix.

**Table 1: Batch formulation**

| Raw Materials | SF 90 | LC 90 |
|---|---|---|
| WTA | 69 | 80 |
| Sillimanite | 16 | 5 |
| Microsilica | 0 | 5 |
| Calcined Alumina | 0 | 5 |
| Reactive Alumina | 10 | 0 |
| HAC | 5 | 5 |
| Dispersant A | 0 | 0.1 |
| Dispersant B | 0.1 | 0 |

CCS for all samples was measured after firing at 1200, 1400 and 1600$^0$C including after drying at 110$^0$C for 24 hours. The variation of CCS is shown in Fig.1. It has been observed that there is no significant variation in CCS between two types of castable.

*Fig.1: CCS for two types of castables*

*Fig.2: HMOR measured against different pre-firing temperature*

Variation in HMOR is plotted in Fig. 2 measured at 1450$^0$C as a function of pre-firing temperature. It has been clearly observed that there is no significant effect in HMOR between two types of castable on pre-firing temperature till 1500$^0$C. However, a wide diffence in HMOR is observed when samples were pre-fired at

$1600^0$C. Another important observation is the values of HMOR, till pre-firing temperature of $1400^0$C, all values are almost similar. However, it has incresed significantly when samples were pre-fired at $1500^0$C. The significant increase in HMOR is basically the formation of $CA_6$ phase and its orientation. Below $1500^0$C, formation of $CA_6$ is not significant and therefore HMOR values were in lower side. The HMOR value of LC90 is showing significantly low when pre-firing temperature was $1600^0$C. This is due to formation of different low eutectic compounds as LC90 samples are having microsilica in matrix.

XRD patterns of both samples pre-fired at different temperatures were also analysed. As an example, patterens after firing at $1500^0$C are shown in Fig. 3 and 4. SF90 sample is having significant amount of sillimanite but it is fully disappeared at $1500^0$C. Sillimanite may dissociates to form mullite which is another reason for high HMOR.

*Fig.3:XRD of SF90 after pre-firing the sample at $1500^0$C*

*Fig.4:XRD of LC90 after pre-firing the sample at $1500^0$C*

SEM analysis was carried out after firing the samples at $1500^0$C and it is shown in Fig. 5. In both the cases there are significant grain growth. However, the grain growth is higher in LC90 samples. Probably, the formation of liquid phases accelerate the grain growth mechanism. The EDAX behaviour is shown in Fig. 6.

*Fig.5:SEM analysis for SF90 (Left) and LC90(Right)*

RUL is another important high temperature thermo-mechanical property for refractory. This property was measured for both the samples after each pre-firing temperature. The behaviour of RUL after pre-firing at $1500^0$C is shown in Fig. 7 and 8.

*Fig.6:EDAX of SF90 (Left) and LC90 (Right)*

*Fig.7:RUL of SF 90 measured after firing the sample at $1500^0$C*

*Fig.8:RUL of LC 90 measured after firing the sample at $1500^0$C*

## CONCLUSIONS

High temperature thermo-mechanical properties of castables depend on several factors like matrix design, pre-firing temperature, formation of $CA_6$ phase and its shape etc. It has been observed that there is no significant effect on pre-firing temperature till $1400^0$C for both the samples having microsilica in matrix and without microsilica. However, there is significant increase in HMOR for both samples after pre-firing at $1500^0$C. This is due to formation of different mineralogical phases like $CA_6$, mullite and others. HMOR is observed significantly low while pre-fired it at $1600^0$C for LC90. Due to presence of microsilica, different low eutectic compounds formed while pre-firing at $1600^0$C resulting in low HMOR against SF90 having no microsilica. This study also indicates to decide the pre-firing temperature for PCPF items to achieve best high-temperature thermo-mechanical properties.

# DESIGN OF SELF–FLOW CASTABLE USING SIOXX (TM) – FLOW AND ITS AGEING ANALYSIS IN TROPICAL CONDITION

Ankita Mishra, Arindam Mukherjee, Hong Peng
Elkem South Asia Pvt Ltd, Nagpur, India

## ABSTRACT

Modern installation techniques like pumping or shotcreting are gaining popularity with refractory users and manufacturers. The rheological behavior of the castables is important to obtain optimum placement properties and to improve the performance of refractory monolithic in the application. Low cement self-flow monolithic are often faced with challenges of reduced flow during installation at site. Such challenges are increased manifold with the ageing of castable, and with varying climatic conditions - which limits the storage life of castables and application. In this work, a low cement self-flow castable mix is designed using SioxX™-Flow to achieve optimum initial self-flow and working time for the application. The rheological properties with SioxX™-Flow are compared with commercially available other dispersants. The effect of ageing (6 months) on the castable properties when stored at site was also studied.

## INTRODUCTION

In the late 1990s, Low cement self-flowing castables joined the family of refractory monolithics. Due to the ease of application over vibration castable, self-flow castables gained demand in the market. A self-flow castable can be used in shotcreting installations, where refractory aggregates, binders & dispersing agents are premixed in a mixer with water and pumped through a nozzle. At the end of the nozzle, setting accelerator is added to reduce rebound losses. But the mix must remain plastic in nature for trowelling or levelling of the surface. Similarly, in pumping castables the wet mix is directly transported through piston pump at the application site. Hence, for good self-flowing castable, rheological properties are a key factor. Often, the loss in flow is compensated by more addition of water, which leads to grain segregation, prolonged setting time, higher porosity after firing and longer curing time to avoid explosion during preheating.

The rheology of castables is affected by particle size distribution, selection of dispersant and hardening time controller (i.e accelerator or retarder, water to matrix ratio, sequence of water addition, ambient temperature at the time of application and storage or ageing condition of castable). In this work, a low cement self-flow castable mix is designed using SioxX™-Flow to achieve optimum initial self-flow and working time for the application. The rheological properties with SioxX™-Flow are compared with commercially available other dispersants. The effect of ageing on the castable properties when stored at site was also studied.

## EXPERIMENTAL WORK

### Castable mix design

Indian grade bauxite (90% $Al_2O_3$) is selected for coarse to midsize aggregate, fine matrix includes reactive, calcined alumina, bauxite fines and tabular alumina fines. Calcium alumina cement (70% $Al_2O_3$) selected as hydraulic binder, microsilica 971U (97% $SiO_2$, origin Norway) was used as silica fume.

Here, three dispersants are selected to compare the rheology of the castable, Mix-A with SioxX™ -Flow, which is a microsilica-based dispersant for low cement and ultra-low cement system, Mix- B with lab grade sodium hexametaphosphate (SHMP) and Mix C with polycarboxylate ether based additive (Castament FS 20). Details of formulation is shown in table 1.

Table 1 Composition of self-flow castable

| Raw Material | Mix-A | Mix-B | Mix-C |
|---|---|---|---|
| Bauxite 3-5mm | 10 | 10 | 10 |
| Bauxite 1-3mm | 28 | 28 | 28 |
| Bauxite 0-1mm | 15 | 15 | 15 |
| Tabular Alumina 0.2-0.6mm | 10 | 10 | 10 |
| Bauxite 200 mesh | 11 | 11 | 11 |
| CT 800SG | 8 | 8 | 8 |
| CA14M | 5 | 5 | 5 |
| MS 971U | 6 | 7 | 7 |
| CL 370 | 6 | 6 | 6 |
| Dispersant –SioxX™-Flow | 1 | | |
| Dispersant –SHMP | | 0.2 | |
| Dispersant –FS 20 | | | 0.075 |
| Setting Retarder-Boric acid | | 0.05 | 0.1 |
| | 100.0 | 100.52 | 100.175 |

During the application of self-flow castable, flow decay is an important factor, as it has to flow over long distances inside a pipeline and face high shear rates and restricted volume. The wet mix must maintain fluidity without clogging the pipe, segregation of grains.

## 2.2 Experimental procedures

### Mix preparation

To conduct comparative study of placement properties of three additives, trial batches of 6kg prepared. To measure the flowability up to 60min and ageing analysis up to 6 months at frequency Day 0, 7, 14, 30, 60, 90 and 180 days. Investigation of ageing was performed using microsilica 971U. All the raw materials were mixed in a planetary mixer as per the composition and mixed with water 6.5% in two steps (80% addition of water to achieve mix wet-out & rest 20% to achieve self-flow). The reason of fixing 6.5%water is discussed in 2.3. The total mixing time for castable is 5min. Dry mix & water temperature was maintained at 22±2°C during all trials.

### Flow measurement and casting

To measure the flowability of castable i.e self-flow and vibration flow, flow cone (ASTM C230) used. Wet mix sample poured in flow cone, levelled it to surface, cone is removed and then due to gravity, the castable spread on the flat surface. After the spread of the castable up to 30s, diameter is measured using vernier calliper. Similarly, the vibration flow is measured after 15s of vibration using a vibration table. To measure the flow after 30min and 60min, the castable is poured into a zip lock bag and secured from evaporation. Hardening time is measured through ultra-sonic IP 8 tester, where hardening time is determined by the propogation of ultrasonic waves through the material. With time, castable loses its plasticity & gets hardened. Therefore, the velocity of sonic waves increases. Deviation in curve of Sonic velocity (m/s) vs Time (min), initial and final set of the castable is estimated.

To understand the impact of ageing, all 21 batches were packed in a 25kg HDPE bag with additional inner liner and stored in a warehouse, where no temperature and humidity conditioning facility is available, to replicate the site condition. Thrice a day the

169

ambient temperature and the humidity of warehouse were measured using hygrometer and recorded.

### 2.3 Determination of optimum water demand and selection of dispersants

To determine the optimum water demand of the refractory mix, Mix-A trials conducted with water addition of 8%, 7% and 6.5%. With 6.5% of water, desired wet-out time and self-flow of castable achieved as per table 2.

Table 2 Self-flow with different water addition

| Mix-A | Targets | Water addition 8% | Water addition 7% | Water addition 6.5% |
|---|---|---|---|---|
| Wet-out time (s) | <90 | 37 | 60 | 70 |
| Initial Self-Flow_F0(%) | ≥100 | 118 | 110 | 108 |

Further study was conducted at 6.5% of water addition to compare the self-flow up to 30 min with SHMP and FS 20, without any use of setting time controller which is shown in table 3.

Table 3 Comparison of self-flow with different additive

| | Targets | Mix-A | Mix-B | Mix-C |
|---|---|---|---|---|
| Wet-out time (s) | <90 | 70 | 70 | 129 |
| Initial Self-Flow_F0(%) | ≥100 | 108 | 78 | 85 |
| 30min Self-Flow_F30(%) | ≥80 | 86 | 61 | 34 |
| Setting time (min) | | 140 | 100 | 95 |

As Mix-B and Mix-C could not achieve the desired flow without retarder, trials conducted with Citric acid, tri-sodium citrate and Boric acid, where with optimal dosage of boric acid (>99.5% $H_3BO_3$) offered better results.

### RESULTS AND DISCUSSION

#### 3.1 Flowability

Rheological properties with SioxX™-Flow in Mix-A achieved without any addition of retarder whereas with SHMP in Mix-B and with FS-20 in Mix-C of Boric acid (BA) is added with dose of 0.05% and 0.1% respectively. Following are the initial results of flow comparison with microsilica 971U with different additives in table 4.

Table 4 Self-flow with different additives

| | Targets | Mix-A (SioxX™-flow) | Mix-B (SHMP + BA) | Mix-C (FS-20 + BA) |
|---|---|---|---|---|
| Wet-out time (s) | <90 | 80 | 145 | 120 |
| Initial Self-Flow_F0(%) | ≥100 | 107 | 79 | 90 |
| 30min Self-Flow_F30(%) | ≥80 | 97 | 65 | 88 |
| 60min Self-Flow_F60(%) | ≥60 | 80 | 38 | 62 |
| Setting time (min) | < 420 | 290 | 1000 | 450 |

### 3.2 Ageing Analysis

Investigation of the change in rheology of low cement castable is important due to the presence of high alumina cement, microsilica, dispersants and set controller additives, which are more prone to interact with each other and alter the castable behaviour. Fig 1 shows the plot of ambient temperature and relative humidity of the storage facility over the period of 180days.

*Fig. 1 Plot of avg. ambient temperature and relative humidity*

*Fig.2 Storage facility for ageing analysis*

On the day of the trial, dry castables were mixed in a planetary mixer for 1 min, to break any agglomerates formed during storage. Impact of ageing of 180 days on wet-out time and flowability in all mixes are shown in Fig 3 to Fig 6.

*Fig. 3 Impact of aging on wet-out time for all mixes*

Wet-out time of mix with SioxX™-Flow(80s) is lower than SHMP(145s) and FS-20(120s) on Day-1. With increase in storage days, gradual increase in wet-out time observed in Mix-A to 5min on 180th day, whereas in Mix-B and C increase in wet-out time is rapid up to 60days (>200s) and reached 195s and 312s on 180th day respectively
*Fig. 4 Impact of ageing on wet-out and flow in Mix-A*

*Fig. 5 Impact of ageing on wet-out and flow in Mix-B*

*Fig. 6 Impact of ageing on wet-out and flow in Mix-C*

Mix-A self-flow on day-1, immediate after mixing (F0), after 30min (F30) and after 60min (F60) are aligned with target. After 30 days, flow decay (at 30 min & 60min) declined. After 180 days, although the wet out time increased, self flow is close to target.

Mix-B self flow on day-1 is below target for self flow. With ageing, no improvement in flow observed and after 60days samples were found difficult to flow and at the same time high in setting time.

Mix-C self flow on day-1 , immediate after mixing (F0), was below target but offered working time upto 60min. With ageing, wet out time increased , inital flow and workability remain unaffected.

*Fig. 7 Impact of ageing on wet-out and flow in Mixes*

During the application, the loss in plasticity helps in better sticking of the castable on surface. Optimum setting time helps quick installation and change over on site. Mix-A and Mix-C indicate the apt thickening time & setting time, which enable the mix to coagulate, but flow and stick onto the surface, providing high strength and low porosity. Mix-B indicates short thickening and long setting, which will not allow flow and proper sticking of the castable Additionally, long setting hinders the panel removal or demoulding. After 180 days, Mix-B setting time is approximately 50hr, after demoulding of casted sample crack observed in samples. Mix-C 7hr and Mix-A 5hr, which indicated that with SioxX™-Flow, effect of ageing is not significant.

## CONCLUSIONS

a) Selection of admixture / dispersants is important to achieve suitable flow and working time for application of self-flow monolithics. SioxX™ - Flow with 1% dosage in a well-designed self-flow mix demonstrates superior initial flow and workability compared to other dispersants.

b) SioxX™- Flow can eliminate the small quantities of dispersants / retarders and reduces variability of refractory mix design.

c) A mix of reactive alumina-silica fume-hydraulic binder-dispersant is more susceptible to ageing, which may increase wet-out time and setting as well to reduce working time. Mix with SioxX™- Flow demonstrates superior and stable ageing behavior as compared to other dispersants. With 6months of

## ABSTRACT

Alumina-spinel based refractories are excellent furnace linings due to high refractoriness and superior corrosion and slag penetration resistance. Tabular alumina aggregates have been popularly used in alumina-spinel refractories due to their high purity, high melting point and volume stability at high temperatures. Nevertheless, white fused alumina (WFA) aggregates were also considered in this work in the quest to propose a new microstructural design for refractory materials with improved thermo-mechanical properties. The influence of WFA aggregates on the porosity, physical property, microstructure and thermal shock resistance (TSR) of calcium aluminate bonded castables (M-TA resp. M-WFA) were investigated. Calcium hexa-aluminate phases ($CA_6$) were formed along the borders of tabular and white fused alumina aggregates at 1500 °C but in denser layers around white fused aggregates. Residual modulus of elasticity after one and five thermal shocking cycles are comparable for both M-TA and M-WFA castables regardless of original strengths after sintering. Interestingly, residual modulus of rupture for M-WFA castables remains higher than that of M-TA castables after one and five thermal cycles.

## INTRODUCTION

Alumina-spinel castables have been long used in several areas of the steelmaking process including ladle lining [1]. Two types of alumina are widely produced for refractory applications comprising tabular alumina (TA) and white fused alumina (WFA). Nevertheless, tabular alumina has been the main alumina aggregates used in alumina-spinel ($Al_2O_3$-$MgAl_2O_4$) castables. Due to significant amount of closed pores (about 5 vol%.) evenly distributed, tabular alumina is believed to improve thermal shock resistance compared to castables containing white fused alumina [2]. Additionally, tabular alumina consists of elongated, tablet-shaped crystallites with lower open pores than that of white fused alumina grains which are angular shaped [3]. The difference in morphology and particle porosity is mainly due to the different processing routes, that is sintering and electrofusion for tabular and fused alumina respectively. With sodium impurities unevenly distributed and concentrated more at grain boundaries, the deficiency of the large and dense crystallites of white fused alumina in thermomechanical behaviour compared to tabular alumina-based spinel refractories is not well understood. The work reported in this paper seeks to investigate the correlations between microstructural changes and thermomechanical properties of alumina-spinel castables containing tabular (M-TA) and white fused alumina (M-WFA) at high temperatures.

## MATERIALS AND EXPERIMENTAL PROCEDURE
### Raw materials

Tabular alumina, TA (Almatis, Germany) and White Fused Alumina, WFA (Imerys, Germany) were used as the main alumina aggregates (coarse, medium and fines) in the castables. Calcium aluminate cement (CAC, Secar® 71, France) as binder, reactive alumina (P152SB, Alteo, France) and a chemical additive (Peramin® AL200, Imerys, France) as dispersant add up to the castable composition.

The characteristics of tabular alumina and white fused alumina aggregates are given in Table 1. The determination of the apparent densities, open porosities and water absorption of the alumina aggregates was done using the Archimedes method.

Tab. 1: Properties of tabular and white fused alumina aggregates.

| Property | Tabular Alumina | White Fused Alumina |
|---|---|---|
| Apparent density, g/cm³ | 3.6 | 3.5 |
| Open porosity, % | 4.3 | 9.9 |
| Water absorption, % | 1.2 | 3.7 |
| Shape | Blocky | angular |
| $Al_2O_3$, % | 99.9 | 99.8 |
| $Na_2O$, % | 0.3 | 0.3 |

### Castable preparation

Table 2 shows the two types of alumina-spinel castables prepared: (i) one containing tabular alumina aggregates (TA) and (ii) the other containing white fused alumina aggregates (WFA). Both formulations were cast into prisms of 160x30x30 mm³. Castables were cured (at 20 °C, 100 % RH) for 48 h, dried at 110 °C for 24 h and fired at 5 °C/min up to 1100 °C, 1300 °C and 1500 °C for 6 h.

Tab. 2: Compositions of castables, wt%.

| | M-TA | M-WFA |
|---|---|---|
| **Tabular Alumina** | | |
| 3-6 mm | 33 | - |
| 1-3 mm | 16 | - |

| **Water** | + 4.1 | + 4.1 |

### Testing methods

Apparent porosity measurements based on the Archimedes method were performed using water as the immersion liquid. 3-point bending tests were used to measure the modulus of rupture for castables after curing, drying and firing. To interpret the microstructural evolution of the castables fired at 1500 °C, scanning electron microscopy (SEM) studies were carried out with the equipment Quanta FEG 250. Regarding the thermal shock tests, pre-fired samples (1500 °C for 6 h) were subjected to a total of five heating and cooling cycles. Samples were placed in the furnace already heated at 950 °C for 2 h. Afterwards, the samples were removed and air-cooled naturally to room temperature. For each cycle, the damage caused by the thermal cycling was evaluated by elastic modulus measurements (E) *via* frequency resonance at room temperature with the Grindosonic® MK7. Modulus of rupture (MoR) tests were carried out to evaluate the residual strength after thermal cycles.

## RESULTS AND DISCUSSION
### Castable properties
Lowest and highest porosities in both castables were measured after treatment at 110 °C and 1500 °C respectively. The apparent porosities in M-WFA are higher compared to M-TA castables (see Figure 1). However, there is a slight decrease in porosity in M-TA at 1300 °C. One of the reasons for higher porosities in M-WFA castables can be partly attributed to higher open porosities in white fused alumina aggregates.

Fig. 1: Apparent porosity of the tabular (M-TA) and white fused (M-WFA) alumina based castables after drying at 110 °C and different firing temperatures.

Modulus of rupture are relatively low and comparable in both M-TA and M-WFA castables up to 1300 °C. At 1500 °C, both castables have high modulus of rupture but more significant in M-TA castables as seen in Figure 2.

Fig. 2: Modulus of rupture of tabular (M-TA) and white fused (WFA) alumina based castables after drying at 110 °C and different firing temperatures.

### Microstructure
SEM images show the presence of hibonite ($CA_6$) at the borders of the alumina aggregates for both M-TA and M-WFA castables as shown in Figure 3. Despite overall higher open porosities in WFA aggregates, they look WFA aggregates look denser at macroscale compared to TA aggregates but are embedded in a matrix containing bigger pores.

Fig. 3: SEM micrographs of A) tabular and B) white fused alumina-based spinel castables sintered at 1500°C.

However, $CA_6$ seems to be evenly distributed along the tabular alumina aggregates. In M-WFA castables, $CA_6$ tends to form on discrete parts on the surface of the aggregate but in denser layers than in M-TA castables.

### Thermal Shock
M-TA and M-WFA castables show a gradual loss in modulus of elasticity after thermal shock cycles. The residual modulus of elasticity were comparable for both M-TA and M-WFA castables regardless of original strengths after sintering (Figure 4).

Fig. 4: Modulus of Elasticity of the tabular (M-TA) and white fused (M-WFA) alumina based castables after sintering and thermal shock cycles.

The modulus of rupture after sintering is significantly higher for M-TA than M-WFA castables at 1500°C. Likewise, after the first thermal cycle, M-TA castables experiences a bigger drop in strength compared to M-WFA castables. Surprisingly, the residual modulus of rupture for M-WFA castables remains a little higher than that of M-TA castables after one and five thermal cycles.

Fig. 5: Modulus of Rupture of the tabular (M-TA) and white fused (WFA) alumina based castables after sintering and thermal shock cycles.

## CONCLUSIONS
This work shows the significant influence in castable properties at high temperatures comparing the two types of alumina aggregates. Higher modulus of elasticity and rupture could be related to the less porous and dense microstructure of M-TA castables. Thermal shocking results show a higher elastic modulus and residual elastic modulus in M-TA castables after five thermal cycles. Conversely, M-WFA castables exhibit a lower modulus of rupture but a higher residual modulus of rupture of about 50 % after five thermal cycles.

# WHAT IF WE DID NOT HAVE TO DRY TROUGH AND RUNNERS CASTABLES ANYMORE?

Heloisa D. Orsolini; Eric Y Sako; Douglas F. Galesi; Bianca M. G. Silva, Wiliam Alves

Shinagawa Refratários do Brasil, Vinhedo, Brazil

**ABSTRACT**

The constant increase in demand has imposed to the steel industry an intense search for high productivity. Following this trend, the use of monolithic refractories is growing significantly, allowing shorter installation times and consequently greater availability of equipment. The main disadvantage of this class of material is the need for long drying times during its application. In this work, an entirely novel binder system for monolithic refractories is proposed, aiming at the reduction and potential elimination of the drying step during trough and runners repairs. For this purpose, this binder system was evaluated in an $Al_2O_3$-SiC-C castable and compared with the two most used commercial binders: calcium aluminate cement and colloidal silica. The results showed that this system successfully produced a permeable gel-like microstructure, which led to an excellent drying behavior, even in the most aggressive heating conditions, without damaging the product's mechanical, oxidation and corrosion resistance. In the field, runners have already operated successfully using the new binder without any drying step, maintaining their performance with the benefit of a drastic reduction in repair time. Such positive results highlighted that the use of such exclusive binder could lead to the avoidance of up to 500 tons of $CO_2$ emitted into the atmosphere annually per blast furnace.

## INTRODUCTION

The global scenario is challenging for steel producers. The low quality of raw materials, as well as the need for low coke rate and the search for green steel and high competitiveness have increased the stress and pressure for productivity and stability. Therefore, there is a search and incentive to develop products that facilitate and eliminate production steps that bring risks, uncertainties and increase manufacturing stresses.

In this trend, Shinagawa Brasil has developed a new line of monolithic products for trough and runners that do not require drying: the BestDrying[TR] refractories. The working lining refractories in this equipment, which are in direct contact with the pig iron and slag, are traditionally monolithic materials as they allow a fast installation rate, ensuring shorter repair times and consequently higher productivity for the blast furnaces. One of the main issues when it comes to monolithic materials is the drying time required during their application. This is a determining factor in the choice of the binder used for these materials. Historically, the most used binder for monolithic refractories is calcium aluminate cement (CAC), due to its elevated green mechanical properties, suitable cost-benefit, and high chemical stability when in contact with molten metal and slag. The increase in temperature during refractories operation results in morphological and volume changes of the unit cell of the hydrated phases generated during reaction of the hydraulic cements.[1] These changes are caused by the gradual loss of water molecules generating embrittlement of the microstructure and increased internal stresses (vapor pressure). If the generated pressure exceeds the material's mechanical strength, a serious damage on the just-installed material occurs, leading to loss of the refractory integrity, risks of explosion and accidents involving operators and a large financial loss. To minimize these risks, the refractory industry has been using long heating curves for the castable dry-out, so that the dehydration of the cement can gradually take place. When large volumes of castable are applied (general repairs) the required drying time reaches several hours, accounting for approximately 30% of the total trough and runners repair time. In general, such drying stages are carried out using natural gas burners, which results in a significant consumption of this fossil fuel and, consequently, in the emission of greenhouse gas impacting on the carbon footprint of the final steel.

As an alternative to cement and its inherent drying issues, another type of binder widely used for refractory castables is colloidal silica (CS). Whereas hydraulic cements provide castables with mechanical green strength via the formation of crystalline hydrates, colloidal silica fulfills this role by forming a 3D network of permeable structure, which guarantees a much easier drying step, with less risk of explosion [2]. However, the presence of silica in most commercially applied refractories causes the generation of a low viscosity glassy phase resulting in reduced refractoriness and low resistance to chemical attack. Moreover, the use of colloidal silica as binder also generates a castable with challenging workability, due to the instability of the colloidal suspension, besides requiring additional transportation costs.

Therefore, the objective of this study was to develop an innovative and high-performance line of products (BestDrying[TR]) which is easy to dry without bringing along the drawbacks related to the increased silica content. By the introduction of such novel technology in the market, a significant reduction on the drying curves, and consequently on the natural gas consumption, is expected during the casting house repair procedures, leading not only to a higher trough availability, but also to lower $CO_2$ emission rates, increased productivity, operational stability, and safety.

## MATERIALS AND METHODS

To fulfil the objectives proposed in this work, a standard formulation of through and runners castable ($Al2O3$-SiC-C) was used as the reference for the comparative evaluation of the new proposed system (BestDrying[TR]) with the two most traditional binder systems: calcium aluminate cement (CAC) and colloidal silica (CS), as highlighted in Table 1. The amount of colloidal silica used was selected to ensure similar levels of flowability for all castables in the study.

Tab. 1: Formulation of the materials evaluated in this work containing three different binders: calcium aluminate cement (CAC), colloidal silica (CS) and the newly developed BestDrying[TR].

| Raw Material (%wt) | Calcium Aluminate Cement (CAC) | Colloidal Silica (CS) | BestDrying[TR] |
|---|---|---|---|
| Alumina | 56 | 56 | 56 |
| Silicon Carbide | 25 | 25 | 25 |
| Carbon sources | 3 | 3 | 3 |
| CAC 70% $Al_2O_3$ | 2 | - | - |
| CS 40% solids | - | 10 | - |
| BestDrying[TR] system | - | - | 2 |
| Others | 14 | 14 | 14 |

The material's workability was determined by two different measurements: the flowability after mixing and the setting time at 60°C. These two tests are very important as they directly influence the final quality of the samples, as well as the applicability and performance of the refractory at field. The flowability directly influences the material's ability to flow and occupy all cavities and spaces of the region where it will be applied. The setting time determines how much time is required for the material to completely harden and to develop enough mechanical strength to allow the mold to be withdrawn. These properties present crucial importance during the through and runners repair, as they affect the final quality of the working lining, mainly its surface finishing and porosity. The flow values were obtained according to the NBR 13320 standard, where the castable is poured into a mold with well-defined diameter and the flowability is measured after removing the

mold and vibrating the material, comparing the original and the final diameters. For this test, the castable was obtained using a planetary mixer by performing the processing step according to an internal mixing procedure. The same procedure was used to produce samples for permeability, cold crushing strength and fast drying tests.

For permeability measurements, disc-shaped samples measuring approximately 5,7 cm in diameter and 2,1 cm in thickness were tested in an experimental apparatus for permeability using ambient air as the fluid. Tests were performed on three samples of each composition and two tests were performed on each sample. The Darcian permeability or viscous constant ($k_1$) was obtained using the Forchheimer's equation. [3]

To analyze the microstructure formed during the curing step of the proposed new binder system, scanning electron microscopy (SEM) evaluation was performed on polished and gold-coated cubic specimens (2 cm) of the castable after molding and curing at room temperature.

The cold compressive strength was measured according to the NBR 11222 standard. Prismatic samples (160mm x 40mm x 40mm) were casted and after 24 hours curing at ambient temperature, the samples were dried at 110°C and fired at 1450°C at reducing atmosphere, cooled down and tested.

For the fast-drying test at lab scales, 100mm x 100mm cylinders were prepared and cured for either at room temperature for 24h or at 60°C for 3h or 6h and immediately exposed to a temperature of 1000°C for 30 minutes. For the industrial scale test a 500mm x 600mm x 700mm block was molded, cured for 24 hours at room temperature, and directly inserted into a gas burner oven programmed to reach 400°C in a very short time (2h30min). For both lab and industrial tests, a visual inspection was carried out in the samples to check the presence of any damages generated during the fast-drying procedure, such as cracks, chipping, and/or explosion. Only the formulations with no issues during the laboratory test were tested on an industrial scale.

The castable containing the novel binder system was also installed in some casting houses in a Brazilian steel mill to run pilot trials and confirm the results attained at lab scale. The initial field tests were performed in three stages. The first stage consisted of a 50% reduction of the traditional drying curve used in the runners after repair, while in the second stage a 75% shorter curve was performed, finally, the last step consisted of eliminating the drying curve.

## RESULTS
### Laboratory and industrial scale results

Table 2 presents the water (or colloidal silica) content, the flow values, and the setting time at 60°C for the three evaluated formulations. Calcium aluminate cement-bonded castables, in general, present good workability, with very suitable flowability (165 mm) and setting time (100 min). The colloidal silica-bonded castable, as expected, showed an unstable behavior, with flow rate of 154 mm and setting time of 45 min, even using 10% of colloidal silica which provides a residual water content of 6%. The material bonded by the new BestDrying[TR] system showed very similar characteristics to the reference CAC castable, pointing out that this new solution would not bring any issues during the material installation at field.

Tab. 2: Water and Colloidal Silica Content, Flowability and Setting Time at 60°C for CAC, CS and BestDrying[TR] castables.

| Material | Water / Colloidal Sílica Content (%) | Flowability (mm) | Setting Time - 60°C (min) |
|---|---|---|---|
| CAC | 5,6 | 165 | 100 |
| CS | 10 | 154 | 45 |
| BestDrying[TR] | 5,6 | 165 | 110 |

CAC and BestDrying[TR] castables were prepared using water, while CS were prepared using 40%-solids colloidal silica.

The presence of hydrated crystalline phases in the CAC-bonded formulation resulted in very low permeability over the entire temperature range (110-400°C), with a permeability constant ($k_1$) always equal to or less than $0,1.10^{-14}$ (Figure 2). As also expected, and previously reported [2], the permeability results illustrate the benefits of colloidal silica, which helps to generate a more permeable structure when compared to CAC. However, although representing the state-of-the art technology, the $k_1$ values of the CS material was still not as high as the one attained by the very special structure formed by the BestDrying[TR] bonding system, which resulted in a castable with extreme levels of permeability, showing a $k_1$ constant up to two orders of magnitude greater than the CAC formulation.

*Fig. 1: Permeability test comparing the permeability constant k1 of CAC, CS and BestDrying[TR] binders treated at different temperatures (110°C, 250°C and 400°C).*

To better understand the differences in the microstructural evolution of CAC and BestDrying[TR] during the castable curing step, scanning electron microscopy (SEM) analyses were conducted with samples of both formulations (Figure 2). For the CAC composition (Figure 2.a), it is possible to observe the presence of countless needled crystals, resulting from the CAC hydration process and responsible for providing green mechanical strength to the sample. Numerous hydrated phases can be formed during the hydration of CAC ($CAH_{10}+AH_3$(gel), $C_2AH_8+AH_3$(gel/crystal), $C_3AH_6+AH_3$(crystal)), and their formation tendency is dependent on the time, temperature, and water content present in the medium. [4] When observing the microstructure of the BestDrying[TR] - bonded castable (2.b)), it is possible to notice a completely different structure, where an interconnected gel structure is formed throughout the material, with the absence of needle-like crystalline phases. This difference presents a direct impact on the permeability results presented above for the two materials.
*Fig. 2: Scanning electron microscopy of the formulation bonded by a) CAC, showing the presence of several needled phases, resulting from the cement hydration process; and b) BestDrying^{TR}, with the formation of a gel structure that permeates the entire sample and the absence of crystalline hydrates.*

Although it is not a direct demand during use, the mechanical strength is an important parameter for trough and runner materials, as it determines, together with permeability, the drying resistance of the material. Usually when increasing the permeability of a refractory, the mechanical strength is lost, resulting in poor resistance to drying and making the development of a fast-dry material a very tough task. However, that issue was successfully overcome for the new proposed binder (Fig. 3.), as it was able to show proper mechanical strength both after drying (110°C) and firing (1450°C), with values close to those presented by the standard CAC-bonded formulation. The samples prepared with colloidal silica also presented high CCS values, but that was associated with the use of higher amount of binder required for an adequate flowability. As permeability is a property directly related to porosity, it is natural that the system with greater permeability presents greater porosity, however, the BestDrying^{TR} system was carefully developed so its greater porosity did not affect its performance in the field, as will be seen below.

*Fig. 3: Cold Crushing Strength (MPa) and Apparent Porosity (AP) of the castables bonded with CAC, CS and BestDrying^{TR} after dried at 110°C and fired at 1450°C.*

The drying resistance, as mentioned above, is a result of the combination of permeability and mechanical strength. If the water

vapor is not properly released in a non-permeable structure and generates a high internal pressure which overcomes the material's mechanical resistance, it will not resist and will fail during the drying step. Therefore, an efficient fast-drying material should present high permeability, which will facilitate water vapor release, and high mechanical strength so that the internal pressure will always be lower than the castable's bonding structure.

As can be observed in Table 4, the CAC-bonded castable presents good mechanical strength, but poor permeability resulting in a material with difficulty in drying, which failed catastrophically and exploded during the tests. The CS castable, despite showing higher permeability than the CAC one, still did not present enough combination of properties and it was also damaged during the critical drying test. As a result of the very high permeability and adequate mechanical strength, the BestDrying^{TR} material did not present any external or internal damage after the fast-drying test.

Tab. 3: Fast-drying tests results presented by the castable bonded by CAC, CS and BestDrying^{TR} after curing at room temperature for 24 hours and then exposed to 1000°C for 30 minutes. Only the BestDrying^{TR}-bonded material resisted.

| Time | CAC | CS | BestDrying^{TR} |
|---|---|---|---|
| 24 hours of curing |  |  |  |
| | Severely damaged | Damaged | No damage |

After successfully going through all the validation steps in the lab scale, an industrial test was performed for the BestDrying^{TR} formulation using a 500 mm x 600 mm x 700 mm block, in order to evaluate if the drying resistance of the material could be affected by any volume effect. The block passed the industrial fast-drying test again without presenting any damage in its structure, as shown in Fig. 4, indicating that the BestDrying^{TR} binder system proved to be extremely resistant to quick drying procedures, regardless the material volume.

*Fig.4. Industrial scale block of approximately half a ton prepared with BestDrying^{TR} bonded castable after fast drying test.*

Regarding the main properties for trough and runners' materials at high temperatures, such as the oxidation and corrosion resistances, the BestDrying^{TR} bonded castable also showed excellent results. Fig. 5 depicts the oxidation and corrosion behavior of the three evaluated formulations, where one can note that the engineered microstructure developed by the new binder during curing guarantees a low oxidation rate and low corrosion rate, even with high porosity values, which will allow it to keep good performance during use.

177
*Fig. 5. Corrosion and Oxidation tests results of the evaluated formulations. Note the similar performance of CAC and BestDrying[TR] materials and lower performance of the CS one, mainly in contact with slag.*

**Field Tests**

Castables from the BestDrying[TR] portfolio has been successfully applied in different steel houses around Brazil, with approved results in the following general scenarios:

Tab. 3: General scenarios of field tests using BestDrying[TR] refractories in Brazil.

| Trough and Runners | Drying Curve Applied | Drying Evaluation | Campaign Performance (In terms of specific consumption) |
|---|---|---|---|
| Slag Runner | 0% (eliminated) | Successful | Successful |
| Pig Iron Runner | 0% (eliminated) | Successful | Successful |
| Main Trough | 50% | Successful | Successful |
| Entire Casting House (including skimmer, tilting runner…) | 50% | Successful | Ongoing campaign |

In all the tests carried out, the BestDrying[TR] refractories did not show any anomalies during the drying stage, as well as at the start of operation. During the inspections, the materials showed standard wear, without any point of attention. At the end of the campaign, in all the equipment tested, the BestDrying[TR] refractories showed wear levels compatible with standard cement-bonded refractory, allowing the maintenance of the specific consumption standards already practiced.

The excellent results collected in the field, as shown in Tab.3, allowed to proceed the next steps, which includes running the casting house after eliminating the drying curve of both the main trough and the secondary runners. In addition, it was possible to calculate the benefits of customers by eliminating the necessity of drying trough and runners in their plants. In a two-main trough blast furnace with a daily production of 7500 tons in which the productivity must be reduced by 10% during the repair period (tap-to-tap operation in only one main trough), 7000 tons of pig iron could be recovered, with a financial return of $700,000, the non-use of 51.520 Nm³ of natural gas and the non-emission of 100.000 tons of $CO_2$ into the atmosphere per blast furnace during a full campaign.

**CONCLUSIONS**

Motivated by the urgent need to increase equipment availability, reduce risk and stress in the casting house, this work aimed to characterize and analyze in the field the new line of monolithic refractories without drying developed by Shinagawa. That was possible by obtaining a binder system with an open microstructure

and without crystalline hydrate that produces a refractory with high permeability and easy water removal. In addition, the novel technology also maintained good workability, mechanical strength, resistance to oxidation and corrosion. In the field, BestDrying[TR] products are adding up achievements, with slag and pig iron runners operating without any drying and the main troughs already reaching 50% reduction of the drying curve, while maintaining the specific consumption level presented by the line material. Eliminating drying in the main trough is the next step, and the sky as the limit.

# ONLINE DRYING MONITORING SYSTEM FOR REFRACTORY CASTBLES

Thekla Stein, Olaf Krause
University of Applied Sciences, Höhr-Grenzhausen, Germany

Wolfgang Taute, Michael Höft
Kiel University, Kiel, Germany

## ABSTRACT

The careful drying of refractory castable is a crucial step before the final implementation in the industrial process. If not executed correctly it can lead to spalling and even to the destruction of the material and the surrounding installation. Due to the challenging temperature level (up to 600 °C) and the marginal water amount in the material, there is no electronic sensor online monitoring system available yet to control the progression of the drying process in situ. Thus, the drying procedure is based on empirical values only.

Microwave resonators are commonly used to detect moisture in the temperature range from 20 °C to 130 °C in various industrial fields. A new design designated to withstand the temperature range up to 600 °C was developed by Kiel University. A first series of tests was performed at the University of Applied Sciences in Koblenz to understand the system's capabilities and limits in detecting water in castable material during the drying process. It was expected that during heating the evaporation of water and the dehydration of the hydrate phases within the material will influence the resonating frequency and result in a widening of the frequency bandwidth. Simultaneously with the changes in the microwave field the weight loss of the material was monitored. By linking the new approach of observing the resonating frequency with the weight loss as a well understood indicator [1] for the drying progress, the suitability of a microwave resonator as a drying monitoring system for refractory castables will be validated.

## INTRODUCTION

In refractory applications, the physical and the chemical bonded water in the castable needs to be removed prior to the first use. If it is not carefully removed, the developing vapor phase in the pores and the related pressure build up can exceed the material strength. In this case the material disintegrates, and the dreaded spalling occurs [2].

The physical bonded water contained in the pores of a refractory castable is removed in a temperature range up to 200°C. The water chemically bonded in cement hydrates phases is released in a temperature range from 200 °C to 600 °C [3]. Thus, the available commercial systems to monitor the drying progress are not suitable for refractory materials and the harsh environment in the applicating industry.

In various industries like food, paper and concrete, microwave resonators are a commonly used method to measure the humidity [4, 5]. Due to the long experience with such resonators, they provide reliable data about the humidity in real-time and they have proven to detect small changes in humidity independent on the density of the material [6]. Most commercially available systems are designed for an application temperature close to the evaporation of water (max. 130 °C) under atmospheric pressure. An application for higher temperature is not commercially available.

To develop a microwave sensor capable to measure at high temperatures would close a monitoring gap in the industrial process control. The application temperature of the existing microwave resonators is limited by the heat resistance of the solder joints and the delicate electrical parts like cables and other electronic components which are necessary for the proper functioning of the sensor.

Another challenge for the measurement in a high temperature environment is that all electrical properties are temperature dependent. Thus, temperature will influence the measurement result and a distinction between wanted measurement and inevitable temperature effect is necessary. Hauschild et al. [7] measured the complex permittivity at 1000 °C of solid materials. The knowledge about the material's complex permittivity at higher temperature is necessary to distinguish the thermal influences on the material properties from those of the decreasing humidity and dehydration of castables. Prior to this study this is still unknown for castables and a blank reading needs be performed to differentiate between the thermal influences on the material and the change in water content. In case the developed microwave resonator proves to be valid, the missing data can be generated by performing a relevant amount of test series.

When successfully developed a microwave resonator suitable for high temperature has a major potential of saving energy and time in the industrial castable application processes (for example steel production) and the enhancement in safety for the workers.

## METHOD

In an electrical field water molecules will orientate according to the field polarisation, due to the dipole molecule structure. The necessary energy for the reorientation of the water molecules is taken from the electromagnetic field energy. Simultaneously the propagation speed of an electromagnetic wave is reduced. Dielectric solid materials also influence the propagation speed and the field energy [8]. Depending on the construction of the electromagnetic field excitation, the penetrated material and the chosen frequency, the electrical field forms resonances. Resonances are highly sensitive to changes in material humidity due to the ongoing field penetration [9]. The resonator is operated in transmission mode, i.e. the resonator is coupled in series to two coaxial ports [10]. The resonance frequency and its bandwidth can be determined by the frequency sweep of the scattering parameter S21 [10] and will change depending on the humidity in the material. The S21 value is the transmission coefficient between port 1 and 2 of the used VNA (Vector network analyser) [10]. In case the dielectric properties are known and well understood, the change in propagation speed and field energy and their impact on the resonances can be used to determine the humidity of a material.

For this work a microwave resonator was constructed by Kiel University. The resonator head is completely made of brass and can withstand temperatures up to 700 °C. The resonator head is attached to two long coaxial brass tubes for an inductive coupling arrangement of the two port measurements. The sensitive electrical cables need to have enough distance to the heating source to avoid a thermal decomposing of this sensitive parts. The operating frequency range is 0.6 GHz to 1.6 GHz. The dimension of the sample and the constructed resonator are specifically designed to form resonance in the investigated material, thus the dimensions and the distance between resonator and sample must be maintained to achieve reproducible results. The resonances are evaluated by a Lorentz curve fitting [11].

To identify the thermal impact on the resonator during the heat-up, the resonator measurement method must be based on a blank measurement (measurement without sample). For the presented system this cannot be achieved in the usual way. The material parameters (i.e. its dielectric properties) and the temperature dependence of the same are not sufficiently known. Thus, the drying (release of physical bond pore water) and dehydration (decomposing of hydrate phases) cannot be distinguished from the impact which the thermal influence are having on the material and likewise on the test station and in consequence on the results. To overcome that lack of knowledge every sample is heated up twice.

179

During the first heat-up, the drying and the dehydration occurs. In the second heat up, the sample is already free of water and all changes in the detected signals can be linked to thermal influences either on the material or the testing station.

The base of the testing station is a scale to measure the weight change during the experiment. On top of the scale a heating plate is located, that can achieve a maximum temperature of 600 °C and initiates the drying and dehydration of the castable. A metal container (tube closed on one side by a welded-on plate) is placed on the heating plate. Inside this metal container the castable sample is centrally positioned. The inductive coupling arrangement for the excitation of the microwave resonator is located above but without direct contact to the sample and emits a microwave field in the sample (Fig. 1).

*Fig. 1: Microwave field simulation for the resonating frequencies 0,99 GHz. The light grey cylindric shape represents the castable sample. The partially shown cylindric shapes represent the surrounding metal container. The coloured lines indicate the electric field of this eigenmode.*

During the measurement the weight loss of the sample is detected by the scale, the VNA (Vector network analyser) is determining the parameters of the microwave field. The temperature is not measured in the sample, because a thermocouple would strongly disturb the microwave field. Thus, the temperature is measured at the heating plate surface.

**EXPERIMENTAL PROCEDURE**

**Sample treatment**

The investigated material (Tab. 2) was mixed in a compulsory mixer and casted into cylindric shape (diameter 100 mm and height 50 mm). For the preliminary tests the castable represented in Tab. 2 was used. The treatment of the samples was altered for the preliminary test series. All samples were stored in a climatic chamber at 20 °C and 95 % humidity for 48 hours, to ensure stable conditions and a stable hydrate phase growth after mixing. Thereafter they were divided in two groups (Tab 1).

*Tab. 1. Sample treatment for preliminary test series*

| Sample nomenclature | Climatic chamber 20 °C and 95 % humidity | Drying chamber 110 °C |
|---|---|---|
| Sample A | 48 h | 24 h |
| Sample B | 48 h | - |

Sample A one did not receive a further treatment prior the drying test. Sample B was stored for 24 h in a drying chamber at 110 °C to remove the pore water before testing. The heating rate generated by the heating plate for all tests was 60 K/h. For all samples the heat treatment was performed twice in succession. The first heat-up

resulted in the sample's drying and dehydration. The second heat-up was used as a blank reading to eliminate the thermal influences on the measured results.

*Tab. 2: Castable recipe*

| Component | Addition wt % |
|---|---|
| Tabular Alumina 0 – 3 mm | 78 |
| Calcined Alumina | 10 |
| Reactive Alumina | 7 |
| CA-Cement | 5 |
| Dispersant | 0.15 |
| Water / % | 5.20 |

**Determination of the suitable resonance**

Before performing investigation the refractory castable the suitability of the resonance must be evaluated. Two samples were prepared and tested (see Sample treatment). The pore water in sample A was dried out at 110 °C. In sample B the pore water and the hydrate bond water remained. The heating rate was set at 60 K/h with a dwell time of 3 hours. In Fig. 2 the results for sample A are represented. The S21 value is shown vs. the frequency. The frequency sweep covers the range from 0.6 GHz to 1.6 GHz.

*Fig. 2: Results for sample A cured 48 h at 20 °C and 24 h at 110 °C. The measurement of S21 value of the frequency band over the frequency sweep is shown in the diagram. The pore water was dried out at 110 °C. The dehydration was performed in the test station. The red curve represents the resonance frequencies for the hydrated sample. The black curve represents the signal in the middle of the heat treatment. The blue curve represents the dehydrated sample after the completed heat treatment.*

The three different curves represent three different drying states of the sample. The red curve shows the results for the sample at the beginning of the heat treatment. The chemical bonded water in the hydrate phases is still intact. The black curve represents the middle of the heat treatment, and the blue curve represents the status for the dehydrated sample after the heat treatment. For three frequencies a resonance is formed, at 0.99 GHz, at 1.15 GHz and at 1.4 GHz each recognizable as peaks for the S21 value.

In Fig. 3 the results for sample B are represented. The S21 value is shown vs. the frequency. Again, the frequency sweep covers the range from 0.6 GHz to 1.6 GHz. The three different curves represent three different drying states of the sample. The red curve shows the results for the sample at the beginning of the heat treatment. The physical bonded pore water and the chemical bonded water in the hydrate phases are still present. The black curve represents the middle of the heat treatment, and the blue curve represents the status for the dehydrated sample after the heat treatment. Resonances are formed at 0.99 GHz, at 1.15 GHz and at 1.4 GHz each recognizable as peaks for the S21 value for the black

and the blue curve. The red curve only shows a resonance at 1.4 GHz. The development of the red curve does not show the resonances at 1.15 GHz and 0.99 GHz.

*Fig. 3: Results for sample B cured 48 h at 20 °C. S21 value of the frequency band over the frequency sweep. The pore water and the hydrate phases were intact at the beginning of measurement and the related heat treatment. The red curve shows the first signal of the sample with intact pore water and hydrates phases. The black curve shows the middle of the heat treatment. The blue curve shows the sample after the heat treatment was completed.*

**Conclusion about suitable resonance for further test series**

For sample A and sample B the resonance at 1.4 GHz does not show significant changes in dependence of the humidity and cannot be used to determine the drying or the dehydration of the castable. The resonance at 1.15 GHz shows for sample A and sample B a drastic change depending on the humidity. The bandwidth of the red curve for the untreated sample A is too broad for a curve fitting evaluation and the peak of the resonance is shifting strongly. For sample B in the completely undried status the resonance is not visible in the curve. Thus, this resonance is not suitable for further investigations.

For sample A the resonance 0.99 GHz is suitable for a Lorentz curve fitting. Sample B in an undried status is not suitable for a Lorentz curve fitting at this frequency. With enhancing drying progress, the resonance at 0.99 GHz for sample B becomes more defined and suitable for a curve fitting.

The main difference between sample A and B is the physical bonded porewater. The sample B contains primarily physical pore water and a relatively small amount of chemical bonded water in the hydrate phases. The influence of pore water on the microwave resonator is too dominant for the chosen design and frequency span for a suitable evaluation. This leads to the conclusion that the resonance at 0.99 GHz cannot monitor the pore water dry-out completely, due to the high amount of water at the beginning of the drying process. The preliminary tests show that dehydration of a castable in the presented test station can be determined with a sufficient accuracy at the frequency 0.99 GHz.

Thus, the frequency 0.99 GHz will be used for the further investigation of dehydration progress in the castable material.

**RESULTS FOR DRYING MONITORING OF A CASTABLE**

After identifying the suitable resonance for the new testing station, a series of tests was performed to investigate the drying progress in castables. The samples were prepared and treated as described in the chapter, Sample treatment. The investigated material was mixed according to the recipe shown in Tab. 2. Before the testing procedure the sample was stored in a climatic chamber at 20 °C for 48 h and in a drying chamber at 110 °C for 24 h. The heating rate in the testing station was set at 60 K/h until it reached a maximum of 600 °C. The maximum temperature was maintained for 3 h,

followed by a passive cooling phase. Due to the complex data the common link between the parameters are the measurements points (N) (0 to 10,000 for a complete heat-up session). Thus, all the represented results show the measurement points at the x-axis.

*Fig. 4: Resonance frequency for the consecutive heat-ups vs. measurement points. The blue line represents the first heat-up. The red line represents the second heat-up. The green graph indicates the temperature development during both measurements.*

In Fig. 4 the resonance frequency is presented at the left y-axis and the temperature of the heating plate at the right y-axis. The blue graph represents the resonance frequency for the first heat up. The red graph represents the second heat up of the castable sample. The green line indicates the temperature development during the measurement. The data is linked to the number of measurement points. The different parameters are saved by different devices and the link over the measurement points is the most suitable one for the used evaluation software. The temperature increases till the measurement point 4000. From there on it remains stable at 550 °C till measurement point 4600. Due to the passive cooling the temperature drops rapidly and reaches room temperature at measurement point 8000. During the heating the resonance frequency drops for the first and the second heat-up. During the dwell time the resonance frequency shows a continuous development. As soon as the heating plate is turned off and the cooling starts, the resonance frequency rises in reverse proportion to the temperature.

*Fig. 5: The red curves represent the delta from the resonance frequency form Fig. 4. In green the weight loss due to the water transport out of the sample is presented. The x-axis shows the measurement points for the test. The heating, dwell and cooling phase is indicated in the diagram.*

Fig. 5 shows the delta of the resonance frequencies between first and second heat-up presented in Fig. 4 and the weight loss of the

181

sample during the heat up. The measurement points on the x-axis are identical to Fig. 4. The heating, dwell and cooling phase are indicated in the diagram. During the heating phase the delta of the resonance frequencies increases with a drop in the signal at measurement point 1900 (the related temperature is approximately 220 °C). The weight loss curve shows an increase in weight at the beginning of the heating phase and a decreasing weight from measurement point 2100 on. During the dwell time the delta resonance frequencies rises at first and has a more linear development afterwards, likewise the weight loss. As soon the heating is turned off and the passive cooling is initiated the delta resonance frequencies increases in invers proportional to the weight loss till measurement point 6000. From there on both develop linear.

## DISCUSSION

By linking the delta resonance frequency with the weight loss, the castable dehydration is monitored with two systems and leads to evaluable results (Fig. 5). The apparent sample weight increases at the beginning of the heating phase. The convection flow around the scale is most likely responsible for this effect and a constant weight loss at the beginning of the measurement can be assumed. Shortly before reaching the maximum applied temperature the progression of the weight loss curve shows an inflection point and the weight loss progresses much slower afterwards. The difference in weight loss progress can be interpreted as a twostep dehydration process. Because the temperature is only measured at the surface of the heating plate the values cannot be linked to the temperature in the material. Thus, a specific identification of the different dehydrations processes and the decomposition of the related hydrate-phases is not possible. Also, the heating plate temperature is set at 600 °C, but the thermocouple only measures a maximum temperature of 500 °C. Therefore, it would be necessary to improve the thermal insulation of the test station.

The delta resonance frequencies show minima at the measurement point 1900 (220 °C) and at 3000 (400 °C). The change in the resonance frequencies can be interpreted as an increase in the amount of water molecules that interfere with the electromagnetic field. The increase in water molecules occurs because the decomposing of the hydrate phases releases water inside the material. The weight loss decreases in a linear way till measurement point 3800 (500 °C) Thus the weight loss is not directly linked to the decomposing of the hydrates phase. The time needed to transport the water from the sample inside to the surface is way dependant. Thus, the weight loss decrease is delayed compared to the decomposing of the hydrate phases indicated by the delta resonance frequencies. At the beginning of the cooling phase, the apparent weight drops dramatically. This effect is related to the collapse of the convection flow around the scale. The cooling also effects the resonance frequency. This needs to be evaluated by further experiment.

## CONCLUSIONS

For the newly developed testing station the resonance at 0.99 GHz has proven to be suitable for the monitoring of the dehydration of castables. The drying of physical bond water cannot be monitored because the high amount of pore water influences the resonance frequency too strongly for a valid interpretation. Thus, the sample needs to be treated at 110 °C before the measurement in the testing station.

To minimise the thermal influences on the measured signal the sample was heated up twice consecutively and the delta of the two measurements was calculated. Both resonance frequencies in Fig. 4 are strongly influenced by the temperature change. The delta resonance frequency in Fig. 5 does not show this influence and the assumption, that the thermal influence on the results can be eliminated by consecutive heat up is proven correct.

The resonance frequency is also affected by cooling. The cause of that effect needs to be evaluated by further experiments. Also, the

knowledge about the dielectric properties of refractory castables during the heat treatment is not sufficient for a final interpretation of the results and needs further investigation.

## OUTLOOK

By looking at the state of art is was expected that the detection of the physical bonded water and the dry-out of the pore water would be possible (already successfully implement for different materials [4,5] till 130 °C). The detection of the chemical bonded water and the decomposing of the hydrate-phases was never monitored before by a microwave resonator and results were unpredictable. The newly develop microwave flied resonator has proven to monitor the decomposing of hydrate-phases. Based on the presented work the next step would be to develop a system that is able to monitor the drying of the physical bonded water likewise the decomposing of the hydrate-phases. Due to the existing knowledge on monitoring physical water till 130 °C the construction of such is within reach.

## ABSTRACT

The drying process of hydraulic bonded refractories represents a crucial bottleneck to the widespread adoption of this significant class of materials. Mitigating the risk of explosive spalling is of paramount importance as it entails extended heating procedures, resulting in substantial $CO_2$ emissions and reduced end-user productivity. To minimize the occurrence of such explosions, two commonly deploying strategies involve the utilization of semi-empirically defined temperature plateaus and the incorporation of permeability-enhancing additives. Among these later, polymeric fibers have emerged as a preferred choice due to their cost-effectiveness and efficacy. Nevertheless, despite the ability to tailor various properties such as fiber melting temperature and melt viscosity, the underlying mechanisms by which these synthetic materials enhance permeability remain not clearly understood. Hence, the present study proposes the use of neutron tomography to provide insights into the influence of these fibers on the drying process. Notably, alterations in the velocity of the drying front and moisture accumulation were quantified. The anticipated outcomes of this investigation encompass advancing fundamental understanding of these mechanisms, providing practical guidelines to optimize the potential of polymeric fibers in averting explosive spalling, thereby inducing safer and faster drying processes for refractory castables.

## INTRODUCTION

Drying is a process in which water is extracted from a partially or completely saturated porous material through various mass transport mechanisms, such as the diffusion of water molecules and capillary pressure driven flow [1]. These phenomena occur due to gradients in pressure, temperature, concentration or a combination thereof, leading to the removal of moisture from the material [1].

This process can even occur at room temperature depending on the environmental relative humidity thanks to the imbalance in the partial pressure of water vapor between the gaseous mixture present within the material's porous structure and the one in its surroundings. An analogous behavior is observed when washed laundry is hanged for drying after washing.

In the context of refractory castables, where quick procedures to reach operational conditions is essential, the intrinsic permeability is low, the structures have significant dimensions, and water is also present as free and combined forms, thermal gradients are frequently employed to control and induce faster water withdrawn [1, 2].

Still, this is the most time-demanding stage within the refractory castables processing route, impacting directly the costs with energy consumption and, most importantly, the production halt of products that involve high temperature processes [3].

The risk of explosive spalling, which refers to the sudden and destructive failure of the refractory castable which arises from the combined effects of pressurized water vapor trapped within the material's pores and thermomechanical stresses [4], is the main reason for the extended time length of the drying stage, as the use of slower heating rates and temperature plateaus prescribed by semi-empirical laws are the most common strategies to ensure safe drying of the lining [1, 2].

As shown by Cunha et al. [5], the aforementioned strategies result in large energy consumption and may actually be an overconservative approach. A distinct line of development on this matter is the study of composition optimization to mitigate the risk of pressurization and, ultimately, explosive spalling [6]. This can be carried out through the incorporation of polymeric fibers into the castable composition, which increases its intrinsic permeability during the heating process.

Much has been theorized about the mechanisms of permeability enhancement of the compositions containing fibers. For instance, Zhang et al. [7] have proposed that the inclusion of polypropylene fibers may induce the formation of microcracks due to thermal expansion differences between the polymer and the castable matrix. On the other hand, Innocentini and colleagues have proposed that the enhancement could arise from the melting of the fibers and their subsequent burning out [8]. However, as highlighted by the recent review by Mohammed [9], the precise manner in which these additives improve the spalling behavior of concrete remains elusive.

This leads to a conundrum: even though synthetic polymers can be meticulously tailored to have properties that fulfill multiple concurrent requirements, a definitive guideline regarding the specific attributes that the optimal drying additive should possess is currently lacking.

The efforts to study this class of additives include: i) permeability measurements [8]; ii) differential scanning calorimetry (DSC) characterization of the fibers' behavior during heating [7]; iii) thermogravimetry analysis (TGA) of the compositions or the additives themselves [1]; iv) explosion tests (TGA performed with high heating rates in equipment designed to withstand extreme conditions) to assess their effectiveness to prevent explosive spalling [1]; and v) electronic micrography analysis after the drying process, which cannot determine which microstructure features were originated during the test, or the cooling, or even in the sample preparation [7].

More recently, Stelzner et al. [11] investigated the moisture transport and reconfiguration (determined by the bonding state of water) in high-performance concrete (HPC) either with or without PP-fibers using X-ray-CT and $^1H$ NMR. Results showed that the samples with the permeability-enhancing additive exhibited a faster drying front. Moreover, the dried zone (DZ) after the heating procedure was 40% longer in the PP-containing sample, and the total moisture content at the samples' bottom increased by approximately 5 vol.% and 2 vol.% for the fiber-free composition and the containing one, respectively, after heating. However, the study did not compare different additives, and the mechanisms behind the increase in permeability were not thoroughly discussed.

Barakat et al. [12] explored the drying process of refractories incorporating polymeric fibers through NMR experiments. It was found that the increased permeability during fiber melting speed-up the water removal and reduced both the drying front temperature and the resulting maximum pressure. However, the results didn't quantify the water distribution or fiber placement. Recently, neutron tomography was used to observe directly the drying of refractory castables providing unequivocal proof of the accumulation of water that occurs at the innermost position of the sample, also known as the "moisture clog phenomenon" [13]. Additionally, the heating rate effect on the moisture clog was studied and it was found out that higher heating rates resulted in a faster and longer lasting water accumulation at the innermost position of the sample [14].

Thus, the current work aims to apply neutron tomography in-situ observation methods to compare the behavior of refractory compositions with different types of fibers.

## MATERIALS AND METHODS

The current study considered high alumina castable compositions with 5 wt. % of calcium aluminate cement, consisting of tabular alumina and calcined and reactive $Al_2O_3$. As a drying additive, polypropylene, polyethylene or cellulose fibers were added and the detailed castables compositions can be found in Table 1. It should be noted that changes in the water content were necessary to ensure similar levels of flowability for the samples with distinct fibers and the reference material without any drying additives. Also, the weight percentage of the fibers was different as the cellulose fiber is less dense than its synthetic counterparts, and it was decided to maintain the volumetric fiber content constant for all different additives tested.

Tab. 1: High alumina refractory castables compositions considered in the current study.

| Raw Materials | | 5CAC (wt.%) | 5CAC-PP (wt.%) | 5CAC-PE (wt.%) | 5CAC-Cel (wt.%) |

The castables without additives, with PP and PE fibers, were obtained following the standard protocol of pre-mixing the powders for 1 minute in a regular rheometer. Next, the water was added, and the composition was mixed for an additional 3 minutes. The sample with cellulose fibers was obtained using a different methodology. As its mechanism is based on the swelling of the fibers, before the castable preparation, half of the water added to the composition was mixed with the cellulose fibers in a bench mixer for 5 minutes. After that, the mixture of water and cellulose was added to the castable, following similar protocols to the ones used for the other compositions.

Afterwards, the compositions were cast in dense alumina cylindrical ceramic casings with internal diameters of 3.6cm and 5cm high with open ends (the bottom part was closed with adhesive tape during casting and curing) for the neutron tomography tests. The experimental layout of the in-situ drying tests is present in Figure 1. The sample is dried from an infrared heater placed close to its top surface. The heating rate applied was 20°C/min up to 600°C, with a plateau afterwards for 30 additional minutes. The whole setup is fixed on a turntable table with screws. To fill the gap between the sample and the Teflon container, and to avoid lateral heating, a thermal insulator is used. Regarding the sample, Figure 3 b), shows

a slice of the neutron tomography highlighting the impermeable ceramic casing. Finally, it should be noticed that the samples were placed in the opposite direction of the casting.

*Fig. 1: (a) Experimental set up for the neutron tomography test in the NeXT equipment at Institut Laue-Langevin (ILL) and (b) vertical slice of the 3D reconstruction of the neutron tomography of the sample showing the alumina casings.*

The neutron tomographies were acquired using the NeXT instrument at the Institut Laue-Lavengin (ILL). The true spatial resolution was around 190 µm whereas the time interval between two successive tomographies was 58.5s, as described in the tests reported by Tengattini et al. [15]. After the tests, the 3D volumes were reconstructed using the Feldkamp filtered back projection using a commercial software (X-act, by RX Solutions).

Considering the post-processing of the images, the drying front progression used for calculating the sizes of the dried zones (DZ) volumes was obtained through a gradient based algorithm, visually described in Figure 2.

*Fig. 2: Drying front position detection algorithm. Firstly, the mean of the intensity value on the radial direction was calculated inside the region of interest, then a Savitzky-Golay filter was used to reduce the noise of the data. Finally, the minimum of the derivative of the radial mean intensity with respect to the height defined the drying front position, which is represented by the blue line (notice how it is defined by the maximum of the yellow line on the derivative plot).*

A different method also used to quantitatively analyse the evolution of the water content during drying was the calculation of the normalized intensity evolution over slices of the sample. This is calculated using the ratio between the intensity of an image at a given moment and the median of the first 10 tomographies (representing the initial state before drying).

**RESULTS AND DISCUSSION**

The mass loss between the sample preparation and the experiment execution (the storage aging mass loss) and after the test is summarized in Table 2. It is possible to see that all samples lost between 2 wt.% to 7 wt.%, regardless of the composition.

Tab. 2: Summary of the water loss of each sample. All percentages are calculated as a fraction of the total water added in each composition.

| Test | Composition | Storage Aging Mass Loss (wt.%) | Experiment Mass Loss (wt.%) |
|------|-------------|-------------------------------|-----------------------------|
| 1 | 5CAC | 3.1% | 9.4% |
| 2 | 5CAC | 4.2% | 7.5% |
| 3 | 5CAC-PP | 3.3% | 14.4% |
| 4 | 5CAC-PP | 4.4% | 17.6% |
| 5 | 5CAC-PE | 3.0% | 15.4% |
| 6 | 5CAC-PE | 2.2% | 14.5% |
| 7 | 5CAC-Cel | 5.9% | 20.7% |
| 8 | 5CAC-Cel | 3.5% | 21.9% |

Direct comparisons between different samples using the data of Table 2 are not possible as the tests did not have the exact same duration, nonetheless, an overall trend can be identified when considering the experiment water removal, with the reference 5CAC composition without any additive displaying the smallest amount of water removed, followed by the PE and PP samples. The samples with cellulose were the ones with the highest quantity of water lost during the drying test.

In order to draw a clear comparison between the different tests, a relative time scale, $t_r$, is considered, in which the initial time is defined by the start of the drying front progression obtained through the methodology depicted in Figure 2. Axial slices of the normalized intensity sample are shown in Figure 3. It is possible to see that the sample with no additives (5CAC) was indeed the one with the smallest dried region (the area characterized by a smaller normalized intensity - in blue - at the top of the sample).

The evolution of the mass transport within the composition containing PP fibers showed a more intense drying between $t_r = 0$ min and $t_r = 12$ min, however, the size of the dried zone (DZ) remained similar to the 5CAC composition. At the end, the DZ is roughly 1.5 times bigger than the one seen on the sample with no additives.

The 5CAC-PE sample showed a moisture distribution at $t_r = 12$ min similar to the reference composition. This might highlight a permeability enhancing mechanism that starts later when compared to what is seen for the 5CAC-PP and 5CAC-Cel. The final condition shows a larger DZ than 5CAC, suggesting that the water removal rate increased over time. Moreover, the dried zone is not as intense as the other compositions containing additives.

Finally, 5CAC-Cel shows a fast and intense drying that proceeds with a constant water removal rate, as the DZ is the largest at both $t_r = 12$ min and $t_r = 20$ min and it has the smallest values of normalized intensity.

To further investigate these observations, quantitative analyses considering the relative drying volume percentage are presented in Figure 4. The reference composition was the one where the water removal was the slowest. For instance, it took around 30 minutes to reach the 20% of relative drying volume. That mark was reached after only 18 minutes for the 5CAC-PP, 13 minutes for 5CAC-PE and 10 minutes for the 5CAC-Cel. This is directly linked to the different mechanisms of actuation of the fibers.

Fig. 3: Normalized intensity at 0 min, 12 min and 20 min of relative time, $t_r$. This temporal scale considers the initial time ($t_r = 0$ min) as the beginning of the drying front progression detected by the gradient based algorithm.

It is known that cellulose can lead to higher permeability even before reaching 110º C [6], due to the removal of water from the swelled fibers, thus leading to a faster water withdrawn at presumably smaller temperatures. Polypropylene and polyethylene, on the other hand, depend on thermally-activated changes of their state that take place at higher temperatures [6, 7, 8], leading to the initial behavior closer to the reference one. After that, the permeability increases and the process is faster than in the 5CAC samples.

Fig. 4: Relative drying volume versus the relative drying time for all compositions. The dried volumes were obtained from the drying front position detection algorithm presented in Figure 2.

185

To investigate the influence of fibers on the moisture clog, the evolution of the normalized average gray value within a disk of the sample was analyzed, as shown in Figure 5. Among the compositions studied, the 5CAC composition exhibited a more prolonged moisture accumulation period (marked by gray values higher than the initial ones), while the 5CAC-cellulose composition showed a shorter duration. However, the total moisture accumulation was slightly more intense and occurred at a significantly faster rate. This observation indicates that the enhanced moisture transport occurs in both directions, towards the hot surface and into the center of the sample. The increased permeability, though, eases the rapid withdrawal of this accumulated moisture, before dangerous higher temperatures are reached, resulting in a faster and safer drying process. Similar behavior was observed for samples containing polypropylene (PP) and polyethylene (PE) fibers.

*Fig. 5: Normalized averaged gray value evolution for the central disk of the sample, shown in the inset.*

Thus, when considering unidirectional drying, additives that rely on mechanisms that are triggered at too high temperatures might actually be not as beneficial, as the entrapment of moisture can still take place in the colder regions of the refractory castable and potentially induce explosive spalling.

## CONCLUSIONS

The understanding of the drying process in refractories castables holds great potential for reducing the carbon footprint of the processing of these materials, thanks to the long drying curves, which are often overly conservative. Efforts to provide safe and efficient drying of refractory castables entail cheap and readily available additives that won't affect any of the required properties during their use.

Polymeric fibers have emerged as the most promising and widely adopted choice. Thus, the objective of this study was to investigate the impact of various permeability-enhancing additives from an unprecedented perspective. By employing neutron tomography, the drying process of compositions with polypropylene, polyethylene, cellulose fibers, or with no additives was observed in real-time.

It was found out that the 5CAC sample was the one with the smallest drying zone after the test followed by 5CAC-PP and 5CAC-PE. 5CAC-Cel was the one with the largest portion dried, indicating faster water removal with a constant drying rate. The moisture clog observed when cellulose was used was also the largest one observed, while being the shortest one in duration. The composition with no additive showed the longer lasting moisture accumulation.

In future works, modifications in the current methodology will be explored to enable the direct examination of the thermal behavior of fibers, aiming at uncovering the underlying mechanisms responsible for the increase of the castables' permeability. Once these mechanisms are better understood, synthetic fibers could be engineered to enhance their effectiveness, or alternative natural fiber options could be explored based on similar mechanisms. This approach would further contribute to greener practices, ensuring secure and faster drying processes.

# PRACTICAL EXPERIMENTATION AND MODEL DEVELOPMENT FOR THE DRYING OF MONOLITHIC REFRACTORY CASTABLES

Matthew Lambert[1]; Dana Goski[1]; Luke Gritter[2]; Kyle Koppenhoefer[2]

[1]Allied Mineral Products, LLC, Columbus, OH, United States; [2]AltaSim Technologies, LLC, Columbus, OH, United States

The presence of liquid in refractory ceramic protective linings can be detrimental or dangerous to many industrial processes. The removal of this liquid, usually water, via heating of monolithic refractory ceramics is a critical first step for their in-service use post-installation. If not carefully performed, however, temperature increases can lead to a build-up of steam pressure within the refractory due to a lack of steam escape pathways. If the pressure increases to above the refractory strength, the material can mechanically fail and spall. The physical properties of refractory ceramics, such as strength, permeability, and thermal conductivity, can be important variables that will determine the likelihood of an explosive spalling event. Using small scale experimental data and extensive numerical relationships from literature as input to a COMSOL Multiphysics model, the temperature and pressure evolution within a refractory monolithic material can be estimated. Medium and large scale experimentation can be used for nominal comparison and validation of the modelling results

# NUMERICAL MODELLING ANALYSES OF STEEL LADLE WEEP HOLE EFFICIENCA

## ABSTRACT

Refractory castable drying is a key processing step where explosive spalling can happen if the combination of generated vapor pressure within the material's pores and the thermomechanical stresses exceeds its mechanical strength. Therefore, to avoid major problems, refractory producers usually select conservative heating schedules. To attain lower energy consumption and faster drying, deeper analysis considering the material's composition and heating profiles can be carried out via computational simulations. Additionally, in the context of refractory castables applied for the lining of steel ladles, the drying process can be improved with the help of weep holes in their metallic shells. To the authors` knowledge, studies considering the effectiveness of weep holes in the decision-making process involving this equipment have not been reported in the reviewed literature. Nevertheless, refractory producers commonly adopt them based on experimental observations and their practical efficiency. In this context, this study aims to carry out computational simulations to highlight the behavior of a steel ladle lining drying designed with weep holes. The simulations enabled a better understanding of the pressure build-up and moisture flow to optimize the drying step without detrimental side effects.

## INTRODUCTION

The steelmaking industry relies on using of steel ladles for holding and conducting secondary refinement on steel. Because this process takes place at high temperatures, refractory linings are employed at the interface between the metallic shell and the transported material. These linings act as a barrier to prevent both thermal loss, liquid leakage and corrosion. [1].

In recent years, there has been a notable transition from the utilization of pre-shaped refractory bricks to monolithic working layers within the steelmaking industry [2]. This shift is driven by the numerous advantages offered by monolithic working layers, which include, but are not limited to, the absence of expansion joints and greater design flexibility in terms of shape and in some instances, higher installation rate. [1, 3].

However, in the process of obtaining the castable from powdered raw materials, water and additives are typically added. This addition acts both as a mixing medium and the required formation of hydrates when considering hydraulic binders, leading to an increase in green strength [3]. Consequentially, it is crucial to remove the water through a controlled heating schedule. Failure to do so may lead to the accumulation of vapor within the material's porosity, resulting in a pressure buildup. This process poses the risk of explosive spalling of the lining, which can cause damage to equipment and personnel. Thus, lasting maintenance time and loss of productivity may occur [4] thanks to overconservative and long heating protocols.

In previous studies conducted by the research group, methodologies for optimizing the heating schedule were examined. However, they have a limitation in terms of how much the heating rate can be increased before reaching a maximum threshold [5].

Therefore, this work focuses on exploring an alternative approach to drying through the numerical evaluation of incorporating weep holes into the metallic shell, which can release water through through the cooler surface of the ladle. Typically, these holes are manually drilled into the shell by operators and are commonly applied in the industry [6].

However, despite their widespread use, there is limited information available in the literature regarding general practices of weep hole design. Minimal details are provided, such as the importance of maintaining cleanliness and the typical diameter of the drilled holes [7]. Additionally, in case of lining failure, the likelihood of liquid metal pouring accidents poses an optimization task between increasing the number of weepholes while still keeping the security of the process. Thus, numerical modelling is proposed as a tool to assess the effect of weepholes on the drying behavior of refractory castables.

For such analysis, the mesh used in this study was initially generated using gmsh. Following, the FEniCS python library was employed for solving a numerical problem of drying using the finite-element methodology. The objective was to simulate the water removal process from the refractory castable lining of a steel ladle wall, evaluating the moisture vapor pressure and temperature at each point. The presence or absence of weep holes in the metallic shell was considered during the evaluation. Post-processing was conducted using tools such as numpy, matplotlib and scipy. These particular tools were selected for their open-source nature and large community users, reliability and efficiency.

## MATERIALS AND METHODS
### Material and Properties

The material considered for the simulations is a high alumina calcium aluminate cement-based castable, with a 5%wt content of this cement. The composition of the material is summarized in the Table 1.

Tab. 1: 5CAC castable composition.

| Raw Material | Mass Fraction (%) | Supplier |
| --- | --- | --- |
| Tabular Alumina (< 5 mm) | 74 | T-60, Almatis |
| Calcinated Alumina | 11 | CL370, Almatis |
| Reactive Alumina | 10 | CT30000SG, Almatis |
| CAC | 5 | Secar 71, Imerys Aluminates |
| Dispersant | 0.2 | Castament FS60, BASF |
| Water | 4.5 | - |

The particle size distribution of the material was adjusted using the Andreassen model with a packing coefficient of 0.21. Subsequently, the powder was homogenized with water and a dispersant using a home-made rheometer [8]. The resulting mixture was then shaped into samples for various tests, including:

1. TGA (Thermogravimetric Analysis) samples: cylinders with dimensions of 50 mm in height and 50 mm in diameter.
2. Three-point bending test samples: rectangular prisms with dimensions of 25 mm x 25 mm x 150 mm, following ASTM C583-15 standard with a loading rate of 12.9 N/s
3. Thermal conductivity measurement samples: rectangular blocks with dimensions of 233 mm x 114 mm x 64 mm, measured by the hot wire method, ISO 8894-2.
4. Permeability at room temperature measurement samples: cylinders with 25 mm height and 50 mm in diameter, following ASTM C577.
5. Density: small cylinders for the measurement using Archimedes methodology, as outlined in the ASTM C830-00 standard.

After shaping, the samples were cured for 24 hours at 30°C and 90% relative humidity. Following, all samples except the TGA ones were subjected to firing at temperatures ranging from 300°C to 500°C with 5 hours dwell time.

By conducting these measurements, the required physical properties were obtained to accurately define the material's constitutive laws in the numerical simulation.

Both thermal conductivity and permeability are crucial parameters for the numerical simulation [9]. The thermal conductivity evolution was evaluated at various temperatures, and the resulting behavior was fit to a polynomial curve to obtain a temperature-dependent law.

Regarding permeability, the method to obtain an extrapolation of the high temperature behavior can be found in [10].

Fig. 1: a) Thermal conductivity as a function of temperature. b) Extrapolation of the permeability curve. The measured value at room temperature is highlighted by a black point, whereas the methodology for the acquiring of the rest of the curve can be found at [10].

To compare the vapor pressure obtained by the numerical simulation with the local mechanical strength, a parameter called the "resistance ratio" was introduced, and it is defined as the ratio between the local vapor pressure and the local triaxial stress strength of the material. To assess the material resistance, the mechanical stress obtained from the three-point bending tests was converted to the resistance ratio using the method described in Figure 2.

Additionally, two different hydraulic conductivity values were assumed for the different layers of the material. For the permanent layer a value of 1e-8 m/s was considered whereas for the insulating one, 1e-6 m/s. These values were chosen to represent the permeability properties of each respective layer in the numerical simulation.

**Geometry and Meshing**

The chosen geometry for this study is the section of a wall from a steel ladle, as depicted in Figure 3. Its design is based on the works by Santos et al. [1]. To implement it and generate a mesh,

the gmsh software was used. Initially, a basic geometry was generated, considering the following thicknesses: 200 mm for the working layer, 50 mm for the permanent layer, and 34 mm for the insulating one, as the wall illustrated in Figure 3.

Fig. 2: a) Conversion schedule of the strength from three-point bending test (3p) to uniaxial (uni) to triaxial (tri). b) Values obtained in each of these steps. [5, 10]

Fig. 3: Schematic for a steel ladle, displaying the many layers in which this work was based at [1].

Previous studies conducted by the research group have observed that the thermal gradient in the metallic shell is relatively low due to its high thermal conductivity. As a result, it was found that this specific layer could be replaced by a Dirichlet boundary condition on the cold face. This approach offers several benefits, including easier manipulation of results and faster simulation times.

In the study, a 2 cm weep hole was incorporated into the ladle shell identifiable in Figure 4 as a more refined zone located on the ladle's rightmost face and the white face color of the polygons.

Local refining techniques were implemented in the interface zones between the different layers. Additionally, near the weep hole, this strategy was also employed. The purpose of it was to reduce the local moisture velocity computing error, as larger elements can lead to larger pressure gradients.

Figure 4 presents the meshed geometry, specifically representing a quarter of a weep hole and the adjacent region.
*Fig. 4: Meshing of the selected geometry, units are in meter.*

For the final geometry, the boundary conditions enforce symmetry on the side planes of the ladle sample. Specifically, the larger sides of the ladle, measuring 284 mm x 100 mm in Figure 4, exhibit symmetry. As shown in Figure 5, the weep holes are arranged in a square mesh pattern with a distance of 200 mm between the centers of the weep holes.

*Fig. 5: Representation of simulated geometry. Black lines identify the symmetry planes whereas the red circles are the weep holes.*

**Simulation setup and post-treatment**

The problem at hand was solved using the FEniCS python library, which provides a finite element environment for numerical simulations. The model is based on the works by Bazant [11] and Gong [12], which consider a single flowing phase percolating through the materials porosity. Further details about the specific numerical model and its application can be found in previous publications by the research group [5, 10].

In the simulation, the heating conditions were applied to the hot face, which corresponds to the interface between the working layer and hot air. This was achieved using Dirichlet boundary conditions. On the other hand, the cold face (where the weep hole is located) was subjected to cooling by convection and radiation. Surface mass transfer was allowed at the hot face and also at the weep hole when it was present, while the remaining portion of the cold face, representing the metallic shell, was assumed impermeable.

Because the model considers a single flowing phase, local refinement was implemented between the different layers to enhance numerical convergence. The properties assigned to the working layer were measured from the reference material, whereas the properties for the permanent and insulating layers were adapted from the work by Santos et al. [1];

The simulations have an initial temperature of 25°C which is gradually increased at a rate of 100°C/h on the hot face until

reaching 825°C. This temperature profile was applied to assess the impact of the presence or absence of the weep hole on the drying process of castable.

For post-processing, the meshio, numpy, and scipy libraries were employed to compute water content and velocities. Water content was calculated based on the current pressure and temperature, whereas the velocity was determined using the pressure gradient according to Darcy's law. The obtained data were visualized using matplotlib, which served as a tool for data visualization and analysis.

**RESULTS AND DISCUSSION**

Following the completion of the simulations, the results were extracted and analyzed as described earlier. Figure 6 illustrates the evolution of the maximum pressure at each time step over the time. In the early stages of the drying process, there is no significant difference observed between the simulations with and without the weep hole. This is due to the drying front being located closer to the hot face, resulting in minimal moisture flow towards the colder regions, where the effect of the weephole's presence is the largest.

As the drying process progresses, the pressure gradient at the drying front leads to the accumulation of moisture within the cooler zones of the ladle wall, which, in turn, triggers the moisture clogging. This effect is highlighted by the significant pressure peak in the red curve, which reaches values exceeding 20 MPa. This peak indicates the formation of localized high-pressure vapor region within the ladle wall as a result of moisture accumulation.

*Fig. 6: Evolution of the maximum pressure for each geometry as a function of time.*

This phenomenon occurs when the drying front transfers humidity from hotter zones to cooler ones, causing water to readsorb into the inner regions of the castable lining. It can happen in any monolithic wall setup, but it is more pronounced when the cold face lacks permeability for moisture transportation. Without it, water accumulates, leading to higher pressures and potential issues like damage to the vessel. Therefore, weep holes provide a controlled means of moisture transportation, diminishing the accumulated pressure and the risk of explosion of the lining.

In the present model, which considers a single flowing phase, it is not possible to define the specific physical state of water. However, it is feasible to observe the accumulation of free adsorbed water or changes in local relative humidity, as supported by experimental observation [13].

In Figure 7, the water content evolution in each layer is shown, normalized to the initial content. With the temperature increase, the sample with a weep hole experiences faster drying of free adsorbed water, while the sample without a weep hole only redistributes the water in the cooler zones, resulting in a minimal difference in total adsorbed water in the body. Between 200°C and 400°C, structural water is released, but trapped moisture leads to increased adsorption and the overall water content. As free water dries up, vapor pressure decreases, and higher temperatures result in a quick water withdrawal due to pressure gradients.
*Fig. 7: Evolution of the free adsorbed water for each geometry as a function of time. The peak in the red curve indicated the phenomenon of moisture clogging.*

Figure 8 illustrates the calculated exit velocity at the hot surface. The presence of a weep hole reduces the velocity in this zone, as moisture can exit through the opposite side of the lining. Conversely, the absence of a weep hole leads to slightly higher and delayed velocity peaks, resulting from the limited withdrawal of trapped moisture. Additionally, non-zero velocity values at the early stages of drying for the design without a weep hole indicate that there is moisture exiting through the heated surface in the same way it is being released in the lining with the hole. This suggests that water is being transferred in the cooler zones at a similar rate, indicated by the low variance in the total free water content as shown in Figure 7, as a decrease should be expected if water was not being adsorbed within that region.

*Fig. 8: Evolution of the fluid velocity at the hot face for each geometry as a function of time.*

## CONCLUSIONS

In this study, the drying process of a steel ladle wall was analyzed and the effect of weep holes on moisture transfer was evaluated. Using numerical simulations based on the finite element methodology, the pressure, water content and exit velocity of water during the drying process was assessed.

The simulations showed that weep holes played a crucial role in enhancing moisture removal. In the absence of it, water accumulated in cooler zones, lead to pressure peaks and the phenomenon of moisture clogging, whereas their presence prevented such accumulation and reduced the pressure buildup.

The water content evolution analysis indicated that the presence of such holes resulted in the drying of free adsorbed water, whereas in their absence moisture was redistributed to cooler zones. Structural water released during the drying process increased the overall water content due to adsorption in trapped moisture zones.

Furthermore, the exit velocity of the fluid on the heated linint surface was examined. Weep holes allowed moisture release through the opposite side of the lining, reducing the velocity observed in the heated surface. Conversely, without weep holes,

higher and delayed velocity peaks were observed, indicating limited and delayed withdrawal of trapped moisture.

In summary, the current study highlights the significant influence of weep holes on moisture transfer during the drying of a steel ladle wall. The findings provide an uprecendeted analysis that can enable valuable insights for optimizing ladle lining design and maintenance, helping to improve the efficiency and safety of the drying of castables as well as increase the overall productivity in the steelmaking industry.

## ABSTRACT

Matching industrial activity and environmental protection is one of the toughest challenges of the 21st century. As high consumers of fossil-based materials, refractory manufacturers are consistently seeking processes that can provide higher energy efficiency. In this sense, using microwaves for ceramic sintering has shown significant advantages compared with the conventional route (based on electrical or natural gas heating), reducing lead time, enhancing mechanical properties, and demanding less power. However, this method has been underexplored for such application due to the lack of knowledge about refractory phases capable of effectively interacting with this type of electromagnetic radiation. Thus, this work addressed the potential of applying ZnO as a microwave absorber in $Al_2O_3$-based refractories, comparing microwave-sintered castables with electric-heated ones thermally treated up to 1700 ºC. Although presenting a relatively high vapor pressure, the content of ZnO (11.4 wt%) remained stable at all temperatures applied in the electric-heated furnace, whereas significant evaporation was detected for samples microwaved above 1300 ºC. The mechanisms related to this behavior and strategies to avoid it are discussed. On top of that, the microwave sintering method showed benefits such as higher densified microstructure with open pores remaining homogeneously scattered in the matrix, enhanced mechanical properties at room temperature, 26-fold faster lead time, and roughly-estimated 70%-lower energy consumption. Thus, this sintering method might be a promising alternative to increase the efficiency of refractory manufacturing, lowering environmental impacts and production costs.

## INTRODUCTION

In a world with finite natural resources and where energy production fundamentally relies on the burning of fossil fuels, fulfilling the upcoming energy demand (47 % increase by 2050), ensuring environmental protection is considered one of the greatest challenges of this century[1]. Regardless of introducing new non-polluting energy sources, it is believed that such a balance cannot be achieved without increasing the efficiency of the currently-used processes[1]. Accounting for close to 12 % of all energy consumed worldwide[2], special attention must be given to industrial processes operating at high temperatures, such as the conventional sintering of ceramic materials. In this procedure, temperatures usually between 1000 ºC and 2000 ºC are applied for several hours to compact powder systems aiming at inducing the formation of ceramic bonds between the particles[2]. Aiming at speeding up the sintering step and minimizing the energy consumed for it, different techniques have been developed in recent decades, such as microwave sintering[2]. However, to be effective, this technique relies on the presence of phases capable of interacting with microwaves, converting the electric and/or magnetic fields into thermal energy, or even directly enhancing the diffusion process of the sintering mechanisms. These aspects depend on the materials' dielectric and magnetic properties and, for a broadly used ceramic oxide range (*e.g.* $Al_2O_3$, MgO and $SiO_2$) that are transparent to microwave at room temperatures, they do not allow microwave heating without using susceptors[3]. However, scaling up this sintering process to massive production, as is the case of refractories, remains a challenge[3]. Thus, adding microwave-absorbing compounds may foster using this sintering method for refractories and, as indicated by Bhattacharya and Basak[4], zincite (ZnO) is a promising candidate due to its suitable microwave absorption.

Notwithstanding the changes led to the castables' properties, recent studies[5,6] pointed out the feasibility of applying ZnO in alumina-based castables as these oxides react at intermediate temperatures (~ 800 ºC) forming a spinel-like phase with interesting properties (*e.g.* high refractoriness and low coefficient of thermal expansion). In this work, microwave-sintered ZnO-containing alumina-based vibrated castables were produced at different temperatures. Some of their key properties, microstructural features and energy demanded for sintering were assessed and compared to their conventionally fired counterparts.

## EXPERIMENTAL PROCEDURE

The vibrated castables analysed in this work were produced with a packing distribution according to the modified Andreasen's model (q = 0.26) and following the procedure described in[5]. Calcined and tabular alumina (CL370 and T60/T64, Almatis, Germany) were used as $Al_2O_3$ sources, whereas 11.4 wt% of ZnO (analytical grade, Basile Química, Brazil) was added to induce the formation of 23.1 vol% (25.7 wt%) of $ZnAl_2O_4$ after firing. The castables were bonded with 6 wt% of calcium aluminate cement (CAC, Secar 71, Imerys Aluminates, France) and dispersed using 0.2 wt% of a commercial surfactant (Castament FS60, BASF, Germany), as shown in Tab. 1.

Tab. 1: Overall castable composition.

| Raw material | wt% |
|---|---|
| Tabular alumina (<6 mm) | 77.6 |
| Calcined alumina (CL370) | 5.0 |
| Calcium aluminate cement | 6.0 |
| ZnO | 11.4 |

This dry mixture was firstly homogenized for 5 minutes in special rheometer equipment designed to process refractory castables, followed by the addition of 3.8 wt% of distilled water. The fresh suspension was molded into bars (25 mm x 25 mm x 150 mm), cured in a climatic chamber (VC 2020, Vötsch, Germany) for 24 h under 50 ºC and 80 % of relative humidity, dried at 110 ºC for another 24 h, and calcined at 600 ºC for 5 h.

The calcined samples were then sintered at different temperatures up to 1600 ºC using a conventional electric furnace (model BF51314C, cavity capacity of 2.5 L, Lindberg/blue, USA) or up to 1700 ºC in microwave equipment (model MS6K, multimode cavity, 2.45GHz, useful cavity capacity of ~ 3 L, Cober Electronics, USA) with effective power (also referred to as non-reflected or forward power) up to 4 kW and silicon carbide as susceptors[4]. In the former case, a constant heating rate of 2 ºCmin$^{-1}$ and a dwell time of 5 h was applied, whereas for the latter, 50 ºCmin$^{-1}$ up to 1100 ºC and 20 ºCmin$^{-1}$ above it, and dwell time of 15 minutes at the selected temperature, was used. To ensure proper temperature control, a type-B thermocouple (Thermo Fisher Scientific, USA) or a pyrometer (MA2S, Marathon Series, Raytek, USA) were applied in the conventional and microwave equipment, respectively. Moreover, the electric power required for the set firing schedule in both furnaces was tracked down using the potentiometer embodied in each piece of equipment (BF51314C and MS6K, for the electric and microwave furnaces, respectively).

The previously described sintering conditions gave rise to the nomenclature system, depicted in Tab. 2. After the sintering step, all samples had their mass loss assessed with an analytical balance (model TS400D, Ohaus, USA). Young's modulus was measured by the non-destructive sonic resonance technique (Scanelastic equipment, ATCP Physical engineering, Brazil). Cold modulus of rupture (CMOR) was carried out in MTS 810 equipment (MTS Systems, USA) under 3-point bending (ASTM C133 – 97) and

using 8 specimens for each sintering temperature. Quantitative mineralogical content was conducted by applying Rietveld's refinement (Topas software, version 4.2, Bruker, USA) on the X-ray diffraction patterns (D8 Focus, Bruker, Germany) obtained for grounded samples. Open porosity and density were evaluated by the immersion method based on Archimedes' principle and using kerosene as liquid media (ASTM C830-00). Based on the samples' density and the theoretical density considering the quantitative phase content (XRD), the total porosity was estimated. The microstructure of some selected samples was evaluated by scanning electron microscopy (Inspect S50, FEI, USA) coupled with an energy-dispersive X-ray spectroscope (EDS). Additionally, thermodynamic calculations (FactSage 6.4, CRCT, Canada) were carried out to assess the oxygen partial pressure ($pO_2$) inside the microwave cavity during the sintering.

Tab. 2: Nomenclature used for the distinct sintering methods.

| Firing Method | Maximum temperature | Nomenclature |
|---|---|---|
| Electric furnace | 1150 ºC | EF-1150 |
| | 1300 ºC | EF-1300 |
| | 1500 ºC | EF-1500 |
| Microwave | 1150 ºC | MW-1150 |
| | 1300 ºC | MW-1300 |
| | 1500 ºC | MW-1500 |
| | 1700 ºC | MW-1700 |

**RESULTS AND DISCUSSIONS**

Aiming at addressing the effect of the sintering method on the microstructure of the castable, the total and open porosity were measured and are depicted in Fig. 1. For conventional firing, it could be seen that the increase in the thermal treatment temperature resulted in a decrease in both open and total porosity, especially in the former. Additionally, for the same sintering process a general trend between total and open porosity could be seen (indicated by the red dotted line), in which the total porosity scales with the open porosity. This behaviour is expected for this traditional sintering technique as the densification process will usually act similarly on open and closed pores located among the particles (whereas pores within the grains require much higher energy to be eliminated), reducing their amount[3].

Fig. 1: Open and total porosity of rupture for conventional (EF) and microwave (MW) sintered castables. Adapted from Ref. 12 with Elsevier permission (nº 5577640295991).

As higher heating rates favoured the densification process rather than grain coarsening, a more significant reduction in both types of pores was expected for microwave sintering[7]. Nevertheless, for these samples, the increment in the sintering temperature led to a significant total porosity decrease, as expected, but with an open porosity increase. Therefore, although more effective to densify the castable composition evaluated in this work, the microwave heating technique also induced a higher number of open pores. It is worth highlighting that this additional open porosity is not necessarily detrimental to the castables' properties. On one hand, if they are small and well dispersed, these open pores can induce fracture energy increase by crack branching and/or increasing the crack tip curvature radius[8]. On the other hand, if coarse and preferentially

located, this open porosity will act as critical defects and paths for slag infiltration, reducing the mechanical and corrosion resistances. To evaluate the impact of each sintering condition on the mechanical properties of the castable, Youngs' modulus (E) and cold modulus of rupture (CMOR) tests were carried out and are presented in Fig. 2.

Fig. 2: Elastic modulus and cold modulus of rupture. Adapted from Ref. 12 with Elsevier permission (nº 5577640295991).

Analysing these results, one can see a clear relationship between E and CMOR for both sintering techniques. Additionally, although increasing the sintering temperature resulted in enhanced mechanical properties for conventional and microwave-sintered samples, this effect was much more significant for the latter. The joint analyses of Fig. 1 and Fig. 2 points out, as expected, that the total porosity plays a major role on the mechanical strength. Therefore, the significant densification led by microwave sintering resulted in samples with higher E and CMOR, which is attributed to the higher heating rate and enhanced ion diffusion induced by this sintering technique[2]. Note that the samples sintered by microwave radiation at 1150 ºC for 15 minutes presented equivalent strength to those conventionally fired at 1500 ºC for 5 hours. Thus, while the conventional sintering (1500 ºC) lasted 17.5 h to complete the firing schedule, the microwave heating (1150 ºC) required less than 40 minutes to produce castables with similar E and CMOR, which is twenty-six-fold faster.

Besides the time saving, the energy consumption to manufacture the specimens was also highly impacted by the firing method. Fig. 3 shows the energy required to run the sintering procedure in the electric furnace (2 ºCmin$^{-1}$ up to 1500 ºC and 5h of dwell time) and in the microwave one (50 ºCmin$^{-1}$ up to 1100 ºC and 20 ºCmin$^{-1}$ above it, with a dwell time of 15 minutes). Analysing it, one can see that the conventional furnace demanded 3.5 kWh per sample, whereas the microwave consumed 1 kWh per sample, which is ~ 70 % lower. This higher efficiency can be attributed to the lack of energy loss for heating up the air and insulating refractories inside the microwave equipment. Conversely, in conventional heating, all the systems (air and refractories included) will reach high temperatures, implying higher energy losses[2].

Fig. 3: Energy demanded for each bar sample to be sintered (● denotes the end of the firing process). Adapted from Ref. 12 with Elsevier permission (nº 5577640295991).

Therefore, to reach equivalent E and CMOR in the analysed system, the microwave sintering (1150 ºC / 15 min) was 26-fold faster and 70 % more energy-efficient that the conventional electric-heated equipment (1500 ºC / 5 h). Although these are eye-catching features, it is worth noticing that suitable E and CMOR are

just two of several other key properties that must be fulfilled by the refractory material, depending on the application. Therefore, further analyses are required to assess the feasibility of applying such a sintering technique to a broad production of refractories. Moving forward on these characterizations, the microstructural changes resulting from the distinct sintering methods were evaluated by BSE/SEM, depicted in Fig. 4, of samples thermally treated at 1150 ºC and 1500 ºC. It is worth noticing that the comparison between samples produced by both sintering techniques must consider that the microwaves electromagnetic fields affect samples' thermodynamic stability and enhance the ion mobility[9]. On top of that, the quite distinct heating rate used for each sintering technique also helps to induce different microstructures, as previously reported by several other authors[3].

Fig. 4: Microstructure of samples sintered at 1150 ºC or 1500 ºC assessed by SEM/BSE. Adapted from Ref. 12 with Elsevier permission (nº 5577640295991).

Initially, firing at 1150 ºC by both sintering methods resulted in similar microstructures comprised of well-defined alumina aggregates with $ZnAl_2O_4$ formed in the matrix, which also presented several pores and undensified regions attributed to the significant Kirkendall effect undergone by this composition[5]. As the temperature increases to 1500 ºC, some distinctions between the heating methods stand out. In tune with total porosity analysis (Fig. 1), the conventionally fired samples remained with a less densified gahnite-based matrix. Moreover, at 1500 ºC, the samples also presented acicular-grown calcium hexaluminate ($CaO·6Al_2O_3$ or $CA_6$) as a result of the calcium aluminate cement (CAC) addition. On the other hand, for the microwave sintering, heating at 1500 ºC led remarkable microstructural changes, with nodular-like $CA_6$ formation in a highly densified matrix containing spherical pores. These types of microstructures agree with the porosity results presented in Fig. 1, in which the microwave sintering was more effective to reduce total porosity, but induced the formation of a higher number of open pores.

Aiming at assessing the mechanism that led to this open porosity increase for the microwave sintering, calcined samples had their mass loss analyzed after subsequent thermal treatments, as shown in Fig. 5 (a). At temperatures in the range of 1150 ºC up to 1500 ºC, no appreciable mass loss was detected for conventionally fired samples, which is assigned to the lack of organic or hydrated phases, as they were decomposed in the calcining step. However, the mass loss faced by microwave-heated samples stood out. Firing at 1500 ºC and 1700 ºC in the microwave equipment resulted in a mass decrease of 1.3 wt% and 4.3 wt%, respectively. To track down the causes of these mass losses, quantitative XRD analyses were conducted and Fig.5 (b) depicts the changes in gahnite content for the conventionally- or microwave-heated samples.

Fig. 5: (a) Mass variation after firing; (b) $ZnAl_2O_4$ (gahnite) content measured by quantitative XRD. Adapted from Ref. 12 with Elsevier permission (nº 5577640295991).

Conversely to the conventional firing, in which gahnite was stable at all analyzed temperatures, the microwave heating led to partial gahnite decomposition at 1500 ºC and 1700 ºC. Moreover, as no other Zn-containing phase was detected and the reduction in $ZnAl_2O_4$ content took place along with alumina content increase, gahnite decomposition could have happened by the Zn volatilization, which was withdrawn from the spinel structure as gaseous zinc, leaving $Al_2O_3$ behind. The zinc removal from the spinel structure was already studied in the literature, especially applied to zinc recovery from the blast furnace dust, which presented up to 5 wt% of zinc ferrite ($ZnFe_2O_4$) and gahnite ($ZnAl_2O_4$) in its composition[10]. Nevertheless, in that dust, zinc volatilization just takes place close to 1300 ºC at reducing atmospheres[10]. Although neither the electric furnace nor the microwave equipment had a controlled atmosphere, the latter presented susceptors made out of silicon carbide, which could be oxidized at high temperatures leading to a reducing environment inside the microwave chamber.

To evaluate this hypothesis, a piece of the silicon carbide susceptor used for a single sintering (1500 ºC / 15 min) in the microwave equipment [a picture of distinct pieces before and after such thermal treatment can be seen in Fig. 6] had its transversal sectioning evaluated by SEM, depicted in Fig. 6. A $SiO_2$ layer on the surface of the SiC susceptor was observed and its mean thickness measured was 64.9 µm. Based on this oxidative reaction zone, a $pO_2$ down to $10^{-15}$ atm and $10^{-13}$ atm are foreseen by the thermodynamic simulation to be formed inside the microwave chamber at 1500 ºC and 1700 ºC, respectively. Therefore, although experimental measurements are required to precisely determine the real $pO_2$-value during the microwave sintering, it can be inferred that the SiC oxidation will lead to a reducing atmosphere inside the microwave chamber during sintering.

Fig. 6: Distinct SiC-based susceptors pieces before (as received) and after the microwave treatment up to 1500 ºC for 15 minutes under uncontrolled atmosphere, and SEM image of the $SiO_2$ layer formed on the SiC susceptor surface after one heating at 1500 ºC for 15 minutes. Adapted from Ref. 12 with Elsevier permission (nº 5577640295991).

As previously discussed, well-distributed small pores in the highly densified matrix of the castable are not necessarily undesirable. However, for some applications in which the castable will be in contact with molten media (slag or metal), these open pores can increase the susceptibility to corrosion. Thus, a likely strategy to merge the high strength (E and CMOR) provided by the microwave sintering at higher temperatures (> 1300 ºC) with the minimization of the open porosity is attained by applying a purging gas flow inside the microwave chamber to reduce the SiC oxidation, avoiding the formation of a reducing atmosphere during the firing procedure. To assess such an approach, argon (Ar, analytical grade) was used to continuously purge the microwave chamber (flux of 1.5 L min$^{-1}$) when heating at 1500 ºC for 15 min, resulting in the castable microstructure depicted in Fig. 7. Although not fully avoided, the porosity created due to ZnO volatilization was minimized and the mean size of the pores was reduced. Compared to the samples fired at the same temperature and dwell time, but without atmospheric control, lower mass loss after sintering (0.65 wt% vs. 1.3 wt%), a decrease in the total and open porosity (21. 2 % and 16.4 % vs. 22.9 % and 18.7 %, respectively), higher E (154 GPa vs. 142 GPa) and improved CMOR (48 MPa vs. 41.4 MPa), were achieved. Moreover, another interesting aspect was the formation of the $ZnAl_2O_4$ phase within the alumina aggregates. Thus, conversely to the microstructure obtained for the microwaved samples (1500 ºC / 15 min) in an uncontrolled atmosphere, the gahnite formed inside the alumina aggregates could be preserved in a saturated argon environment.

Fig. 7: Microstructure (SEM/BSE) of microwaved samples processed at 1500 ºC for 15 minutes under a controlled atmosphere (Argon, 1.5 L min$^{-1}$). Adapted from Ref. 12 with Elsevier permission (nº 5577640295991).

These results indicate that the zinc volatilization was minimized by controlling the atmosphere during the microwave sintering, but it was not completely halted. Two non-mutually exclusive mechanisms could explain such behaviour: (i) the electromagnetic microwave fields imposed on the sample at high temperatures may change the thermodynamic stability of zinc in the structure (it is worth noticing that all thermodynamic calculations were conducted considering no electromagnetic fields due to the lack of data under such conditions); (ii) the gas flux applied (1.5 L min$^{-1}$) increased the $pO_2$ during the sintering, but it was not enough to avoid the formation of a reducing atmosphere. The evaluation of such a hypothesis requires further analysis, however, for the second case, replacing silicon carbide susceptors by oxide materials could be a suitable way to avoid a reducing atmosphere during the microwave sintering procedure[4]. In this sense, some promising alternatives are being evaluated.

## CONCLUSIONS

The feasibility of applying microwave sintering to ZnO-containing alumina-based castables bonded with CAC was assessed using SiC susceptors up to 1700 ºC with a dwell time of 15 minutes. To enable comparisons, conventionally fired samples were produced in an electric furnace after sintering for 5h at selected temperatures. Due to the higher heating rate and enhanced ion mobility provided by the microwave technique, denser (lower total porosity) and stronger (higher E and CMOR) samples were produced in a much faster and 70% less energy consuming sintering procedure. The microwave processing also induced an increase in open pore content, as shown by SEM micrographs. The pores were relatively small in size and homogeneously scattered in the matrix of the castable, which could positively impact some thermomechanical properties. Despite these worthwhile aspects, mass loss and quantitative XRD indicated zinc volatilization for microwave samples heated above 1300 ºC in air. When a purging inert gas flux was applied to the microwave sintering up to 1500 ºC, mass losses were significantly decreased, corroborating the hypothesis that a reducing atmosphere is fostering such ZnO volatilization. Therefore, even though some parameters must be optimized, the present work highlights that microwave radiation could be applied to thermally treat some pre-shaped refractory compositions, leading to environmental, productivity and performance benefits.

# ONE SIDED DRYOUT DEGRADATION

Joshua Sayre, Jeffrey Bogan, HarbisonWalker International, Pittsburgh, USA

## ABSTRACT

Dryout of monolithic products is the last step of a successful installation. Depending on the nature of the dryout; steam and internal pressures can degrade the mechanical properties of a product even before the material is put into service. In extreme cases, the lining spalls and needs reconstructed. While a spalled lining is an obvious, mechanical properties of a lining that has not spalled may be decreased that can reduce the linings service life without any visual evidence of damage. Studying the residual properties of samples from panels dried from one side, degradation in mechanical properties were observed that influence the rate at which lining can be heated up.

## INTRODUCTION

One of the key attributes of a successful monolithic refractory installation is the dryout or the removal of the water. The water takes two forms within a monolithic product either physical or chemical, bound in cement hydrates. Two typical situations occur upon dryout either the lining survives the dryout and is put into service, or the material can spall and thus require removal or additional repair. However, even if the lining has not spalled the lining may have been degraded on dryout from the introduction of cracks and potentially reducing the life span of the lining. Refractory producers recommend following carefully controlled dryout profiles to maximize the performance of a lining. These profiles take into lining configurations and factor in a degree of safety to reduce any degradation to the material.

Calcium aluminate cement (CAC) bonded refractories dominate the monolithic refractory products due to their relative ease of installation, green strength, and suitable properties. Upon installation, the CAC forms four major hydration products: free water (100°C), $7C_3AH_6$ (227°C), $C_3AH_6$ (277°C), and $C_3AH_{1.5}$ (549°C). As the temperature of the lining increases; steam possesses an exponential increase in pressure with temperature. If the pressure exceeds the strength of the material, cracks will form, and the material can catastrophically fail. Cracks can also be formed by the differential thermal expansion due to the transient heat wave through a refractory upon the initial heat-up. Any cracks can cause permanent detrimental reduction in mechanical strength, because steam pressure cannot be relieved quickly through crack propagation without catastrophic spalling. Organic dryout fibers are utilized to help form channels to increase the permeability of the product and allow for the successful dryout.

The work here focuses on the cracks and observable changes based on different dryout rates utilized in one sided dryouts. The goal is to better understand how faster one side dryouts permanently degrade the mechanical properties of a lining

## TEST PROCEDURES

Samples of 46cm x 30.5cm x 20cm were formed inside a metal shell with 101.6cm solid sides (see Fig 1 & Fig 2). The samples were either cast, gunned, or rammed into place. After curing, the test pieces were placed into the door of a gas fired kiln. Three Type-K thermocouples were used to monitor the test panels inside the door of the kiln: two on the front face and one thermocouple mounted in the back of the panel.

Three types of products were chosen to perform the one-sided dryout testing: lightweight gunite mix, 60% alumina low cement dense gunite mix, and 85% alumina phosphate plastic mix. Three samples (23cm x 11.5cm x 5cm) were cut from each panel representing the hot surface, intermediate surface and back (see Fig

3). A set of standard samples were reheated using standard heating rates for property testing - cut before reheating.

The kiln ramp rate was varied depending on the product and desired testing. The lightweight product had the most testing performed: 55°C/hr, 167°C/hr (2x), 277°C/hr, and 417°C/hr. (See Fig 4). One 166°C/hr run experienced a rapid heat-up with an excursion straight to 204°C before aligning with the set point for the kiln. The low cement dense castable was tested at 111°C/hr and the 85% alumina phosphate plastic at 277°C/hr. All pieces were ramped to 815°C and held for 16 hours before cooling at 55°C/hr.

Fig. 3: Schematic of the Samples Cut from the Prepared Panels

Fig 4: Kiln Profile of Heat-ups for the lightweight gunite mix.

## RESULTS AND DISCUSSION

The concern with increasing the ramp rate is degradation in the mechanical properties of materials due to the increase in cracking as steam escapes due to the physical and chemical water contained in the refractory[1-3]. An additional degradation most likely can occur due to the differential thermal expansion of the material with faster heat-ups with extreme cases being thermal shock. Combining these two forces together can lead to increased cracking and degradation of the final properties of the monolithic lining. When examining the degradation of the lightweight castable this became the focal point of the analysis.

Fig 5: Percent Change in CCS from 55°C/hr to faster dryout rates for 1.28 g/cc LW Gun Mix

With each increasing ramp rate, the resulting CCS shifted lower with the 417°C/hr ramp rate resulting in over a 1/3 reduction in CCS strength after ramping the simulated lining (See Fig 5). No visible cracks were apparent. The observed trends in MOR did not align with the shifting ramp rate, which likely indicates the degradation due to the dryout is less apparent in MOR since this is more related to internal macro crack generation for a middleweight refractory. The sample that experienced a rapid excursion to 204°C before adjusting the temperature profile exhibited the highest loss in CCS due to the extreme excursion. While not targeted to be part of the analysis, this provided very insightful data on very rapid heating rates because these types of excursions are not uncommon due to the difficulties of maintaining low temperatures with process heaters versus utilizing specifically designed excess air burners for dryout.

Shifting to the dense 60% alumina gunite mix, a 167°C ramp rate caused extensive cracking that didn't affect the CCS as much as the MOR (see Table 1). While the CCS did decrease by 10-20%, the MOR decreased between 50-65%. The cracking emanated from the hot face of the block, which is likely the difference between the larger percent drop in MOR versus the lower percent drop in CCS. While the cracks will leave a permanent reduction in the mechanical properties, they may be acting as channels for moisture to escape the castable.

Table 1: 60% Alumina Dense Gunite Mix After 167°C/hr. STD is 55°C/hr samples dried separately

| 815°C | | | |
|---|---|---|---|
| | STD | Hot | Mid | Cold |
| Density (g/cc) | 2.26 | 2.23 | 2.23 | 2.22 |
| MOR (MPa) | 10.4 | 3.7 | 5.0 | 7.3 |
| CCS (MPa) | 54.1 | 47.6 | 44.6 | 44.3 |

Rammed 85% alumina phosphate plastic also produced significant degradation in mechanical properties when heated at 417°C/hr. Phosphate plastics are often recommended to be heated at faster rates due to their typical usage as patches and phosphate bonding. Phosphate bonding does not produce permeability reducing hydrate phases and contains less water that needs to be removed. However, phosphate bonded materials still require a controlled dryout. The phosphate materials go through a softening as phase changes occur with the final crosslinking occurring after 250°C. Due to the softening and lower strength until reaching the desired temperature, the transient heating conditions through the block led to cracking that radiated with the temperature profile through the block. This isn't surprising as layers of material would have changing phases and varying strength creating stress planes within the mix. The degradation yielded a 75% reduction in CCS and 90% reduction in MOR (see Table 2).

Table 2: 85% Alumina Phosphate Plastic Testing After 417°C/hr

| 815°C | | | |
|---|---|---|---|
| | STD | Hot | Mid | Cold |
| Density (g/cc) | 2.62 | 2.38 | 2.41 | 2.28 |
| MOR (MPa) | 10.3 | 1.5 | 2.1 | 1.7 |
| CCS (MPa) | 44.3 | 13.1 | 11.0 | 9.2 |

197

## CONCLUSIONS

Monolithic dryout is a critical aspect of a successful installation. While the focus of most dryout testing and analysis is on successfully removing the water and surviving; the work presented here identified cracking from the heat-up causing permanent degradation in the mechanical properties of the lining with accelerated heat-ups in one-sided drying situations. The faster the heat up rate the greater the strength loss even without catastrophic failure occurring. A lightweight gunning mix was able to be dried out at an accelerated rate due to the high porosity/permeability (higher water) nature of the mix with only minimal strength degradation. For a dense castable and phosphate bonded ram mix, 38°C/hr is still recommended. This aligns with most fired brick manufacturer recommendations due to the inherent concerns with thermal expansion and lowering the chance of cracks.

## ABSTRACT

Colloidal silica has been used as a CaO-free binding system over a long time. The drawback of colloidal silica castable has been the low green strength and long setting times compared to CAC-based castable [1]. Yaghoubi et al. found that siloxane bond formation increases when CAC is added to colloidal silica-bonded castable [2]. CAC as the setting agent showed good green strength in the castable [2]. Development has been done with various SolCast castables to increase green strength but to still have good drying properties. Drying is usually the longest and the most critical process observed when heating refractory lining to process temperature. The development of high steam pressure may lead to explosive spalling and mechanical damage to the refractory lining [3]. Luz et al. [3] wrote a review article about theoretical aspects related to the drying process, the influence of the phase transformations derived from the binder additives and the experimental techniques to assess the water removal from consolidated castable pieces [3]. Industrial scale drying tests were done with various CAC amounts and different heating curves. The optimum CAC had good green strength but didn't weaken drying properties. A rapid drying curve was found for 400kg precast shapes without drying damage.

## INTRODUCTION

Monolithic materials have developed a lot but still these products require special attention during their curing, drying and firing stages. [3] Drying is the most critical process for monolithic lining since the reduced permeability of lining may lead to explosive spalling or mechanical damage. [4] Steam pressure buildup can be avoided by applying more permeable lining. [4] Colloidal silica-bonded castables have higher permeability compared to calcium aluminate cement (CAC) bonded castables and are thus known for their good drying properties. [1]

There has been a lot of research on the differences between CAC and colloidal silica. [1] Low green strength and long setting time has been the drawback for colloidal silica castables. [2] Yaghoubi et al. [2] found that siloxane bond formation increases when CAC is added but this may affect the workability of castable. Nouri-Khezrabad et al. [5] studied effects of CAC and hydratable alumina (HA) addition to colloidal silica-bonded castable and found out CAC+HA had the most positive impact on the green strength. Nonetheless HA has poor drying properties and this will hinder good drying properties of colloidal silica-bonded castable. CAC addition showed good green strength for the castable. [5]

Still it is not clear what is the optimum amount of CAC addition to have good drying properties and to have higher green strength for the castable. In this study industrial-scale drying experiments were carried out to find out optimum CAC addition and efficient drying curve for practical applications.

## MATERIALS AND METHODS

### Studied materials

Drying tests were carried out in two stages. First, tests with alumina castables with different amounts of CAC were conducted. Various tests were carried out on these alumina castables. Later, drying tests were made to alumina-silicate castables with fixed CAC amounts but with different drying curves. All the castables with colloidal silica and CAC were formulated using the Alfred packing model with q = 0.28.

Castable compositions for alumina castable can be seen in Table 1. The amount of fine tabular alumina varies to achieve the same particle size distribution for all of the castables. Tabular alumina, calcined alumina and calcium aluminate cement were supplied by Almatis. The magnesia content of dead burned magnesia was 90.5%. Used dispersants and retarders were sodium polyacrylate, boric acid and sodium tripolyphosphate. The consistency and fluidity of the mixtures were determined according to ASTM 860. The material was mixed dry for 4 minutes and 4 minutes after colloidal silica and water addition. Specimens for testing were cast under vibration.

Alumina silicate castable aggregates were chamotte and bauxite with a fixed CAC amount of 0.5 wt-%.

Tab. 1: Castable composition (wt-%)

|  | 0 | 0.5 | 1 | 1.5 |
|---|---|---|---|---|
| Tabular alumina (Almatis) | 84.8 | 84.3 | 83.8 | 83.3 |
| Calcined alumina (Almatis) | 12.9 | 12.9 | 12.9 | 12.9 |
| DBM | 0.2 | 0.2 | 0.2 | 0.2 |
| CAC 70% (CA-14 Almatis) | 0 | 0.5 | 1 | 1.5 |
| Colloidal silica suspension (40 wt.% solids) | 2% solids | 2% solids | 2% solids | 2% solids |
| Dispersant | 0.1 | 0.1 | 0.1 | 0.1 |
| Water (wt. %) | 3.5 | 3.5 | 3.5 | 3.5 |

### Experiments

Specimens (160x40x40 mm) were cured first at 20°C for 24h and then at 110 °C for 24h. Thermal treatment at 1600 °C was performed for 2h with Entech SF 6/17-S. The oven was heated to 1600 °C for 2h and the cooling was passive. Cold crushing strength (CCS) was determined according to EN 933-5:2018 with Pilot Controls 50-C92C22. Density and permanent linear changes (PLC) during the thermal treatments were determined according to ISO 1927:2012. Weight loss was determined between temperatures 110 °C and 1600 °C. Weight loss was calculated according to Eq. 1.

$$\text{Weight loss \%} = (W_{\text{Before firing}} - W_{\text{After firing}}) / W_{\text{Before firing}} \qquad (1)$$

The drying tests were performed using Nabertherm Mod W1500/A. Heating rate was 50 °C/h from 20 °C to 500 °C. Hold time was 12 h at 500 °C, and the furnace was allowed to cool to ambient temperature. Specimens for drying test were cast into 500x500x500mm mold. A thermoelement was installed during casting to the center of specimens.

199

Two test series were made: small-scale in the laboratory and industrial-scale drying tests. Small-scale tests were made only for alumina castables. Industrial-scale drying tests were made to get practical results from the drying. The surface area of laboratory-scale samples is too big to have practical results out of drying tests. The analyses conducted are tabulated in Table 2 along with relevant test specifications.

Tab. 2: Overview of analysis methods.

| Test series | Laboratory scale | Industrial scale | Note |
|---|---|---|---|
| Cold Crushing Strength | X | | EN 933-5:2018 |
| Density | X | | ISO 1927:2012 |
| Permanent Linear Change | X | | ISO 1927:2012 |
| Weight Loss | X | | Equation (1) |
| Casting properties | X | X | ASTM 860 |
| Drying properties | | X | 0.5m × 0.5m × 0.5m cube |

## RESULTS AND DISCUSSION

### Physical tests

Table 2 shows a compilation of the physical tests conducted. Results of CCS, density, PLC and weight loss are presented in Table 3. The values shown represent averages from three samples. CAC addition affects the low-temperature cold crushing strength. The addition of more than 1% of CAC has a clear effect on CCS at 20 °C. Differences in CCS at 110 °C and 1600 °C are minor, and variation, especially at 1600 °C, was extensive. CAC doesn't have a significant effect on CCS at higher temperatures since different sintering reactions have a greater effect. A decrease in density can be seen when CAC addition increases. The reason for this is the higher density of tabular alumina compared to CAC but also higher porosity in the castable when CAC is used. This result is in line with the results by Gao et al. [6]. There are minimal differences in PLC and weight loss, but there is no trend with increasing CAC amount. There were no differences in the flowability and workability between castables.

Tab. 3: Measured properties oft he castables

| T (°C) | Property | 0 | 0.5 | 1 | 1.5 |
|---|---|---|---|---|---|
| 20 | CCS (MPa) | 22.08 | 22.72 | 33.87 | 33.23 |
| 20 | Density (kg/m$^3$) | 3.10 | 3.08 | 3.08 | 3.05 |
| 110 | CCS (MPa) | 47.00 | 41.61 | 56.68 | 63.13 |
| 110 | Density (kg/m$^3$) | 3.05 | 3.04 | 3.04 | 3.02 |
| 1600 | CCS (MPa) | 180.99 | 157.02 | 167.13 | 171.94 |
| 1600 | Density (kg/m$^3$) | 3.15 | 3.15 | 3.14 | 3.12 |
| 1600 | PLC (%) | −1.30 | −1.50 | −1.43 | −1.45 |
| 1600 | Weight loss (%) | 0.30 | 0.27 | 0.33 | 0.37 |

### Drying tests

The drying tests were conducted for 0.5m × 0.5m × 0.5m cube elements in an furnace while the temperature of the pieces and the furnace was measured. The measured temperatures and heating rates are presented in Figures 3 and 4, respectively. Photos of the elements after drying are presented in Figure 5. The temperature difference between furnace control and temperature measurement from the furnace atmosphere was detected. The maximum temperature for the drying test was 460°C, while the average recorded heating rate was 41.11 °C/h, a value somewhat lower than the aimed heating rate of 50 °C/h.

The results of the drying tests indicate that the CAC content increases the damage to the castable when the heating rate is high. Damage occurs even in the element where 0.5% CAC was used. Damage occurs when vapor pressure inside the element becomes higher than the strength of the castable. The sample with 0% CAC content had the steadiest heating rate of the samples. Only between 110°C and 140°C the heating rate slowed down due to the ebullition of water. A steady heating rate indicates that there are no restricting reactions from CAC to the ebullition of water.

Damage to the samples occurred when temperatures were between 300 °C to 400 °C. Wang et al. [7] found out that at this rapid dehydration stage from 220 °C to 340 °C Young's modulus decreases by approximately 50% compared to the room temperature when CAC is used as a binder.

*Fig. 1: Temperature measurements from the drying test.*
Fig. 2: Heating rates of samples on the drying tests.

Fig. 4: Drying test results with 0.5% CAC content and 25 hours drying time.

Fig. 3: Drying test results for 400kg pieces with different amounts of CAC: a) 0 wt-%, b) 0.5 wt-%, c) 1 wt-%, and d) 1.5 wt-%

Fig. 5: Element after 30-hour drying time with 0.5 wt-% CAC content.

A successful drying process is important when good results are wanted in practice. Even hair cracks that are formed during drying degrade the performance of refractory lining. Results from the alumina castable drying bring out possibilities of energy saving and better productivity with shorter drying times. Consequently, drying tests were continued with a fixed amount of 0.5 wt-% CAC. Aggregates in this mix are bauxite and chamotte, and DBM was not used, but otherwise, these castables are comparable. 0.5 wt-% CAC addition was used since it was found that CAC acts well as an accelerator for the colloidal silica binder. Binding was more robust compared to DBM, where setting time was more volatile. These additional drying trials are intended to find the optimal drying curve for the castable. The first drying was done in 30 hours up to a maximum temperature of 400 °C. Results from this drying are presented in Figure 4. Ebullition temperature can be seen from the temperature measurement since temperature isn't rising during ebullition. Ebullition temperature in the test was between at 170°C indicating high steam pressure inside the cube. After drying, there were no cracks or other damage in the cube element (see Figure 5).

The next drying trial was only 16 hours long, and the maximum temperature was set to 300 °C. Since the CAC amount is low, there are low amounts of alumina hydrates in the castable, and it is not necessary to heat the castable up to 400 °C. Results from this drying are presented in Figure 6. Ebullition temperature in this test was at 195 °C which is significantly higher compared to the previous test. After drying, there were no cracks or other damage in the cube element (see Figure 7).

201
*Fig. 6: Drying test results with 0.5% CAC content and 16 hours drying time.*

202

*Fig. 7: Element after 16-hour drying time with 0.5 wt-% CAC content.*

Drying trials with a fixed amount of CAC did not result in cracks or other damage and were thus considered successful. The employed drying time of 16 hours is very short for this kind of element with a width of 0.5 metres. Most of the applications for this kind of castable can be dried with the employed drying curve. Ebullition of water finishes actually after the drying curve is already terminated and the passive cooling of the oven is going on, which can be seen in Figure 6. Ebullition temperature is about 190 °C in the latest test which indicates high pressure inside the element. The strength of the element is enough to withstand this internal pressure.

## CONCLUSIONS

Results from this research clearly state the benefits of colloidal silica-bonded castables. 0.5 wt-% CAC amount was found to be a robust accelerator for the colloidal silica, and it also presents some strength development for the castable. Drying trials were conducted successfully with this low amount of CAC without any damage or cracks in the elements. Elements were so large (0.5m × 0.5m ×

0.5m cube) that practically almost all of the corresponding applications could be dried with this short 16-hour drying curve. Differences in the higher temperatures were not found in the alumina castables.

# EFFECT OF CURING TEMPERATURE AND CURING TIME ON THE PROPERTIES OF LOW CEMENT BONDED CORUNDUM – SPINEL CASTABLES FOR WELL BLOCK

Sisi Zhang, Guotao Liu, Guojie Liu, Zongzhe Li

Puyang Refractories Group Co., Ltd., Puyang, China

## ABSTRACT

This study involved an investigation of the influence of curing temperature and curing time on the properties of low cement bonded corundum-spinel castables for well block. The physical properties of the castables treated at different temperatures and the HMOR at 1500℃ were compared after short-term curing at 35℃, 45℃ and 55℃ for 4h, 6h and 8h, respectively. The structure evolution of specimens under different curing conditions were studied by SEM. The results showed that the CMOR and HMOR were unexpectedly the highest after curing at 35℃. The strength of cement bonded castables depends on cement hydration products, but the completion of the hydration reaction requires a certain temperature and time, and the generation of new hydration products may destroy the original structure, and then show differences in performance. This work provides guidance for the curing condition of the well block production.

## INTRODUCTION

Low cement bonded corundum-spinel castable has been widely used in different areas as working lining like steel ladle as well as in different prefabricated refractory items like well block, seating block due to its excellent thermal stability[1-2]. In practical manufacture process, due to the limitations of workers' working time and work efficiency, under normal circumstances, the demoulding time of the well block will not exceed 16 hours. Therefore, the curing step of the well block is critical. Calcium aluminate cements (CAC) is used as binder agents for low cement bonded corundum-spinel castable, providing relatively fast green mechanical resistance [3-5]. Reactions between CAC and water lead to the formation of diverse hydrated phases, which also results in difference at drying and firing stage. Additionally, this process mainly depend on the curing time and temperature [6-7], which is this work focused on, the effect of short curing time(4h, 6h and 8h) and temperature(35℃, 45℃ and 55℃) for the low cement bonded corundum-spinel castable is investigated to provide guidance for the curing condition of the well block production.

## EXPERIMENTAL

The main raw materials used in the experiment are corundum(Haicheng, China) with various article sizes (6-3mm, 3-1mm, 1-0mm and 325mesh), calcium aluminate cement (CAC, Secar 71, Kerneos, Tianjin, China), α-alumina powder(Almatis, Qingdao), spinel powder and additives. The chemical compositions and partical size of main raw materials are shown in Tab.1. All samples used in this work had the same initial composition. The aggregates and matrix were first mixed in a mortar mixer for 3 min, and then water was added to continue the mixing for another 3 min. After that, the prismatic samples were casted to a size of 40mm× 40mm× 160mm under vibration. The curing experiments took place at three temperatures, 35℃, 45℃ and 55℃, and for each temperature, the samples were cured for 4h, 6h and 8h to simulate a real production environment. The samples were labelled A-B, where A stands for the curing temperature, and B stands for the curing time. After curing, the samples were dried in a 110℃ chamber for 16h and then fired at 1600℃ with a holding time of 3h for basic performance tests. The hot modulus of rupture (HMOR) was carried out at 1500℃ with a holding time of 0.5h (using specimens pre-fired at 1600℃ for 3h). In order to analyse the microstructure of the castables at different treatment, the castable fracture was observed under SEM.

Tab.1: Chemical compositions and partical size of raw materials

|          | Al₂O₃ | CaO   | MgO  | SiO₂ | Na₂O | D₅₀ |
|----------|-------|-------|------|------|------|-----|
| Secar 71 | 69.50 | 29.50 | 0.31 | 0.31 | 0.20 | 12.68μm |
| CL370    | 99.86 | 0.03  | 0.04 | 0.00 | 0.02 | 2.57μm |

## RESULTS AND DISCUSSION

### Physical properties and mechanical properties

The curing samples were investigated because they should correspond to green bodies that are placed in the oven once they are firm enough to be demoulded. Fig.1 and Fig.2 present the CMOR and CCS of specimens after curing for various temperatures and time, Fig.3 and Fig.4 show their strength after drying. As can be seen that the green strength of specimens cured at 35℃ for 4h is sufficient for demoulding. And as expected, the demoulding strength increased with the raise of curing temperature and curing time. However, after dying at 110℃, the strength presents an unexpected different trend, the CMOR and CCS decreases with the temperature rising. This goes against a lot of research, and the possible cause may relate to the formation and destruction of hydrate products. The hydration products in the specimen aggrandized with the increase of curing temperature and the extension of curing time, which might introduce different phase composition as prevailing in the inner part. The compact cohesion and continuous distribution of large number of hydration products are cemented between the aggregate and fine particles, which is conducive to the improvement of the strength of the specimen after demoulding. After short time curing, the specimens were immediately heated to 110℃ for drying treatment, and the incomplete hydrated CAx continued to undergo hydration reaction, lead to the continuous increase of strength. However, the hydration products like CAHx decomposed rapidly when the temperature rose sharply, result in structural damage. As more hydration products are generated, theoretically the strength loss caused by dehydration and decomposition of hydration products will be more serious[8-9], thus the strength of specimens cured at 55℃ is lower than that of 35℃.

*Fig.1: The CMOR of specimens after curing*
*Fig.2: The CCS of specimens after curing*

*Fig.3: The CMOR of specimens after drying*

*Fig.4: The CCS of specimens after drying*

The bulk density and the apparent porosity after demoulding and drying are displayed in Tab.2. Under the same curing temperature, the bulk density of the sample increases with the prolonging of curing time, while the apparent porosity decreases. This can be attributed to the continuous formation and crystallization of hydration products. As for the specimens cured at different temperatures, no apparent regularity was found.

Tab.2: The BD and AP of specimens after drying

| Curing temperature | Curing time | Bulk density(g/cm$^3$) | Apparent porosity(%) |
|---|---|---|---|
| 35℃ | 4h | 3.20±0.01 | 11.9±0.2 |
| | 6h | 3.21±0.00 | 11.9±0.1 |
| | 8h | 3.24±0.02 | 9.6±0.2 |
| 45℃ | 4h | 3.18±0.01 | 12.1±0.4 |
| | 6h | 3.20±0.01 | 9.8±0.2 |
| | 8h | 3.20±0.00 | 10.0±0.1 |
| 55℃ | 4h | 3.18±0.01 | 11.9±0.3 |
| | 6h | 3.21±0.02 | 9.9±0.1 |

| | 8h | 3.20±0.01 | 9.0±0.1 |
|---|---|---|---|

The early curing conditions will affect the formation and crystallization of hydration products, and furthermore, cause the variations in sintering and microstructure of materials after high temperature treated [10]. Fig.5 and Fig.6 dipicted the CMOR and CCS of specimens fired at 1600℃ respectively. Interestingly, it's observed that specimens cured at 35℃ obtained highest strength, and there was a gradual decline with the raise of curing temperature especially for the short time curing of 4h.

*Fig.5: The CMOR of specimens after firing at 1600 ℃*

*Fig.6: The CCS of specimens after firing at 1600 ℃*

The bulk density, apparent porosity and permanent liner change of the specimens after high temperature firing are shown in the Tab.3, with slight difference. It can be seen that the overall bulk density of the sample after curing at 35℃ is higher, and the apparent porosity is lower, which indicates a more compact structure. Yet the permanent liner change was still expansion, owing to the formation of CA$_6$ crystals by calcium aluminate cement [9], which will be discussed later.

Tab.3: The BD and AP of specimens after firing at 1600℃

| Curing temperature | Curing time | Bulk density(g/cm$^3$) | Apparent porosity(%) | PLC/% |
|---|---|---|---|---|
| 35℃ | 4h | 3.13±0.01 | 16.9±0.1 | 0.37±0.04 |
| | 6h | 3.14±0.00 | 16.7±0.1 | 0.31±0.02 |
| | 8h | 3.13±0.01 | 17.0±0.2 | 0.28±0.03 |
| 45℃ | 4h | 3.12±0.01 | 17.2±0.3 | 0.21±0.02 |
| | 6h | 3.12±0.01 | 17.3±0.1 | 0.37±0.01 |
| | 8h | 3.11±0.00 | 17.6±0.3 | 0.38±0.04 |
| 55℃ | 4h | 3.08±0.01 | 18.2±0.2 | 0.38±0.05 |
| | 6h | 3.11±0.02 | 17.5±0.1 | 0.20±0.01 |
| | 8h | 3.10±0.01 | 17.4±0.3 | 0.17±0.01 |

The HMOR at 1500°C for 0.5h is shown in Fig.7. Similarly, specimens cured at 35°C gained higher HMOR, and the variation trend is consistent as before.

*Fig.7: The HMOR of specimens pre-fired at 1600 ℃*

**Microstructures**

To better understand the variation of the performance for specimens, the microstructure of the fracture was observed. The SEM images of specimens after drying at 110°C are illustrated in the Fig.8 and Fig.9. It can be seen that with the increase of curing temperature, the pores inside the castable become larger and more numerous, and a less compact structure can be observed. This is because the more hydration products generated in the early stage, the more structural damage caused by the decomposition of hydration products after drying, which further confirms the difference in the performance of the specimens after drying. The magnification images displayed in Fig.9 show that cubic aluminum micro-powder particles and hydration products were coated on the surface of cement particles at the fracture of the specimen, and flaky hydration products were filled in the pores. With the increase of curing temperature, less flaky hydration products can be observed due to their decomposition [8].

*Fig.8: The SEM images (200× magnification) of specimens after drying*

*Fig.9: The SEM images (20000× magnification) of specimens after drying*

Fig.10 and Fig.11 provide the microstructure of the specimens after firing at 1600°C. As is shown in the graphs that there are pores in the fracture surface, and the size of pores tends to slightly increase with the increase of curing temperature. This may explain the higher strength of specimen 35-4 after high temperature treatment. In the magnification images(Fig.11), extensive columnar $CA_6$ are generated in the voids, interlacing with each other to form an interlocking structure. On the one hand, the reaction is an expansion reaction, that's why the PLC shows swelling; and on the other hand, the $CA_6$ crystals form a staggered network structure to block the void inside the castable, result in the densification of the materials, which is of great benefit to the strength and high temperature performance of castable [10].

## CONCLUSIONS

The castable with a size of 40mm×40mm×160mm made in this experiment, when the cement content of 5wt%, cured at 35℃ for 4h has obtained sufficient demoulding strength, and the performance is a little better than that of the sample cured at 55℃ under the same conditions. This is related to the rapid hydration reaction that occurs inside the castable during short time curing and the damage of the structure caused by rapid decomposition of the hydration products after drying. The formation and decomposition of the hydration products in the early stage will also affect the formation and structure of the crystalline phase after high temperature firing, thus lead to the difference in performance.

What is remarkable is that in practical production applications, the dimension of our refractory products such as the well block and the seating block, is significantly larger compare to the laboratory test sample (shown in Fig.12 is 360mm×360mm×380mm well block), and the water vapor in the castable will travel a longer distance and exist for extended period, result in more complex hydration reaction. Generally, the curing temperature and time of the product in the curing kiln is determined according to the material system, the type and content of the binder in the formula and the weather conditions. The well block combined with low cement corundum spinel castables manufactured by our company can obtain sufficient strength after curing at 35℃ for 6-12 hours, which can save energy and improve efficiency at the same time. Moreover, the performance can also be guaranteed.

## ABSTRACT

During drying of modern highly dispersed cement bonded castables, hydrothermal conditions appear because the water cannot evaporate fast enough from the bulk of the dense castable body. Under such high pressure conditions, problems such as explosive spalling can arise. Different curing temperatures lead to the formation of different hydrate phases and accordingly, different microstructures can develop in the hardened material. Under hydrothermal conditions, the original hydrate phases can transform into new hydrate phases, but still leave a footprint of the initial microstructure behind. This study presents the changes in porosity and mineralogical composition of a refractory castable model system under hydrothermal conditions depending on the curing temperature (5, 23 and 40 °C).

Quantitative X-ray diffraction (QXRD) measurements show that different hydrate phases are formed during curing, while $C_3AH_6$ and boehmite are formed in the same quantities after hydrothermal treatment in an autoclave at ~11 bar/180 °C. Although the mineralogical composition after autoclaving is not different, the three samples differ in their microstructure. Mercury intrusion porosimetry measurements reveal that although the total porosity after autoclaving is the same, the 40 °C samples have a higher proportion of large pores. SEM images also show that the appearance of $C_3AH_6$ in the 40 °C autoclaved samples varies, which originates from the starting phase composition and microstructure after curing.

## INTRODUCTION

High performance refractory castables are formulated to give a high density matrix . In the production of castables, a mixture of different types of aggregates, fine components, additives and a binding phase is mixed with water and poured into a mould. In the first step, the hydration/curing step, the binder phase, typically calcium aluminate cement (CAC), reacts with the water and after a certain period of time sufficient green strength is achieved so that the body can be demoulded. The castable body is then dried with the aim of removing the remaining unreacted and crystalline water from the body before the castable can be used in the final high-temperature application. The drying step is particularly critical as problems such as cracking or even explosive spalling can occur. These issues arise because modern highly dispersed cement bonded castables are so dense that the water cannot easily leave the green body when heated and the steam that potentially forms causes an increase in pressure inside the castable. This increase in temperature and pressure can cause hydrothermal conditions, which lead to a change in the hydrate phases that have been formed during hydration. The hydration of CAC is extremely temperature dependent. This affects the reaction speed, the formation of different hydrate phases and also the microstructure. At low temperatures (<20 °C) $CAH_{10}$ is typically formed [1,2]. It can be stable even up to 30 °C [3], but typically at moderate temperatures $C_2AH_x$ and $AH_3$ are formed [2,4]. The amount of $H_2O$ in $C_2AH_x$ can vary [5,6,7]. However, it is most usually referred to as $C_2AH_8$. $AH_3$ has a gibbsite-like structure and its crystallinity can vary from amorphous to nano and microcrystalline [3,8]. Its crystallinity increases with increasing temperature and time. At higher temperatures the thermodynamically stable calcium aluminate hydrate $C_3AH_6$ is formed in addition to $AH_3$ [2,3,9].

Depending on the temperature during the curing step, different hydrate phases are formed and a different hydration progress is reached. This material is then affected by the hydrothermal processes, which also leads to different microstructures, i.e. porosity and permeability. This study therefore aims to determine which mineral phases are formed when hydrothermal conditions occur in a calcium aluminate cement bonded castable and how the initial curing temperature affects the phase composition and microstructure.

## MATERIAL AND METHODS

All samples that were investigated in this study had the same initial composition (40 wt.% calcium aluminate cement and 60 wt.% alumina filler). The 40 wt.% CAC used in this study is a significantly higher amount of calcium aluminate cement than is typically used in modern castables. This large amount was chosen to better visualise the effect of the cement and the hydrate phases that form during hydration and hydrothermal conditions. For the same reason, a very simplistic system with only one alumina filler was chosen. A commercial 70% $Al_2O_3$ CAC (Almatis CA14-S) was used. The main phases in the cement are CA and $CA_2$, but also some $\alpha$-$Al_2O_3$. The alumina filler (Almatis tabular alumina T60/T64 <45 µm) consisted of corundum with traces of $\beta$-$Al_2O_3$ ($NaAl_{11}O_{17}$) (Fig. 1 start). The dry mixture was homogenized with deionized $H_2O$ and then cured for 48 h at 5, 23 or 40 °C. When solid the sample was then transferred to a PTFE-lined stainless-steel autoclave for the hydrothermal experiments. After autoclaving, the samples were analysed using X-ray diffraction (XRD), scanning electron microscope (SEM) and mercury intrusion porosimetry (MIP). The XRD measurements were carried out with a D8 Advance diffractometer (Bruker). The quantitative phase composition was determined by applying the G-factor method [10] to Rietveld data [11] using quartz as an external standard. Back-scattered electron (BSE) imaging and energy dispersive X-ray (EDX) spectroscopy were used for microstructural characterization of the samples. BSE imaging and EDX analysis were carried out at a 12 kV acceleration voltage and 1.6 nA electron current using a high-resolution field emission SEM. The mercury intrusion measurements (MIP) were carried out with a Poremaster 60 (Quantachrome). The smallest measurable pore diameter was 3.6 nm. The sample preparation and the methods used in this study are described in more detail in the publications by Koehler et al. [12,13].

## RESULTS AND DISCUSSION

### Phase composition after curing and autoclaving

The mixture of calcium aluminate cement and alumina filler was hydrated for 48 h at 5, 23 and 40 °C in a closed system to make sure no water can leave the samples during hydration. The phase composition before (start) and after hydration is shown in Fig. 1. A different degree of hydration of the clinker phases CA and $CA_2$ is reached after 48 h. Also different calcium aluminate hydrates are

207

formed. At 5 °C, only $CAH_{10}$ was formed as a crystalline phase. The clinker phases, especially $CA_2$, reacted only slightly at this temperature. In the samples hydrated at 23 °C, $C_2AH_8$ and $AH_3$ are also formed together with some $CAH_{10}$. At this temperature more CA and also some $CA_2$ have reacted. At 40 °C both clinker phases have completely reacted and $C_3AH_6$ and $AH_3$ are formed. All three samples show a different phase composition and hydration progress after 48 hours. These samples were then placed in the autoclave at 180 °C and ~11 bar for 12 h to simulate the hydrothermal conditions that can occur during the heating step of refractory castables.

Fig. 1: Phase compositions of the samples after curing for 48 hours at 5, 23 and 40 °C. Start column: phase compositions of the paste before curing.
After autoclaving all samples have exactly the same phase composition (Fig. 2). They consist of 18.4 ± 0.2 wt.% $C_3AH_6$ and 19.4 ± 0.4 wt.% boehmite (AlOOH) plus the unreacted alumina. In the 5 and 23 °C samples, $C_3AH_6$ was formed from the remaining unreacted CA and $CA_2$, and also from the conversion of $CAH_{10}$ and $C_2AH_8$, due to the hydrothermal conditions. In the 40 °C samples, $C_3AH_6$ was already present after curing and was not formed first in the autoclave. In contrast, the boehmite was newly formed in all three samples, transforming entirely from $AH_3$ in the 40 °C sample and from different sources in the 5 and 23 °C samples. It can be concluded that regardless of the initial composition, $C_3AH_6$ and boehmite are formed as stable phases under these hydrothermal conditions. This is in line with the results of Jensen et al. [14] and Auvray et al. [15] who observed the formation of $C_3AH_6$ and boehmite in a $CaO$-$Al_2O_3$ system under hydrothermal conditions.

Fig. 2: Phase compositions of the samples hydrated at 5, 23 and 40 °C after autoclaving at ~11 bar/ 180 °C.
The development of the phase composition with increasing temperature and pressure was also determined using a 23 °C cured sample as an example. (Fig. 3). At 120 °C/ 2.0 bar all hydrate phases have already converted to $C_3AH_6$ and $AH_3$. While $C_3AH_6$ stays stable with increasing temperature and pressure, $AH_3$ is converted to boehmite at ~140 °C. From 160 to 180 °C no change can be observed. This is consistent with the results of Serena et al. [16] who showed in a thermodynamic modelling that from 140 °C/ 3.6 bar $AH_3$ is converted into boehmite, which then remains stable up to 300 °C. This means that the formation/conversion into $C_3AH_6$ happens first and then, at higher temperature and pressure, the formation of boehmite takes place.

Fig. 3. Phase composition development of a sample hydrated at 23 °C with increasing temperature and pressure.
The evaluation of the XRD analyses of the curing samples shows that a completely different phase composition is produced at different hydration temperatures. However, due to hydrothermal conditions, exactly the same hydrate phases are formed in the same quantities from 120 °C. This means that the original phase composition has no effect on the final phase composition once hydrothermal conditions occur. However, the question arises whether the microstructure formed during hydration influences the final microstructure produced by the hydrothermal conditions.

**Microstructure after autoclaving**

SEM images in combination with EDX analysis were taken of 5, 23 and 40 °C samples after autoclaving to identify the mineral phases and image their morphology and microstructure. An overlay of the Ca- and Al-element distribution by EDX analysis enables the three phases ($Al_2O_3$, $C_3AH_6$ and boehmite) occurring in the autoclaved samples to be distinguished. A 5 °C autoclave sample is shown as an example in Fig. 4. The minerals in the 23 and 40 °C samples look similar to the 5 °C sample. The largest amount in the sample is $\alpha$-$Al_2O_3$, with $C_3AH_6$ present as larger aggregates.

Fig. 4: Overlay of Ca, Al and BSE images of a 5 °C autoclave sample. Green phase: $C_3AH_6$, light blue: $Al_2O_3$, dark blue: boehmite, black: pores.
Boehmite has a fine-grained sheet-like structure (Fig. 5) and is located between the bigger alumina and $C_3AH_6$ crystals. Since boehmite is newly formed due to hydrothermal conditions, the crystal appearance is similar in each sample. This leaf-like structure can also be observed when boehmite is hydrothermally synthesised [17]. While boehmite, corundum (dense and sharp edged) and $C_3AH_6$ (massive irregular aggregates) appear similar in the 5, 23 and 40 °C autoclaved samples, the microstructure observed in the SEM images differs.
*Fig. 5: SEM-BSE image of a 40 °C autoclave sample.*

Fig. 6 shows two examples of SEM-BSE images of an autoclaved 5 °C sample (top image) and a 40 °C sample (bottom image). The 5 °C and 23 °C samples are very similar and both differ in the same way from the 40 °C samples. The pores coloured red in these images show that the pores in the 40 °C autoclaved sample are significantly larger and more heterogeneously distributed than in the 5 °C (and 23 °C) sample. On the other hand, the pores of the 5 °C sample are smaller in average but more evenly distributed.

*Fig. 6: Large-area segmented SEM-BSE images of 5 °C (top) and 40 °C (bottom) autoclave samples with pores coloured in red. Both SEM images have the same scale.*

Another difference between the 5/23 °C and the 40 °C autoclave sample is also evident in the appearance of $C_3AH_6$ (Fig. 7). While the $C_3AH_6$ aggregates are smaller and more evenly distributed in the 5/23 °C autoclave samples, they are clearly much larger in the 40 °C autoclave samples. The amount of $C_3AH_6$ however, is the same, as shown by the XRD analyses (Fig. 2). The difference in the $C_3AH_6$ is explained by the fact that after curing for 48 h at 40 °C CA and $CA_2$ were reacted completely and the maximum amount of $C_3AH_6$ was already formed during hydration. $C_3AH_6$ was formed at 40 °C curing temperature in the paste, where the material is still plastic and growth is not hindered. On the other hand, $C_3AH_6$ is formed in the 5/23 °C samples from the remaining clinker phases and from conversion of the metastable hydrate phases $CAH_{10}$ and $C_2AH_8$ only due to the hydrothermal conditions. When these conditions occur, or when the samples enter the autoclave, they are already solidified and the growth of $C_3AH_6$ to bigger grains is only possible to a certain extent.

*Fig. 7: Large-area segmented SEM-BSE images of 5 °C (top) and 40 °C (bottom) autoclave samples with $C_3AH_6$ coloured in red. Both SEM images have the same scale.*

To verify the differences in porosity that were observed in the SEM images, MIP measurements were performed on the autoclaved samples. The total porosity and bulk density are exactly the same in all three samples (Tab. 1). This was to be expected, as the chemical and mineralogical composition of these samples is exactly the same and no change in volume of the samples could be observed due to the autoclaving process. The rather low bulk density (1.69 g/cm³) and rather high total porosity (~43 %) in our study can be explained by the chosen water/cement ratio used in the investigated mixtures. In technical refractory castables, the total porosity would be significantly lower due to a lower cement and water content and also a better balanced particle size distribution of the matrix material. Nevertheless, the effect of curing temperature on the pore size distribution is present (Fig. 8), albeit on a smaller scale.

Tab. 1. Bulk density and total porosity after the autoclaving 12 h at ~11 bar/ 180 °C determined with MIP.

| Temperature | Bulk density [g/cm³] | Total porosity [%] |
|---|---|---|
| 5 °C | 1.69 ± 0.01 | 42.8 ± 0.3 |
| 23 °C | 1.69 ± 0.01 | 44.1 ± 1.2 |
| 40 °C | 1.68 ± 0.02 | 43.3 ± 0.7 |

The pore size distribution (Fig. 8) shows that all three autoclaved samples exhibit a pore diameter maximum of ~1 μm. The 40 °C sample, however, has a significantly lower peak than the 5/23 °C sample and instead a second maximum at ~3 μm. The 40 °C autoclaved samples have less fine pores but a proportion of large pores that does not appear in the 5/23 °C samples. The results of the MIP measurements match the observations of the SEM images. Although hydrothermal conditions result in the same phase composition ($C_3AH_6$, AlOOH and α-$Al_2O_3$) regardless of the initial composition, the microstructure of the samples differs. The reason for this is that the curing conditions (in this case the temperature) already create a different microstructure, of which a "footprint" remains in the samples despite hydrothermal conditions and the resulting phase transformations.

The proportion of larger pores (2-10 μm) that only appears in the 40 °C autoclave samples can be explained by the initial phase composition after curing. At high hydration temperatures, a large amount of $C_3AH_6$ and $AH_3$ is formed after a short time. Of the calcium aluminate hydrates, $C_3AH_6$ has the least amount of $H_2O$ incorporated into its structure. It also has the highest density (2.53 g/cm³) [18]. As a result, the water after curing is located in either very crystalline phases or remains as "free"/unbound water in the pores. When hydrothermal conditions occur, the already formed $C_3AH_6$ remains stable and only the $AH_3$ converts to boehmite,

releasing additional water. This leads to additional porosity. Thus, the microstructure is not particularly altered by hydrothermal conditions.

In contrast, the microstructure of castables that are cured at low/moderate temperatures changes significantly as soon as hydrothermal conditions arise. After curing, these samples consist of $CAH_{10}$ (1.78 g/cm$^3$), $C_2AH_8$ (1.95 g/cm$^3$) [18], low crystalline or amorphous $AH_3$ and unreacted clinker phases. The microstructure is more complex, with fewer large pores, because of these different, less crystalline and less dense hydrate phases. The microstructure is probably less permeable and could additionally prevent the water from leaving the castable body during heating, which then leads to steam pressure and therefore hydrothermal conditions. When these conditions occur, the phase composition changes completely to $C_3AH_6$ and boehmite. However, the microstructure with finer pores remains.

*Fig. 8: Pore size distributions of the autoclaved samples shown by the first derivative of the MIP pore volumes as function of pore diameter.*

## CONCLUSIONS

Curing calcium aluminate cement bonded castables at different temperatures leads to the formation of different mineral phases, resulting in different microstructures. Hydrothermal conditions can occur if water cannot leave the castable body fast enough during drying/heating. Under these conditions the stable phases $C_3AH_6$ and boehmite are formed from all hydrate and remaining clinker phases. While the mineral composition, bulk density and total porosity are exactly the same, when these conditions occur, the microstructure of the high temperature hydrated samples differ from the low and medium temperature samples. Castables that already consist of $C_3AH_6$ after curing due to high temperatures (40 °C) have significantly larger pores and do not change as much if hydrothermal conditions arise. Since samples cured at low/moderate temperature already contain smaller pores after curing and retain them under hydrothermal conditions, it can be concluded that these castables are more prone to explosive spalling or other pressure related problems.

## ABSTRACT

In general two different lining concepts exist for the wear lining of modern continuous casting tundishes: wet gunning and dry mix. Both concepts have specific advantages and disadvantages.
The dry mix technology has been standard in thyssenkrupp plants Beeckerwerth and Bruckhausen for more than 20 years. The reduction of energy consumption and the reduction of CO$_2$ emissions could be achieved in part by switching from wet spray to dry mix. The last continous caster changed to dry mix at thyssenkrupp Steel in 2015. The thin slab caster changed after some years of parallel wet spray usage. In the second step, the heavy 90 DBM was successfully replaced by the light magnesia to reduce the consumption quantities per tundish. The light magnesia product has been used and established in both plants since 2012. The aim of this work is to prove that it is possible to cast the same grades and sequences with a new European olivine-based formulation, which has a much lower carbon footprint than magnesia (and light magnesia) in production and transport. The objectives are to first optimize the dry mix product for thyssenkrupp and then implement field trials to change the technology of baking the dry mix with today`s hot air mould to eMould, an electrical heating solution, to save even more CO$_2$ emissions, time and energy in the future.

## PROCESS FROM WET SPRAY TO DRY MIX

The use of wet gunning mixes for the tundish wear lining has a long history in the steel industry. The quality of a lining depends on the individual skill of the supplier, employees and the drying equipment employed in order to heat out approximately 25-30% water, equivalent to 250-300l of water per ton. This consumes a high amount of energy and time. Favorable insulating properties, low material consumption, as well as the non-necessity of pre-drying are usually attributed to this type of refractory material, when the possibility of spraying on hot permanent lining is given. The fact that no pre-drying is required, usually depends on the thickness of the sprayed wear lining. Disadvantages have been ascribed to the presence of water and SiO$_2$, originating from the binders. Water can readily affect the hydrogen pick up during casting. Wet gunning mixes are currently available which contain solely SiO$_2$-free binders and which are inherently different from conventional wet gunning mixes with regard to the reduction potential.[1]

With the dry mix, it is possible to achieve lower hydrogen pick up over the long term on average, due to stable dry material conditions, lower lining costs are incurred and the plants achieve higher tundish availability. The disadvantages consist of lower insulation properties, due to higher densities resulting in higher consumption, and the necessity of baking prior to casting. Thyssenkrupp was able to reduce the disadvantage of the 90 DBM (bulk density 1.80-1.90 g/cm³) dry-mix by switching from heavy to light magnesia (bulk density 1.40-1.50 g/cm³) product in 2012. This step has reduced the consumption of the material nearly 20% per tundish and the CO$_2$ footprint from 3100kg (90 DBM) to 1100.2kg (light magnesia) CO$_2$ per ton raw material, which is a scope 3 emission. The technical data of the plants as well as the current consumption quantities of dry mix material are shown here in Table 1.

Tab. 1: Technical informations about the plants OX I and OX II

| Steel plants | OX I | OX II | |
|---|---|---|---|
| Annual production capacity [t] | 5,2 Mio. | 5,4 Mio. | |
| Main steel grades | 33% Thin-plated 40% Thin-slab 13% Silicon grades | 40% ULC + IF Steel 43% High-strength steel 10 % Sheet Others | |
| CCM*[quantity] | SGA 3 | SGA 1 | SGA 2 |
| Tundish capacity in liquid steel [t] | 86 | 75 | 75 |
| Lining thickness bottom [mm] | 30-40 | 30-35 | 30-35 |
| Lining thickness wall [mm] | 30 | 30 | 30 |
| Consumption per tundish in heavy DBM [kg] | 3300 | 2700 | 2700 |
| Consumption in light weight magnesia [kg] | 2700 | 2200 | 2200 |
| Ø casting sequences [Ladle] | 4.5 | 4.5 | 5.4 |

*CCM = Continues casting machine

With the bulk density of 1.50-1.60 g/cm³, the olivine based mix had a 4.5% higher material consumption, equivalent to 100kg per tundish in the trials at the plants OX 1 and OX 2. This surplus in consumption was not included in following CO$_2$ savings calculation, as the final consumption per tundish is not yet validated.

## SWITCHING FROM LIGHT 90 DBM TO OLIVINE BASED DRY MIX PRODUCT

The calculating of the carbon footprint of refractories starts with the raw materials. It must be taken into account how much CO$_2$ the suppliers generate during the production of one ton of raw material. In this case for example, the Chinese supplier currently generates 3.1 tons of CO$_2$ in the production of one ton 90 DBM.[2] As climate-neutral fuels are used for the production of "light megnesia", the CO$_2$ amount is about 1.1 tons per ton of raw material.[3] The transport distances for the raw materials as well as the values for the production of one ton of dry-mix must also be taken into account when calculating the emission values. It is possible to further reduce these CO$_2$ amounts even further by trying to economically integrate European raw material sources into the formulations. In this project we are replacing 2/3 of light magnesia DBM with European olivine. The supplier from Europe creates only 0.007 ton CO$_2$ per ton of olivine production.[4]

The results of the carbon footprint calculation for the production of 1 ton dry mix are shown in the table 2.

Tab. 2: $CO_2$ calculation for 1 ton dry mix at WEERULIN GmbH

|  | DBM 90 China dry mix [kg $CO_2$ / t] | Light magnesia China dry mix [kg $CO_2$ / t] | 100% Olivine Norway based mixed dry mix [kg $CO_2$ / t] |
|---|---|---|---|
| Transport | 79.30 | 52.50 | 21.87 |
| Production raw material | 3,100 | 1,100 | 7 |
| Mixing at Weerulin | 5 | 5 | 5 |
| **Total** | **3,184.3** | **1,157.5** | **33.87** |
| **Savings of $CO_2$ per t dry mix** | **0** | **2,026.80** | **3,150.43** |

Replacing heavy 90 DBM with 100% Olivine saves approx. 3151kg per ton (Tab. 2). Assuming up to a 2/3 exchange of DBM with olivine in the recipe 2100kg of $CO_2$ per ton of dry mix is saved. With an annual consumption of approx. 13000 tons material corresponds to a total savings of 27300 tons $CO_2$ emission per year for the thyssenkrupp plants OX 1 and OX 2. Assuming that the change would be based on 100% light magnesia dry mix, the total consumption per year would be only 10400 tons and therefore the change to the olivine based dry mix would end up saving 745kg $CO_2$ per ton refractory material or approx. 7750 tons of $CO_2$ per year.

Thyssenkrupp`s feedback shows that the lining of the tundish with the olivine based dry mix has been successful with no negative effects reported so far. There was no increase in loose material after baking in the bottom. The wall construction was very stable, good baking behavior, no abrasion. The same casting sequences with olivine based were achieved without any problems. There was no significant wear in the slag zone. The quality requirements could be met. The metallurgical effects in produced grades are currently being assessed.

**COMPARISON OF ENERGY CONSUMPTION**
The best amount of energy required for the baking process of the dry mix is 200°C. Based on the experience Weerulin and Sievering, the energy requirement was calculated on average per 1m² area of working lining (regardless of the tundish form) for the products in Table 2. In this calculation, only the energy demand for gas consumption during baking was taken into account. The energy consumption of the electrical auxiliary (cooling/air fan) of the hot air mould system is not included in these values.

When drying with the hot air mould, the energy requirements were determined for the products with heavy 90 DBM, light 90 DBM and the olivine based dry mix. The same calculations were then used for the eMould and compared Table 3 below.

Tab. 3: Determination of the energy requirements for the dry-mix masses in comparison with the baking technology

| Energy requirement | Hot air mould [in MJ/m²] | eMould [in MJ/m²] |
|---|---|---|
| Heavy 90 DBM dry mix | 144 | 19 |
| Light DBM dry mix | 144 | 21 |
| Olivine based dry mix | 147 | 23 |
| Average | 145 | 21 |
| **Energy efficiency** | **11%** | **73%** |

The energy efficiency of the energy used per m² to bake, which is converted into heating of the mould, is mathematically only 11% for the hot Air mould and 73% for the eMould. This study showed that an energy saving of 85% could be achieved with the eMould. In addition, the manifold delivery process could be $CO_2$ free if purely renewable electricity is used.

By using the eMould, additional huge time savings can be achieved in the baking process of the tundish compared to the hot air mould. This in turn has a major influence on the overall setting time of a tundish and thus increases the number of the tundishes available in the plants. The time required for one baking cycle (baking + cooling) is 120 min. for OX 1 and 90 min. for OX 2. By using the eMould, the time required can be reduced to 30 min. per baking cycle in total. This results in savings of 4575 hours for OX 1 and 4800 hours for OX 2 per year (Fig.1). [5]

*Fig. 1: Backing time comparison hot air mould to eMould*

Another disadvantage of the hot air mould is the uncontrollable heat distribution within the mould. The simulation results (Figure 2) show the heat distribution in comparison to eMould. In order to bring the cold spots of the hot air mould to the target temperature, more energy is required, which in turn can lead to the formation of unwanted hot spots.

*Fig. 2: Heat distribution in the moulds*

With the eMould, a maximum ΔT of 10 Kelvin is possible and the complete baking process is controllable. Ramps and holding points can be combined with each other as desired (Fig.3).[5]

Fig. 3: Heating curve of control panel eMould

In the experiment with the eMould prototype, homogeneous heating of the eMould was successfully demonstrated. As shown in Figure 4 – thermal image, the tundish could be baked in 15 min. and the eMould could be pulled without problems after only 10 min. cooling time.

Fig. 4: eMould thermal image on baking temperature

Fig. 5: Baked dry mix in lap test with eMould

For energy savings, the type of electricity used must still be taken into account, and the value listed here for energy savings must be corrected by the corresponding factor. In the case of electricity generated from renewable sources, the transmission losses must be calculated. In the case of electricity from cogeneration, the efficiency of the power plant must be taken into account. With a total of 7850 baking processes per year, energy savings per baking

process of 0.764 MWh are calculated with the eMould. This means an annual energy saving of 5997 MWh equivalent to approx. 600000 Nm³ of natural gas compared to the hot air mould.[5]

Further savings in energy consumption were achieved at the OX 1 and 2 plants by converting the heat up process on the casting platform. This was already done many years before by switching from heating the entire tundish to heating the strands with the chimney technique. The energy consumption is in the range of 1 – 2 GJ (3,6 GJ ≙ 1 MWh) per tundish. The holding at a maximum temperature of 1200°C consumes 1 GJ per hour. The rest of the tundish starts off relatively cold (Fig. 6).

Fig. 6: For dry mixes merely special areas (tundish nozzles) require a heating process.

As can be seen from Fig. 6 the energy balance is clearly favorable for the dry mix in comparison to wet spray tundish practice. Additionally it is increasing the number of tundishes available due to the lower time for baking. Finally, the cold start up practice is again favorable with respect to reduced $CO_2$ emissions (Fig. 7).

Fig. 7. Dry mix after baking thyssenkrupp Steel with the chimney technique

**CONCLUSIONS**
Practical trials with the olivine based dry mix compound in thyssenkrupp Steel plants OX 1 and OX 2 have shown that the use of this product is technically possible. The metallurgical effects in produced grades are currently being assessed. In comparison to conventional heavy 90 DBM dry mixes, which are still in use in the market, the olivine based dry mix material provides a consumption saving of approx. 15-20% and a total $CO_2$ reduction of up to 27300 tons per year. Even in comparison with the more modern light magnesia dry mix, the $CO_2$ savings sum up to 7750 tons. The

213

material consumption in the trials indicates a 4,5% higher consumption, but is matter of further improvements. According to this trial the future changeover from hot air mould to eMould, the plants will be able to achieve together an annual energy savings compared to hot air mould of 7850 baking processes per year, energy savings per baking process of 0.764 MWh are calculated with the eMould. This means an annual energy saving of 5997 MWh equivalent to approx. 600000 Nm³ natural gas compared to the hot air mould. Thyssenkrupp will also save approx. 4575 hours for OX 1 and 4800 hours for OX 2 in baking time. Which means a total saving with the eMould of approx. 9375 hours together in both plants and a much higer tundish availability.

This work has clearly shown that by adapting the recipes and increasing the use of European raw materials in combination with the use of eMould, high $CO_2$ emission savings are possible in the area of the tundish working lining.

# INVESTIGATION OF THE DRYING BEHAVIOR OF LOW CEMENT CASTABLES

Uwe, Klippel, Patrick, Malkmus
Calderys Deutschland GmbH, Neuwied, Germany

Steffen, Möhmel
Imerys Villach GmbH, Villach, Austria

**ABSTRACT**

Monolithic refractory castables still comprise a hydraulic bond in the vast majority of the cases despite of many new developments for chemical as well as non-cement castable (NCC) binders in the last decade. In particular deflocculated dense castables of the low cement castable (LCC) range can be considered as the workhorse in this field. The drying of such monolithic deflocculated dense refractory linings during the first heat up maintained to be a challenge while complying with constantly increasing market demands for simpler procedures and quicker drying regimes. Quite a few publications have been released on this topic for the last ten years, indeed. However, mostly either the product is altered in regard to its bond nature and/or harsh steam spalling test conditions were investigated to qualify new product types in regard to their spalling resistance. This paper, however, introduces a simple laboratory scale test setup to study and iteratively improve the drying schedule of a given castable lining to deliver both: enhancing the drying effectiveness in avoiding steam spalling as well as the drying efficiency in releasing physically and chemically bonded water as quick as possible. The influence of the matrix and the bond is showcased by an experimental design comprising self-compacting and vibro-casting LCC's either with or without silica fume in combination with or without drying fibers, respectively.

**INTRODUCTION**

Since the beginning and rise of deflocculated low cement castables five decades ago [1] the performance of such hydraulically bonded monolithic refractory concretes has been significantly enhanced through improved particle size distributions and incorporation of submicron particles such as silica fume [2-4]. Nevertheless, the drying of deflocculated hydraulically bonded castables is still considered as the major drawback among minor disadvantages in comparison to competing bonding mechanisms such as chemical, colloidal or other no cement castable bonds until today [5]. The common practice of incorporating drying aids, e.g. organic fibers, to enhance the permeability and, thus, supporting the removal of water steam during drying, has been investigated and reported throughout the years and is still under investigation today [6-13]. The incorporation of drying aids or modifications of the bond nature [14-17] were accompanied by further investigations on the mechanisms of the drying process to qualify materials for their respective drying ability or sensitiveness in regard to steam spalling [18-22]. Eventually, further developed experimental setups gave way to analyse the drying process for actual heat up curves and lining configurations including approaches of conducting simulations of the same [23-28].

Consequently, the experimental pressure-temperature-mass (PTM) setup, presented earlier [18, 21], was upgraded by applying a programmable heating plate as temperature source for the reason of offering a simple and robust laboratory method. As a result, the impact of various factors on the drying effectiveness to prevent catastrophic steam spalling as well as drying efficiency to remove physically and chemically bonded water from the hydraulically bonded refractory castable lining was studied. Complementary to the refractory castable type as a common factor, the speed as well as the design of heat up curves (HUC), e.g. ramp-and-hold and/or continuous ramp, were investigated. Results of the applied method are presented and discussed exemplarily for vibro-casting as well as self-compacting LCC formulations following the suggestions of Schnabel et al. [29] and are compared against their physical properties such as pore size distribution as well as air permeability.

**EXPERIMENTAL**

Generally, ALMATIS white tabular alumina (WTA) was used to formulate both: the vibro-casting as well as the self-compacting castable formulations (table 1-2). ELKEM 971U microsilica (MS) was applied as silica fume source whereas super ground reactive alumina CT 3000 SG from ALMATIS was used for silica fume free formulations. Additionally, fine ground calcined alumina MR30A from HINDALCO was incorporated into self-compacting castable formulations. Eventually, CA-14 W calcium aluminate cement (CAC) in combination with either the dispersant ADS1 or M-ADS1 from ALMATIS completed the formulations. BAUMHÜTER 2.8dtex monofilament shortcut polypropylene (PP) fibers in 6mm length were employed as drying aids.

The consistency of the freshly made castable was determined according to EN 1402-4 with the 80 mm tall cone all times. Specimens were made, temperature treated and characterized according to EN 1402-5 and EN 1402-6, respectively. The air gas permeability, µ, was measured at room temperature according to EN 1402-8. The pore size distribution was determined through mercury (Hg) intrusion method in accordance with DIN ISO 15901-1 with a Micromeritics AutoPore IV.

The PTM setup of Meunier et al. [18-19] was enhanced by an IKA C-MAG HS 7 CONTROL programmable heating plate regulated by an extra thermocouple attached to the hot face of the Ø 190 mm and 150 mm tall cast body. Two different HUC's were applied. The configuration of the steam pressure sensors and the thermocouples remained as same as lastly reported ten years ago [21].

## RESULTS

The castable formulations according to table 1-2 were analyzed for their placement characteristics as well as physical and mechanical properties (table 3). The given average values are simply of informative character and were subjected to a deviation of about 10%. Though, the quantity of applied drying aid PP fibers was with about 1.5 kilograms per cubic meter concrete considerably low; the placement behavior of both: the vibro-casting (C-F, C-FS) as well as the self-compacting (SF-F, SF-SF) formulations was impacted significantly. The respective self-compacting castables had to be subjected to vibro-casting to obtain specimens, eventually. Figure 1 shows exemplarily the visible effect of PP fiber decomposition in generating fine pores at around 10 μm pore size diameter such as already reported by Meunier et al. [8].

Due to the submicron silica fume addition with an about 40 percent lower density than its reactive alumina counterpart, the well-known matrix densification took place for formulations such as C-S, C-SF and SF-S, SF-SF, respectively, visible by the cumulative pore size distribution in figure 2 and by the average pore size diameter, Φ₅₀,ₕₘ given in table 3.

The air permeability, μ, remains about one magnitude behind when comparing silica fume bearing formulations with silica fume free formulations (table 3). The effect of silica fume appeared to be dominant over the different castable types and their respective difference in matrix volume share, i.e. either C or SF. Air permeability values indicated with "max" refer to more than 110·10⁻¹⁶ m² whereas "min" represents less than 0.5·10⁻¹⁶ m².

## Pressure-Temperature-Mass Test Results

The castable formulations were subjected to the aforementioned PTM test procedure with two different heat up curves:

N°1: RT → 43 K/h → 150°C → 12 h → 150°C → 9 K/h → 350°C
N°2: RT → 43 K/h → 150°C → 6 K/h → 350°C

N°1 represents the initial phase of a commonly applied ramp and hold drying curve procedure and N°2 refers to the also commonly applied continuous ramp philosophy whereas both share the first segment until reaching 150°C. However, the new heating plate was lacking heating performance in kilowatts, hence, the specimen did not reach the maximum temperature of 350°C as targeted.

Table 4 summarizes the results for the acquired maximum relative pressures and associated temperatures for given formulations, heat up curves as well as distances from the hot face (depth s). Figures 3-6 show the pressure pattern over heat up time as well as the dewatering by weight loss, -Δm. The temperature profile over the lining depth is given exemplarily for the HUC N°1 and N°2 by figure 3 and 4, respectively. The lower permeability of silica fume containing formulations contributed to significantly higher relative pressures. PP fibers did effectively decrease these pressures to avoid steam spalling. The occurrence of maximum relative pressure peaks after the hold at 150°C (figure 3 and 5) revealed an ineffectiveness of such a hold to prevent steam spalling. Comparing both HUC results, it appears that N°1 shows a decreased efficiency of water removal per time as reported by Fey et al. [24-26].

Silica fume free LCC formulations, (C, SF), appeared not in need for further drying aids in this investigation. Neither showed their respective PP fiber containing counterparts (C-F, SF-F) further improvements and are, thus, not shown. The reason is seen in their sufficient air permeability already at 110°C (table 3) to evacuate the water steam properly without contributing to high steam pressures. To quantify the difference in drying speed, v, the difference of weight loss at 80 wt.% and the already reached weight loss value at

217

150°C in conjunction with the respective elapsed time was used to calculate the values in table 5. Interestingly, the ramp design recorded regularly higher drying speeds versus the hold design. This is traced back to the determined temperatures at peak steam pressures in table 4 which indicate that a hold temperature of 150°C is simply insufficient to create a meaningful pressure to push the water steam out of the lining. The ramp design, however, was reaching an isotherm of about 180-200°C earlier in time, hence, advancing the water removal. Comparing the pressure build-up occurrence during the second ramp with 9 K/h in HUC N°1 and 6 K/h in HUC N°2 shows a pressure flattening for N°2 in particular for silica fume and PP fiber containing formulations (C-SF, SF-SF). Thus, a ramp design appeared to be safer in avoiding steam spalling in this study. Generally, silica fume bearing formulations recorded lower drying speeds as well as the highest pressures (-S, -SF).

Tab. 5: Drying speed per formulation and heat up curve

| Code | C | C-F | C-S | C-SF | SF | SF-F | SF-S | SF-SF |
|---|---|---|---|---|---|---|---|---|
| | average dewatering speed v / wt.% · h⁻¹ | | | | | | | |
| HUC N°1 | 2.8 | 2.8 | 1.9 | 2.1 | 2.5 | 2.5 | 2.1 | 2.2 |
| HUC N°2 | 5.6 | 3.9 | 2.4 | 3.0 | 4.0 | 3.5 | 2.3 | 2.9 |

**CONCLUSIONS**

The modified PTM setup delivered significantly more information about the behavior of refractory castables during the initial heat up than the usually performed material qualification methods. Besides the ability to support materials optimization to avoid steam spalling, the method gives also way to incrementally improve the heat up curve design with considerably low efforts. Consequently, the method contributes to enhancements in drying of monolithic refractories, in particular for hydraulically bonded castables with their references across high temperature applications and industries.

# A NOVEL TYPE OF ANTI–SPALLING NATURAL STRAW FIBERS FOR REFRACTORY CASTABLES

Minghua Zhang, Micael Larsson, Edina Alibasic, Ronald Robles
Höganäs Borgestad AB, Sweden

## ABSTRACT

With the coaction of internal pressure created by water vapor and thermal stress triggered by temperature gradient, cement based castables are prone to structural damage and even explosive spalling during dry-out process; thus to cut down the service life of refractory linings and cause economic loss. Here a novel type of natural plant fibers is introduced in terms of castables' anti-spalling property. The permeability of conventional castables and ultra-low cement castables are tested and presented in combination of the novel fibers and polypropylene (PP) fibers. The results demonstrate those natural plant fibers are functional with enhanced permeable properties and lower risk of spalling. Moreover, laboratorial and industrial practices have confirmed that those fibers make cement based castables excellent anti-spalling during quick dry-out.

## INTRODUCTION

### 1. Natural Plant Fibers

Nature created materials is the natural fibers which are abundantly available, eco-friendly and have renewable in their behavior. The cultivation and on growing harvesting and primary processing conditions to extract the fiber will dictate the homogeneity.

The use of natural fibers is now in demand compared to synthetic fibers as awareness and awareness of the environment is raised among individuals. There are plenty of trees for the fiber production of various trees such as hemp, banyan, neem, palmyra, jute, sisal, banana, etc. As here it is transformation of the waste material into raw material for the composites.

Plant fibers are hydrophilic owing to the presence of functional groups such as hydroxyl in their structure. Therefore, plant fibers absorb a considerable amount of moisture from the surrounding environment. The moisture absorption capacity of plant fibers depends mainly on their chemical composition and crystallinity. Plant fibers are generally composed of cellulose, often in combination with other components such as lignin. Plant fibers are classified according to their source in plants.

- Bast or stem fibers, derived from the fibrous bundles in the inner bark of plant stems.
- Leaf fibers, which run lengthwise through the leaves of monocotyledonous plants.
- Seed-hair fibers, such as cotton.

### 2. Anti-spalling agents for refractory castables

After the castable has been installed and hardened, there are two types of water remaining: physical water and chemical water. Both must be removed before the refractory material can be used in service.

Heat needs to be applied to remove both types of water. The physical and chemical water is released at certain critical temperatures during the dry-out which are as follows:

- Removal of free water: 100°C
- Dehydration of major cement phases: 220°C, 270°C and 549°C.

All water must be removed in a controlled manner and dry-out schedules should pay attention to these critical temperatures.

When water turns to steam there is a volume expansion of approximately 1,600 times. This increase in volume causes high pressures within the lining. At each critical temperature there is a high potential for developing internal pressures that could exceed the strength of the refractory castable and cause the material to spall.

This physical disintegration of the castables often occurs at temperatures between 100 and 300 °C, where water is released in a combined process of (i) evaporation of free water and (ii) dehydration of the calcium-aluminum-hydrates.

The refractory producers have identified several countermeasures that allow a more secure first heat-up, where water (vapor) is released at lower temperatures if CAC is reduced to a minimum in the formulation.

Over the past few decades, with the use of organic fibers, which are known to melt at temperatures below 200 °C, a straightened pore structure introduces additionally permeable pathways that permit easier vapor release toward the surface of the castable.

One of the action mechanisms of the polymeric fibers is activated during the softening and melting of the filaments. The first permeable paths will be formed by the deformation of the molten polymer using the pressurized water vapor generated inside the ceramic microstructure. After the fibers' decomposition, the overall permeability of the castables increases when interconnections are generated between regions presenting different permeability and the formed channels themselves [1-6].

Thereby, polymeric fibers are added to act as sacrificial agents and their effectiveness will depend on the physicochemical properties of the selected polymers. This route may provide the development of refractory castables with more permeable microstructures, reducing the explosions likelihood of these dense materials during drying.

### 3. Permeability & Darcy's Law

Permeability is part of the proportionality constant in Darcy's law which relates discharge (flow rate) and fluid physical properties (e.g. viscosity), to a pressure gradient applied to the porous media. Darcy's Law for incompressible fluids (linear flow) is given below:

$$v = \frac{k}{\mu}\frac{\Delta P}{\Delta x} \qquad (1)$$

Therefore;

$$k = v\frac{\mu \Delta x}{\Delta P} \qquad (2)$$

Where:

$v$-is the superficial fluid flow velocity through the medium (m/s)

$k$ -is the permeability of a medium (m$^2$)

$\mu$- is the dynamic viscosity of the fluid (Pa·s)

$\Delta P$ -is the applied pressure difference (Pa)

$\Delta x$ -is the thickness of the bed of the porous medium (m)

In naturally occurring materials, the permeability values range over many orders of magnitude. Deviating from Darcy's linear law, the porous flow characteristics obey a non-linear law in a low-permeability porous medium, the viscosity of the porous flow fluid, and the permeability values of fluid are not constants. This study uses Darcy's linear law only.

## EXPERIMENTAL SECTION

### 1. Mixes Design

Table 1 shows the composition of the ultra-low cement castables. Guyana bauxite were used as aggregate, and calcium alumina cement, fume silica and a superfine aluminosilicate binder were used as matrix. With or without special plant fiber were used to compare the flowability and permeability. Table 2 shows the

219

overall composition of the conventional cement Tabular based castables.

Tab.1: Mix design of bauxite based ultra-low cement castables (wt %)

| Ultra-low Cement Castables | Flow ULC 851 | Flow ULC 851-1 |
|---|---|---|
| Plant fiber | 0 | 0.2 |

## 2. Permeability Testing

*Fig. 1: Schematic representation of permeability tester fabricated in laboratory*

The apparatus fabricated and used for measuring permeability is illustrated in Figure 1. The castables specimens, treated at different temperatures were coated with a thermosetting resin on the side surface. This is to prevent the gas leak though side surfaces while measuring permeability.

Compressed air at a pressure of 0.5 to 6.5 bars is passed through the specimen to measure the flow rate of gas (ml/min or l/min). Darcy's Law is applied to evaluate the permeability of the material. In this study, the exit pressure is supposed as a standard atmosphere and omitted. Therefore, compressed air at a pressure

of 0.5 to 6.5 bars could be considered as a pressure gradient or difference.

## RESULTS AND DISCUSSION

### 1. The permeability of Bauxite based ultra-low cement castables with different treated temperatures

In the really practice, castable refractories containing superfine aluminosilicate binder has had lower porosity and permeability, explosive spalling during dry-out has been an ongoing problem. Thus mixes of bauxite based ultra-low cement castables in Table 1 was selected to measure the permeability in terms of different treated temperatures.

Figure 2 unmistakably demonstrates that with the plant fibers, the castable held a great streak of success in improved permeability at all temperatures range from ambient temperature to 1600°C; in comparison to without plant fiber one, especially in the lower temperatures.

*Figure 2 The permeability of Flow ULC 851 with/without special plant fiber after treated at different temperatures*

### 2. The permeability of tabular alumina based conventional castables with different treated temperatures

As shown in Figure 3, castable CC95 with polypropylene fibers indicated higher permeability at 220°C, 320°C and 400°C thermal treatment, despite the lower permeability level after thermal treatment at 600 °C.

*Figure3 The permeability of conventional castable CC95 with regular Polypropylene fiber at different temperatures*

Comparison with polypropylene fibers, the special plant fibers cannot make significant permeability till 400°C despite higher permeability after 110°C, as illustrated in Figure 4.

*Figure 4 The permeability of conventional castable CC95-2 with plant fiber at different temperatures*

Combing with special plant fibers and polypropylene fibers, CC95-1 castable has demonstrated optimal permeability after PP fiber molten at 170°C as revealed in Figure 5.

*Figure 5 The permeability of conventional castable CC95 with regular PP fiber and plant fiber at different temperatures*

These results present great technological relevance due to two aspects. Firstly, it was shown that the plant fibers could be used as feedstock to produce drying agents for refractory castables. Secondly, due to the permeability increase dramatically after 170°C, the total drying time during castables' dry-out schedule can be significantly reduced, as well as the risks of explosive spalling.

*Figure 6 Comparison of the permeability among conventional castables with different fibers between 200°C and 300°C critical temperatures*

Furthermore, in the high risk of explosion temperature extent as shown in Figure 6, combination of plant fibers and polypropylene fibers, the conventional cement castable CC95-1 has demonstrated ideal permeability.

### 3. Plant Fiber Analysis

Plant fibers are generally composed of cellulose, often in combination with other components. The main constituents of the plant fibers are cellulose, hemicelluloses, lignin, pectin, and wax. The composition of fibers depends on the geographic location where the plants are grown up.

**Plant fibers TG and DTG analysis**

*Figure 7 Typical TG and DTG curves of the natural fibers* [7]

The thermal behavior of plant fibers was studied through TG and DTG curves provided in Figure 7. The initial thermal decomposition of fiber sample was observed at 60°C which is mainly due to the loss of moisture through evaporation. The second stage of thermal degradation of plant fibers was observed to occur between 250°C and 300°C associated with a mass loss of 20% could be attributed to thermal depolymerization of hemicelluloses. The major sharp peak at 350°C showed a major mass loss of about 60% occurred due to the thermal degradation of cellulose.

The peak observed in DTG curve within temperature 400°C to 650°C indicated the thermal depolymerization of wax and thermal degradation of lignin present in the plant fibers. The complex aromatic molecular structure of lignin makes it thermally more stable.

The results showed that the plant fibers were thermally stable up to 250°C. From 250°C to 350°C, the plant fibers were most unstable thermally.

Those temperature extent made an adaption to the drawbacks of using cement castables that explosive spalling around 200–300°C while the plant fibers were used as ant-spalling agent.

**Fibers Morphological Analysis**

A bauxite based castable with 0.25% plant fobers was casted. After 24 hrs curing in air, a sample was prepared for optical microscope measurement.

*Figure 8 Optical microstructure image of the natural plant fibers within castable after 110°C for 24 hours*

*SEM image of the fiber cross sectional area*
*Figure9 The fiber cross sectional area using the SEM micrographs in ImageJ*

The plant fiber had a structure in which each fiber had numerous individual fiber cells along the length. The fiber cells were composed of four main parts, which were the primary wall, the secondary wall, the tertiary wall, and the lumen. The fiber cells were joined together by means of hemicellulose and lignin, and they are called the middle lamella [7].

The morphology of plant fiber differed in the amount of main voids (or main lumens) that were used to transport the cell sap, i.e., watery fluid that circulated through the plant and carries food and other substances to various tissues.

The microstructural observation performed in plant fibers showed that there are main voids with many small voids. Those voids will become channels to leave vapors whenever castables were heating.

## 4. Laboratorial and industrial trial: explosion resistance testing

Laboratory testing was done by two cuboids. Each one about ~2.7 kg (100 × 100 × 100 mm), casted by CC95 and CC95-1 which containing special plant fiber and polypropylene fiber.

Those two cuboids cured at room temperature for 24 h, de-molded, and dry at room temperature for another 24 hours.

A liquefied petroleum gas (LPG) burner was used to flame the cuboids.

Finally, CC95 cuboid was exploded and CC95-1 was not.

Industrial practices have been done through the applications in cement kilns, mining grate kilns and steel lades.

Generally, drying monolithic refractory means executing a thermal cycle that starts at ambient temperatures and follows a curve specified by the manufacturer.

Eventually, the castable blocks containing plant fibers has remained intact and demonstrated excellent ant-spalling resistance; in spite of all other low cement castables were exploded.

## CONCLUSIONS

- Regarding superfine aluminosilicate powder bonded ultra-low cement castables, the special plant fibers are effective very well for overall temperatures range from room temperature to even more than 800°C which enable to have much higher permeability.
- Regarding conventional cement castables, special plant fibers cannot make higher permeability till 400°C compared with polypropylene fibers.
- Combination of special plant fibers & polypropylene fibers makes conventional cement castables avoiding dangerous explosive temperature extent (200-300°C).
- Laboratorial and industrial trials have confirmed that those special plant fibers work excellently for quick drying castables without any risk of explosive spalling.

## Service and Performance

The German Refractories Association represents and pursues the politico-economic interests of its member companies vis-à-vis public authorities and government bodies in both national and European contexts. The Association covers a broad spectrum of issues and activities: It provides comprehensive support and guidance in all matters pertaining to raw materials supply security, environment and energy policy as well as tax, law, research and technology, including questions relating to standardisation.

Major German companies and international brand leaders have joined the Association, which for its part is a member of the national and European network of associations.

## The Benefit

- Information about current technical and economic policy developments with special attention to the interests of the refractory industry.
- Creation of legally secure statistics on the development, sales and consumption of refractory products, personnel costs, fuel and energy consumption, development of raw material prices and market developments in the customer industries
- Refractory committee work on technical and environmental issues and participation in BBS, BDI or DIN and ISO.
- European Cooperation (PRE and Cerame-Unie) is bundled and in dialogue with the European Institutions. World trade and regulatory issues are discussed in the World Refractories Association (WRA).

# EFFECT OF H₂O₂ ADDITION AN ANTI-EXPLOSION PERFORMANCE OF ALUMINA BASED CASTABLES BONDED BY HYDRATABLE ALUMINA

Wang Zhanmin, Wang Huan, Feng Haixia, Cao Xiying, Cao Yingnan, Liu Jun
State Key Laboratory of Advanced Refractories, Sinosteel LIRR, Luoyang 471039, China

## ABSTRACT

Effect of $H_2O_2$ addition on explosive resistance of alumina based castables bonded by hydratable alumina was investigated in present paper. In order to improve the explosive resistance of the castables, 0.025%, 0.050%, 0.075%, 0.100% and 0.125% (w) $H_2O_2$ were introduced to the castables respectively. Explosive resistances were tested of the specimens cured at room temperature for 12 h at 450, 500, 550, 600, 650, 700, 750 and up to 800°C in order. Apparent porosity, bulk density, cold modulus of rupture, cold crushing strength, air permeability and pore size distribution were determined by specimens cured, dried and heat treated at different temperature. The results show that with the increase of $H_2O_2$ addition, explosive resistances of castables increase, average pore diameters increase, and bulk density, CMOR and CCS decrease gradually. The appropriate amount of $H_2O_2$ should be controlled within 0.075%.

**Key words:** Hydratable alumina; alumina castable; $H_2O_2$; explosive resistance; air permeability; pore size distribution

## INTRODUCTION

Alumina cement using in castables will bring CaO to castables, which affects the hot properties and performance of castables [1]. This problem does not exist when hydratable alumina is used as the binder[2] for castables. However, the hydration products of hydratable alumina show low density and easily block pores, thus resulting in poor permeability of castables, and it rapidly dehydrates at 300-500 °C to form a large amount of water vapor [3], which lead to explosive spalling of hydratable alumina bonded castables during heating.

At present, the main method to improve the explosive resistance of castables is to introduce anti-explosion additives such as aluminum powder, organic fibres, azoformamide and aluminum lactate [4]. However, there are also many problems for these additives [5-9]: aluminum powder easily leads to expansion or cracking of castables, and the hydrogen produced shows the risk of combustion and explosion in case of fire; organic fibres are difficult to disperse evenly in castables; azoformamide easily creates a lot of cracks in castables; and aluminum lactate forms permanent cracks in castables and affects the corrosion resistance.

$H_2O_2$ can spontaneously decompose into water and $O_2$ at room temperature, which is an environment friendly foaming agent [10-11]. In present work, $H_2O_2$ was introduced as the anti-explosion additives of hydratable alumina bonded corundum castables, and the effect of the $H_2O_2$ addition on the physical properties and explosive resistance of the castables was investigated.

## EXPERIMENT

### Raw Materials

The raw materials used for experiments included white fused alumina (5-3mm, 3-1mm, 1-0mm and≤0.074mm), activated ultrafine α-$Al_2O_3$ ($d_{50}$=1.198μm), microsilica ($d_{50}$=0.268μm), hydrogen peroxide solution ($H_2O_2$=30mass%), hydratable alumina powder (d50=2.4μm), and sodium hexametaphosphate. Table 1 shows the chemical composition of the raw materials used.

Table 1 Chemical composition of raw materials used/mass%

| | $Al_2O_3$ | $SiO_2$ | $Fe_2O_3$ | CaO | $K_2O$ | $Na_2O$ |
|---|---|---|---|---|---|---|
| White fused $Al_2O_3$ | 99.40 | 0.05 | 0.15 | | | 0.20 |
| Ultrafine α-$Al_2O_3$ | 0.40 | 96.77 | 0.10 | 0.20 | 0.26 | 0.29 |
| Microsilica | 99.38 | 0.13 | | | | 0.19 |

## Specimen Preparation and Testing

Specimen preparation procedure includes: batching the raw materials according to Table 2, hand mixing for 2-3min in a plastic bag, putting them into a mixing pot and dry mixing for 90s, adding water and wet mixing for 150s, adding hydrogen peroxide solution and stirring for 15s, then putting into mold and vibrating for 120s for the specimens with sizes of 40mm×40mm×160mm, 50mm×50mm×50mm and φ50mm×50mm.

Table 2 Formulations of specimens /mass%

| | | H₀ | H₁ | H₂ | H₃ | H₄ | H₅ |
|---|---|---|---|---|---|---|---|
| White fused alumina | 5-3 mm | 18 | 18 | 18 | 18 | 18 | 18 |
| | 3-1 mm | 30 | 30 | 30 | 30 | 30 | 30 |
| | 1-0 mm | 18 | 18 | 18 | 18 | 18 | 18 |
| | ≤0.074 mm | 25 | 25 | 25 | 25 | 25 | 25 |
| Mcrisilica | | 2 | 2 | 2 | 2 | 2 | 2 |
| Ultrafine α-$Al_2O_3$ | | 2 | 2 | 2 | 2 | 2 | 2 |

| Sodium hexametaphosphate | | 0.2 | 0.2 | 0.2 | 0.2 | 0.2 | 0.2 |
| Deionized water | | 5 | 5 | 5 | 4.9 | 4.9 | 4.9 |
| Hydrogen peroxide solution | | 0 | 0.025 | 0.050 | 0.075 | 0.100 | 0.125 |

The specimens of 50 mm×50 mm×50 mm were cured at room temperature for 12 h and demoulded. The explosion resistance tests were carried out at 450, 500, 550, 600, 650, 700, 750 and 800 °C according to GB/T 36134-2018. The explosion resistance temperature and explosion time of the specimens were recorded. When two specimens in a group explode, the shorter explosion time is taken as the explosion time of the group. When the explosion resistance temperature of two groups of specimens is the same, the specimen with longer explosion time has better explosive resistance.

The rest specimens were cure at room temperature for 24h and then demoulded, dried at 110°C for 24h, and fired at 1400°C for 3h in the air atmosphere. The permanent linear change of the specimens was measured, the apparent porosity and the bulk density were determined according to YB/T 5200-1993, the cold modulus of rupture was determined according to GB/T 3001-2007, the cold crushing strength was determined according to GB/T 5072-2008, the air permeability was determined according to GB/T 3000-1999, and the pore size distribution was tested by the mercury intrusion method.

Specimens without aggregates were prepared by procedure: batching the raw materials according to Table 3, mixing and demoulding according to the same process as above, curing at room temperature for 24h, demoulding and dry at 110°C for 24h. The pore size distribution and the pore structure parameters of the specimens were determined by the mercury intrusion method.

Table 3 Formulations of specimens without aggregates /mass%

| | h₀ | h₁ | h₂ | h₃ | h₄ | h₅ |
|---|---|---|---|---|---|---|
| White fused alumina (≤0.074 mm) | 73.53 | 73.53 | 73.53 | 73.53 | 73.53 | 73.53 |
| Microsilica | 5.88 | 5.88 | 5.88 | 5.88 | 5.88 | 5.88 |
| Ultrafine α-$Al_2O_3$ | 5.88 | 5.88 | 5.88 | 5.88 | 5.88 | 5.88 |
| Hydratable alumina | 14.71 | 14.71 | 14.71 | 14.71 | 14.71 | 14.71 |
| Sodium hexametaphosphate | 0.59 | 0.59 | 0.59 | 0.59 | 0.59 | 0.59 |
| Deionized water | 14.7 | 14.7 | 14.7 | 14.7 | 14.7 | 14.7 |
| Hydrogen peroxide solution | 0 | 0.074 | 0.147 | 0.221 | 0.294 | 0.368 |

The microstructure of the specimens was observed and analyzed by a scanning electron microscope.

## RESULTS AND DISCUSSIONS

### Microstructure

Figure 1 shows the SEM photos of specimens H1, H3 and H5 fired at 1400℃. It can be seen that circular pores are generated by $H_2O_2$ decomposition in the three specimens. With the increases of the $H_2O_2$ additions, the size and the number of circular pores increase.

(a) Specimen H1

(b) Specimen H3

(c) Specimen H5

Fig. 1 SEM photos of specimens H1, H3, and H5 fired at 1400℃

### Air Permeability

Table 4 shows the air permeability of the specimens after demoulding, drying at 110℃ or firing at 1400℃. It can be seen that with the increases of the $H_2O_2$ additions, the permeability values of the specimens after demoulding, drying or firing gradually increase. This is because that the number of pores generated by foaming increases, and the average distance between pores shortens, which smooths the connection between pores. With the increases of the $H_2O_2$ additions, the permeability differences between the dried specimens and the demoulded specimens increases gradually because of the increasing permeability potential.

Table 4 Air permeability of specimens after demoulding, drying and firing

| $\times 10^{-15}$ /m$^2$ | H$_0$ | H$_1$ | H$_2$ | H$_3$ | H$_4$ | H$_5$ |
|---|---|---|---|---|---|---|
| After demoulding | 0.23 | 0.76 | 1.02 | 3.44 | 5.62 | 6.83 |
| After drying at 110℃ | 0.30 | 1.50 | 1.84 | 4.41 | 6.88 | 8.20 |
| After firing at 1400℃ | 130.12 | 143.37 | 180.95 | 211.45 | 342.75 | 356.31 |

## Pore Size Distribution

The pore size distribution of the specimens without aggregates after drying is shown in Fig. 2, and the pore structure parameters are shown in Table 5. It can be seen from Fig. 2 (a) that the main peak of the specimens is in the 0.1-2μm range, but the peak of the specimens added with $H_2O_2$ is lower and moves to the right compared with that of specimen h0. Moreover, with the increases of the $H_2O_2$ additions, an obvious peak appears in the 5-20 μm range for specimens h3, h4, and h5. It can be seen from Fig. 2 (b) that with the increases of the $H_2O_2$ additions, the cumulative distribution curves of the specimens gradually rises, especially in the 1-20 μm range. It can be seen from Table 5 that with the increases of the $H_2O_2$ additions, the total pore volume of the specimens increases gradually; the total pore surface area increases at first and then decreases; and the average pore size decreases at first and then increases significantly. This is because that with the increases of the $H_2O_2$ additions, the numbers of pores formed by $H_2O_2$ foaming increase, leading to the increase of the total pore volume. The less $H_2O_2$ additions, the smaller pore size of the specimens is, so the pore surface area increases. However, with more $H_2O_2$ addition, excessive pores gather and link to form larger pores. When the total pore volume does not increase more, the total pore surface area decreases. The average pore size is calculated through dividing 4 times the total pore volume by the total pore surface area.

(a) Differential distribution

(b) Cumulative distribution

Fig. 2 Pore size distribution of specimens without aggregates after drying

Table 5 Pore structure parameters of specimens without aggregates after drying

| | h$_0$ | h$_1$ | h$_2$ | h$_3$ | h$_4$ | h$_5$ |
|---|---|---|---|---|---|---|
| Total pore volume /(ml·g$^{-1}$) | 0.138 | 0.139 | 0.146 | 0.153 | 0.182 | 0.187 |
| Total pore surface area /(m$^2$·g$^{-1}$) | 7.47 | 7.70 | 8.21 | 7.94 | 7.32 | 7.22 |
| Average pore size /nm | 73.7 | 72.2 | 71.3 | 77.1 | 99.3 | 103.6 |

The pore size distribution of the specimens containing aggregates fired at 1400℃ is shown in Fig. 3. It can be seen that the specimens without $H_2O_2$ have a single peak pore size distribution; the specimens with $H_2O_2$ additions show a double peak pore size distribution, and the second peak continuously moves to the right with the increasing $H_2O_2$ addition, indicating that the numbers of large pores and the average pore size gradually increase. However, the distribution curves of the specimens move to the right compared with those of the specimens without aggregates, indicating that their pore size is larger than that of the specimens without aggregates, which is due to the larger pores formed by the accumulation of aggregate particles.

**Physical Properties**

Figure 4 shows apparent porosity and bulk density of the specimens after demoulding, drying and firing as well as permanent linear change after firing at 1400℃. It can be seen that with the increases of the $H_2O_2$ additions, apparent porosity of the specimens after demoulding, drying and firing increases gradually, bulk density decreases gradually, and permanent linear shrinkage of the specimens after firing at 1400℃ slightly increases.

The cold modulus of rupture and the cold crushing strength of the specimens after demoulding, drying and firing are shown in Fig. 5. It can be seen that with the increases of the $H_2O_2$ additions, the cold modulus of rupture and the cold crushing strength of the specimens after demoulding, drying and firing decrease gradually. This is because the strength of the specimen is positively related to its density and densification.

(a) Apparent porosity

(b) Bulk density

(c) Permanent linear shrinkage of specimens after firing at 1400℃

Fig. 4 Apparent porosity and density of specimens after demoulding, drying and firing as well as permanent linear change after firing at 1400℃

**Explosive Resistance**

Table 6 shows the results of explosive resistance of the specimens after curing for 12 h in moulds at room temperature. It can be seen that the explosive resistance temperature of specimens H0, H1, H2, H3, H4 and H5 is 450, 500, 500, 550, 650 and 750 ℃ respectively, which increase nearly with the increases of the $H_2O_2$ additions. Although specimens H1 and H2 have the same explosive resistance temperature of 500℃, specimen H2 shows longer explosion time than specimen H1, and only one piece of specimen H2 explosive spalling. The explosive resistance of the specimens is in the order of H5>H4>H3>H2>H1>H0, that is, they are really enhanced with the increases of the $H_2O_2$ additions.

The mechanism of $H_2O_2$ addition to improve the explosive resistance of castables can be described as follows: the foaming effect of $H_2O_2$ increases the porosity of castables, which enlarges the space for holding the water vapor generated during heating thus slows down the increase rate of water vapor pressure and reduces the water vapor pressure peak; and when the numbers of pores increase, the average distances between pores shorten, speeding up the escape of water

vapor. Both of them are beneficial to improve the explosive resistance of castables.

Table 6 Explosive resistance temperature of specimens after curing for 12h at room temperature

|  | $H_0$ | $H_1$ | $H_2$ | $H_3$ | $H_4$ | $H_5$ |
|---|---|---|---|---|---|---|
| 800°C | — | — | — | — | — | ×× (146s) |
| 750°C | — | — | — | — | — | OO |
| 700°C | — | — | — | — | ×× (182s) | OO |
| 650°C | — | — | — | — | OO | OO |
| 600°C | — | — | ×× | ×× (220s) | OO | OO |
| 550°C | — | ×× (257s) | O× (314s) | OO | — | — |
| 500°C | ×× (326s) | OO | OO | OO | — | — |
| 450°C | OO | OO | OO | — | — | — |

Note: — means no test, O means no explosion, × means explosion, and the data in brackets are the explosion time.

**CONCLUSIONS**

With the increases of the $H_2O_2$ additions, explosive resistance temperature of the castables. With the increases of the $H_2O_2$ additions, average pore size gradually increases of the castables, and bulk density, CMOR and CCS decrease gradually.

Appropriate $H_2O_2$ additions can improve remarkably explosive resistance of alumina castables bonded by hydratable alumina. By comprehensive consideration, the appropriate $H_2O_2$ addition shall be controlled around 0.075%.

**ABSTRACT**

The workability of refractory castables determines the quality of linings or prefabricated parts made thereof. It is their rheology, particularly the shear rate-dependent dynamic viscosity that defines the workability of refractory castables during various processes such as flowing, levelling, compaction, casting, and pumping. Traditionally, the rheology of refractory castables is assessed through the spread flow test, which is a quick and simple method but does not provide quantified rheological data, including shear rate-dependent viscosity. Consequently, there is a significant gap in our understanding of the rheological properties of refractory castables, impeding the optimization of lining and prefabricated part quality.

To address this issue, a novel method has been developed to determine the shear rate-dependent (dynamic) viscosity of refractory castables. This method employs a lifting sphere rheometer to measure viscosity and utilizes a coupled CFD-FEM analysis to determine the prevailing shear rate during the measurement. By integrating these techniques, comprehensive rheological data for refractory castables can be obtained.

This innovative approach provides a means to accurately measure rheological properties of refractory castables. With this knowledge, the quality of linings and prefabricated parts can be optimised.

## INTRODUCTION

Refractory castables are increasingly being utilized in high-temperature operational units [1]. The rheological properties of these castables, influenced by their composition and processing technique, play a crucial role in defining their processing characteristics. It is essential to adjust these rheological properties according to the specific processing method, such as vibrocasting or self-levelling. Failure to do so can result in sedimentation or voids within linings or prefabricated parts made from the castables, which ultimately reduce their service life. The performance of a refractory castable during service primarily depends on its rheological properties during processing [2, 3, 4]. Insufficient rheological properties can lead to diminished performance or even complete failure of the monolithic structure [5].

The DIN EN ISO 1927-4 standard is commonly used for determining the rheological properties of refractory castables. In the case of self-flowing refractory castables, a cone is filled with the castable, lifted, and the resulting spread diameter is measured after two minutes. For vibrocasting castables, the cone is filled under vibration for 30 seconds. Then, it is lifted, and the castable is vibrated for an additional 30 seconds. Both vibration processes have an amplitude of 0.5 mm and a frequency of 50 Hz. However, a significant challenge with methods that measure spread or slump is the inability to obtain rheological properties based on shear rate, shear stress, or viscosity during the measurement. Consequently, these properties cannot be adjusted and optimized using such measuring methods [6]. As a result, different materials can show the same test result when measuring spread even though their rheological behaviour during processing (such as pumping, compacting, flowing) may vary greatly, because the measurement only represents processing equivalent to spread flow after a certain time. Flowing speed during flow or behaviour in high shear rate areas cannot be obtained. This means that castables may be entirely unsuitable for certain processing techniques despite their seemingly good values of spread flow.

### Challenges in measuring the shear rate dependant viscosity of refractory castables

The major problem with the evaluation of the fundamental rheological units of refractory castables is the coarse components of the castable, since standardized rheometers only allow a gap size (and thus particle diameters) of about 100 μm. Other rheometers, mostly developed for the construction industry, display significant sources of error [6, 7, 8, 9, 10, 11]. No method had been available before with which the shear rate dependant dynamic viscosity of castables could be measured.

### New approach for measuring the shear rate dependant viscosity of refractory castables

The set-up of the new approach is based on a lifting sphere rheometer. A sphere is positioned at the bottom of a test container which is then filled with a refractory castable. The measuring sphere is connected to a force sensor through a cable. The force sensor is attached to a linear motor axis, with which the sphere is lifted through the castable at a defined lifting speed. In the experiment, a predefined speed is set and the force needed to lift the sphere through the castable is measured. Considering the geometric design of the sphere and the measuring container as well as the lifting speed and measured force, one is able to calculate the dynamic viscosity of the castable. The force without lifting and during lifting is measured, to directly calculate the friction force by subtraction the force without motion from the force with motion. This simplifies the Stokes law for the determination of the dynamic viscosity to Eq. 1.

$$\eta_F = \frac{F_R * (1 - 2,1 * \frac{r_P}{R_W})}{6 * \pi * r_P * v_s} \tag{1}$$

With the friction force $F_R$, the radius $r_P$ of the sphere, the radius $R_W$ of the container and the lifting velocity $v_S$. The term in the brackets describes the Faxensche wall correction, which integrates the interaction of the fluid with the container wall into the equation.

The determination of the prevailing shear rate during a measurement of the dynamic viscosity has been a notable challenge and was overcome by CFD-FEM analysis, integrating the dynamic viscosity, density, and lifting speed. The shear rates during measurements with different experimental parameters were then calculated. The results demonstrated a significant correlation between shear rate and lifting velocity, with dynamic viscosity and castable density having a minor impact. This significant finding paved the way for developing a comprehensive database that describes the shear rate in relation to these experimental parameters. The database encompasses a wide range of lifting velocities (1 - 100 mm/s), densities (2500 - 3500 kg/m³), and dynamic viscosities (0.5-5000 Pa*s) as depicted in Figure 1. Notably, when considering errors smaller than 4 % arising from ignoring the influence of dynamic viscosity and density, the shear rate can be calculated based only on the lifting velocity. This implies that the shear rate can now be controlled and predetermined during a measurement by utilizing the correlation between shear rate and lifting speed. Consequently, this enables a controlled measurement of dynamic viscosity in castables, as the shear rate can be effectively regulated during the measurements.

228
Fig. 1: Shear rate in dependence of the lifting velocity, calculated with the CFD-FEM. The datapoints are a set of points which represent all dynamic viscosities and densities.

## Rheological behaviour – influencing factors

It is necessary to separately describe the influencing factors on the rheological properties for two different material classes, self-flowing castables and vibrocasting castables. Excluding the mixing process, the composition of the castables (of both classes) is mainly responsible for the rheological behaviour. The vibration parameters, amplitude and frequency, also define the rheological properties while processing the vibrocasting castables. Depending on the type of composition (coarser or finer PSD) a change in the amplitude or frequency during vibrocasting leads to a different rheological respective flowing behaviour. Therefore, a method for the determination of the shear rate dependant viscosity of the castables is required, that allows the description of the rheological properties under vibration [12, 13, 14].

## MATERIALS AND METHODS
### Materials
*Matrix suspensions (cement free)*
For the evaluation and verification of the new method, three castable matrix suspensions were investigated (Table 1). Their compositions regarding the calcined (CT 9 FG and CT 800 FG, Almatis, Germany) and reactive alumina products (NO 725-10 and NO 713-10 RF, Nabaltec, Germany) were varied in terms of type and concentration/content, whereas the sum of concentration/content of these materials was kept constant. The contents of water and superplasticizer (Castament FS 60, BASF, Germany) were always kept constant. The particle size distribution from coarse to fine was S2 >> S1>S3.

Tab. 1: Castable matrix suspensions.

| Raw material | S1 in wt.-% | S2 in wt.-% | S3 in wt.-% |
|---|---|---|---|
| T60 -45 µm | 51,4 | 51,4 | 51,4 |
| CT 9 FG | 0 | 14,3 | 0 |
| CT 800 FG | 0 | 14,3 | 0 |
| NO 725-10 | 28,6 | 10 | 20 |
| NO 713-10 RF | 20 | 10 | 28,6 |
| Castament FS 60 | 0,3 | 0,3 | 0,3 |
| Water | 15,7 | 15,7 | 15,7 |
| Matrix particle size distribution | medium fine | coarse | fine |

*Self-flowing castables (cement free)*
The matrix suspensions ("S1", "S2" and "S3", abbreviated as "Sx") were loaded with tabular alumina aggregates (T60 0-0.5 mm, 0.5-1 mm, 1-3 mm, 3-6 mm, Almatis, Germany). The proportion of water to matrix suspension as well as the proportion of water to superplasticizer remained constant. Table 2 shows the compositions of the "coarse dispersions" ("CDx"), which are equal to cement free castables.

Tab. 2: Self-flowing castables (cement free).

| Raw Material | CD1 in wt.-% | CD2 in wt.-% | CD3 in wt.-% |
|---|---|---|---|
| T60 3-6 mm | 19 | 19 | 19 |
| T60 1-3 mm | 17 | 17 | 17 |
| T60 0,5-1 mm | 14 | 14 | 14 |
| T60 0-0,5 mm | 15 | 15 | 15 |
| Matrix | 35 (S1) | 35 (S2) | 35 (S3) |
| Castament FS 60 | 0.1 | 0.1 | 0.1 |
| Water | 5.5 | 5.5 | 5.5 |
| Matrix particle size distribution | medium fine | coarse | fine |

*Vibrocasting castable*
One vibrocasting castable ("VC") had the following composition with a particle size distribution with a q-value of 0.34: 26.1 wt.-% T60 3-6 mm, 17.5 wt.-% T60 1-3 mm, 17.5 wt.-% T60 0.5-1 mm, 10.4 wt.-% T60 0-0.5 mm, 13.4 wt.-% T60 0-0.3 mm, 4.1 wt.-% T60 -45 µm (all Almatis, Germany), 6.1 wt.-% NO 713-10 RF (Nabaltec, Germany) and 5 wt.-% Secar 71 (Kerneos, France). As additives NTTP (0.1 wt.-%) and citric acid (0.005 wt.-%) were added. The water content was 6.8 wt.-%.

*Sample preparation*
The matrix suspensions were mixed with a Vollrath stirrer for about 20 minutes. The castables were dry mixed for 0.5 minutes and subsequently mixed for 5 minutes after water addition (batches of 5 kg).

## Methods
*Rheological measurements*
Rheological measurements of the matrix suspensions with a standardized rheometer as reference were carried out with a coaxial cylinder rheometer (Malvern Kinexus Pro+) C 25 SW1177.
The shear rate dependant dynamic viscosities of the matrix suspensions and castables were determined with the new lifting sphere rheometer with coupled CFD-FEM (CFD-FEM database). The materials under investigation were filled into a cylindrical test container with a diameter of 90 mm up to a height of 150 mm. A sphere with a diameter of 15 mm was positioned at the bottom of the test container before starting the measurement and then lifted up with a constant lifting velocity of 3 mm/s ($\approx$ 0.042 1/s), meaning a constant shear rate during the experiments. The force required for lifting was measured and the dynamic viscosity was calculated from this. For the vibrocasting castables, the measurements were done during vibrocasting with an amplitude of 0.6 mm and frequencies of 30, 50 and 70 Hz.

## RESULTS
### Verification of the method
Firstly, the new method was verified and the reproducibility was proven for matrix suspensions of refractory castables (cement-free). Therefore, the shear rate-dependent viscosity of the matrix suspensions S1 (Figure 1), S2 (Figure 2), and S3 (Figure 3) was determined using a standardized rheometer (Figures 1-3, solid green lines) and the new lifting sphere rheometer. For the new lifting sphere rheometer, the calculation of the shear rate was also performed using various formulas from the literature, of which only the most applicable results according to Noor are presented (Figures 1-3, orange lines with "X") [11]. Additionally, CFD-FEM

229

was employed to determine the shear rate (Figure 1: red triangles, Figure 2: blue triangles, and Figure 3: red triangles) in the same experiment. In all measurements, the dynamic viscosity exhibited a more or less regressive decrease with increasing shear rates. When compared to shear rate evaluations based on the previously known formula of Noon (orange lines with "X"), the calculation of shear rate using CFD-FEM (triangles) showed excellent agreement with the results obtained from measurements using the standardized rheometer. Furthermore, the shear rate-dependent dynamic viscosities of the three "S1" measurements demonstrated outstanding reproducibility. These tests verified the new method for use with matrix suspension of refractory castables and validated its reproducibility.

Fig 1: Shear rate dependant viscosity of S1 (medium fine matrix). The X represent the determination of the shear rate according to the formula used by Noor and Uomoto [11].

Fig 2: Shear rate dependant viscosity of S2 (coarse matrix). The X represent the determination of the shear rate according to the formula used by Noor and Uomoto [11].

Fig 3: Shear rate dependant viscosity of S3 (fine matrix). The X represent the determination of the shear rate according to the formula used by Noor and Uomoto [11].

**Determination of the rheology of self-flowing castables**

Figure 4 illustrates the shear rate dependant viscosity of the three self-flowing castables, measured with the new lifting sphere rheometer. The castable with the medium fine matrix (CD1) exhibits a moderate dynamic viscosity at the lowest measured shear rate, which regressively decreased up to a shear rate of about 0.1 1/s and then increased linearly up to a shear rate of about 1 1/s. In comparison the castable with the coarse matrix (CD2) showed a low dynamic viscosity at low shear rates, but also a regressive decrease of the dynamic viscosity in the same range of shear rates as CD1. However, the dynamic viscosity then exponentially increased with increasing shear rate, which represents a strong dilatancy. The castable with the finest matrix (CD3) behaved similar to CD1 but showed nearly two times higher dynamic viscosities at low shear rates.

Fig 4: Shear rate dependant viscosity of the self-flowing cement free castables.

**Determination of the rheology of vibrocasting castables**

The influence of the vibration frequency on the dynamic viscosity of vibrocasting castables at a low shear rate of 0.042 1/s is represented in Figure 5. At a low vibration frequency of 30 Hz, the cable for lifting the sphere tore. This in turn indicates a dynamic viscosity of at least 80000 Pa*s and leads to an unprocessable castable. At a vibration frequency of 50 Hz, the dynamic viscosity is 150 Pa*s, so a good flowability and processability is expected. A further increase of the vibration frequency leads to a strongly rising dynamic viscosity of the castable up to a value of about (10000 Pa*s). This also renders such a castable impossible to process.

The rather large error at the measurement of low dynamic viscosities in low shear rate areas results from the vibration itself respectively the vibration of the cable for lifting the sphere and will be addressed in further research work.

*Fig 5: Dynamic viscosity of VD at a lifting velocity of 3 mm-s (0.042 1/s) and a vibration amplitude of 0.6 mm in dependency of the frequency.*

**CONCLUSIONS**

A new method for determining the shear rate dependent viscosity of castables has been successfully verified and is available for rheological measurements of self-flowing and vibrocasting castables.

Reproducibility and verification experiments conducted on matrix suspensions of castables have demonstrated excellent agreement with measurements obtained using standardized rheometers.

The composition of the matrix plays a major role in determining the shear rate dependent viscosity of castables and can be utilized as a tool for rheology control. By employing the new method, it becomes possible to measure and assess these variations in rheological behavior.

Additionally, the new method has facilitated the evaluation of the impact of shear rate dependent viscosity during the vibration of castables. Among the vibration parameters, the vibration frequency strongly influences the rheological behavior of castables. This observation indicates that different vibration parameters in the laboratory and on installation sites may result in different rheological behaviors of castables, potentially leading to variations in the quality of prefabricated parts or linings.

Using the newly developed database for determining the shear rate during dynamic viscosity measurements with the lifting sphere rheometer, it is now possible for others to replicate the new method. This advancement enables quality assurance and research and development departments within the refractory sector to measure the shear rate dependent viscosity of refractory castables casted through self-flowing or vibration. Consequently, this provides an opportunity for improved quality assurance, faster optimization of existing castables, and the development of new innovative castables.

**OUTLOOK**

The errors encountered during the measurement of dynamic viscosity in castables during vibration will be addressed in further research work that aims at investigating the impact of vibration parameters and castable compositions on rheological properties.

**ABSTRACT**

This article describes a method for improved evaluation of the slump flow according to ISO 1927-4. While the normative method solely compares the averaged diameter of the slump cake with the initial value after a fixed time span, the improved method allows to record three-dimensional pictures over the entire test time. In particular, the height-dependent flow rate and flow velocity can be determined.

This work now shows that considerably more findings can be obtained from this rather simple experiment, if the time dependant spread flow is recorded with a 3D camera. In addition, this part shows how the temperature of the ready mixture, which varies depending on the raw material temperature, affects the rheological properties. The article shows clear differences in the flow behaviour in a temperature range from 21 to 30°C.

**Introduction**

Refractory castables are complex mixtures of granulations of refractory raw materials with grain sizes between approx. 0.1 μm and 6 mm, a binder, and chemical additives [1], [2]. The chemical additives, especially dispersing agents, exert a considerable influence on the rheological properties of refractory concretes.

Refractory castables are homogenised with water in compulsory mixers and then placed in a mould or behind a formwork. This is done by self-flowing, vibration or spraying. Refractory castables can also be pumped.

Depending on the placement method, the refractory castables are subjected to very different shear rates on the process side, ranging from < 0.1 1/s (self-flowing) to 100 1/s (pumping) [3]. In order to be able to adjust the flow behaviour of a refractory castable for the different types of placement, it is therefore of great importance to be able to measure the rheological properties of refractory castables as a function of the shear rate. The rheological properties are crucial for the successful use of refractory castables in the respective application, as they determine the performance of the lining [4], [5], [6]. Poorly adjusted rheological properties lead to reduced performance and even material failure [7], [11]. It is therefore crucial to adjust the rheological properties of refractory castables to the respective processing procedure. For this purpose, the rheological parameters, especially the shear rate-dependent viscosity, must be known.

The most common method in the refractory industry for determining the rheological properties is the determination of the consistency by means of spread-flow according to ISO 1927-4. The standard defines (in the case of self-flowing refractory concretes), a funnel mould with a height of 80 mm, a lower diameter of 100 mm and an upper diameter of 70 mm, which is filled with the refractory castable and placed on a firm base with the opening facing downwards. The funnel is then pulled away upwards and the spread of the refractory concrete after 2 minutes is determined as the average diameter of the pile. Disadvantages: The measurement is a semi-quantitative single-point measurement that cannot reproduce rheological parameters [7], [9], [10], [11]. No shear rate can be specified for the method and the method is limited to the maximum flow rate of the refractory concrete. Another problem is that the flow conditions (e.g. shear rate) during the expansion of the refractory concrete are completely unknown. Thus, the rheological parameters of refractory castables cannot be investigated so far.

This work is intended to show that considerably more findings can be obtained from this rather simple experiment if the entire course of the run-out is recorded with a 3D camera as a function of time. This results in the height-dependent flow velocity as additional values, from which the dynamic viscosity can also be derived in principle, provided that the height-dependent material pressure (hydrostatic pressure) exerted on the refractory concrete can be simulated exactly over the entire course of the test. The results show that this time-dependent method provides significantly more information about the flow properties of refractory concretes.

For this purpose, a cement free coarse grain dispersion was used to demonstrate the capabilities of this time-resolved method.

**MATERIAL AND METHODS**

**Material**

The investigations were carried out on a coarse-grain dispersion, CD6, which does not contain any cement, as the initial aim here is to ensure that the rheological behaviour is not influenced by the setting process of the cement phase. In particular, it should be emphasised here that the early formation of cement hydrate phases leads to stiffening, but also that the change in pH due to the solution of $Ca^{2+}$ ions influence the rheological properties. This ensures that only the particle size distribution in combination with the plasticiser, in this case Castament® FS60, determines the rheological properties.

The coarse grain dispersion, CD6, belongs to a development series of a total of 10 formulations that were developed within the framework of a 2-year IGF project, whereby here the matrix components were permuted in their concentration but kept the same in total. Two further coarse grain dispersions will be discussed in more deepens in the second part of this contribution [12]. The specific surface area varies between 1.29 and 4.93 $m^2$/g. CD 6, at 2.32 $m^2$/g, is in the coarser range of offset variations. CD6 has a low dynamic viscosity at a low shear rate. This increases exponentially with increasing shear rate. This reflects a pronounced dilatant rheological behaviour for this offset. All coarse grain dispersions have been developed to have self-flowing properties.

Coarse grain dispersion, CD6, consists of different grades of tabular alumina T60 (from 6 mm to 45 μm, Almatis, Germany). The matrix components contain four grades of calcined alumina that allow to adjust a variety of matrix compositions that lead to 10 permutations with specific surface of the matrix components. Namely CT 9 FG, CT 800 FG, (Almatis, Germany) NO 725 10, and NO 713 10 RF (Nabaltec, Germany) were used in different proportions over the entire set of coarse grain dispersions. In this study solely CD6 was used (table 1).

Tab. 1: Composition of coarse grain dispersion, CD6

| Raw Materials | CD6 | Raw Materials | CD6 |
|---|---|---|---|
| T60 3-6 mm | 19 | NO 725-10 | 3,5 |
| T60 1-3 mm | 17 | NO 713-10 RF | 3,5 |
| T60 0,5-1 mm | 14 | CT9FG | 5 |
| T60 0-0,5 mm | 15 | CT800FG | 5 |
| T60 0-0.045mm | 18 | FS60 | 0,1 |
| | | Wasser | 5,5 |

## Methods

*Preparation of coarse grain dispersions*

To ensure a proper mixing, an intensive mixer (type R02, Eirich GmbH & Co. KG, Germany) was used with a stick agitator and simultaneous rotation with a rotation speed of 200 rpm, which corresponds approximately to the energy input of a planetary mixer as recommended by ISO 1927. The mixing time was variated to investigate the properties of the coarse dispersions under different energy input.

A total of 9 mixtures of 5 kg each were produced, differing only in the storage temperature of the raw materials (15, 22, 25°C) and the mixing time. All mixtures were premixed dry for 1 minute and then homogenised for 2, 3 or 4 minutes after adding water. With increasing mixing time, the temperature of the processable mass increases linearly (see figure 1). The resulting processing temperatures can be found in table 2.

Tab. 2: raw material storage temperature (T initial), wet mixing time and resulting temperature after mixing.

| T initial | 15 | 15 | 15 | 22 | 22 | 22 | 25 | 25 | 25 |
|---|---|---|---|---|---|---|---|---|---|
| wet mixing time | 2 | 3 | 4 | 2 | 3 | 4 | 2 | 3 | 4 |
| T after mixing | 21 | 23 | 25 | 26 | 28 | 30 | 26 | 28 | 29 |

*Fig. 1: Temperature after mixing. With increased mixing time the temperatures after mixing increase almost linearly. The shift in temperature is due to different initial temperatures.*

*Measurement procedure and device for 3D-slump flow*

The recording of the 3D-slumpflow is realised with an image processing platform and integrated area camera with a projection field size of 250 x 250mm. Here, a 3D point cloud is generated by means of fringe projection, the combination of high-speed camera and structured light from eight projectors, included in model CV-H1X, provided by Keyence Cooperation (fig 1). This process virtually eliminates shadowing effects and reflection artefacts. Following the recording of the test specimen to be analysed, the image data is evaluated by the controller and the integrated image processing software. With the help of tools such as the determination of the diameter and the height of the body, but also the recording of the 3D topography as well as a self-developed function for the calculation of the percentage area growth based on binary representation of the image data, the flow process of the castables is recorded and documented (fig. 3). The collected data is output for further evaluation via a connected mass storage device or direct PC connection with the controller of the image processing platform.

*Calculation of rheologic parameters by using the Image processing platform and integrated area scan camera*

In order to be able to characterise the rheological parameters of castables, it is necessary to determine the flow velocity and the resulting shear rate. It is assumed here that the spreading of the mass is uniformly circular.

The calculation of the flow velocity as a function of the time-dependent height is carried out according to formula 1.

$$V_i = (d_i+1-d_i)/2(t_i+1-t_i) \tag{1}$$

with $v_i$ = flow velocity at time $t_i$ in m/s; $d_i+1 - d_i$ = difference of the yield value of two successive measuring points in m, $t_i +1 - t_i$ = time difference of two consecutive measuring points in s.

To determine the shear rates, the time-dependent flow cake height recorded by the measuring system is required. Since the use of coarse grain (3-6mm) causes measurement deviations in relation to the average height, the values are averaged accordingly and used to calculate the shear rates. The formula for determining the shear rates is shown in formula 2.

$$\Upsilon = v_i/ h_i \tag{2}$$

With $\Upsilon$ = shear rate at time $t_i$ in s$^{-1}$; $h_i$ = flow cake height at time $t_i$ in minutes

In addition, the weight force is a driving force in the course of the flow process and can be calculated as the hydrostatic pressure acting on the mass for the entire duration of the experiment.

The hydrostatic pressure is determined most simplified according to formula 3.

$$p_{hydrost.} = h_i \cdot g \cdot \rho_{castable} \tag{2}$$

with $h_i$ = flow cake height at time $t_i$; g = acceleration due to gravity in ms$^{-2}$; $\rho_{castable}$ = Bulk density of the mass in kgm$^{-3}$

*Fig. 2: Acquisition of the 3D point cloud is generated by means of fringe projection, the combination of high-speed camera and structured light from eight projectors, included in model CV-H1X, provided by Keyence Cooperation*

The bulk density required for determining the hydrostatic pressure is obtained by recording the liter weight immediately after the mixing process and then converting it to the required density.

To be clear, the shear rate dependent viscosities that can be calculated in this way are about 100 times higher than those obtained by Bastian et al. [13] with the lifting sphere rheometer, which has already been implemented as a very suitable method for refractory concretes. The actual problem is based on the fact that the hydrostatic pressure changes dynamically over the whole course of the test and therefore requires a much more complex computational model that will be worked out in the coming two years. Nevertheless, the results of the shear rate-dependent viscosities derived from the 3D spread flow are comparable and can describe the flow behavior of refractory castables with a significantly higher resolution. Even if the determination of the dynamic viscosity does not yet seem realistic, the time-dependent observation of the outflow of coarse-grained dispersions can have

233

great advantages for the development of refractory concretes. For example, the height-dependent flow velocity is a valuable parameter that can be used to make rheological properties more tangible.

*Fig. 3: Acquisition of the 3D topography of a castable in false colour representation with contour line*

### RESULTS AND DISCUSSION

The first part of this two-part article focused on the influence of the temperature of the castables after mixing. In order to obtain a wider range of temperatures, the materials were stored at different temperatures, resulting in variable temperatures ranging from 21 to 30°C (Table 1, Figure 1). From Figure 4 it can be seen that the average flow rate varies between 218 and 271 mm after 120 seconds. Similar trends can be seen when the spread flow is measured at 10, 20 and 30 seconds, of course with lower spread values. In general, the spread values increase with increasing temperature of the castables.

With a little good will, a linear relationship can also be seen here that is independent of the time of measurement. This is a little surprising at first, since a higher flow velocity is actually to be assumed at the beginning, since the weight should still have a much stronger influence here due to the greater height of the mass. Especially if one assumes that masses with a higher temperature should have a lower viscosity, this should have the effect of a faster flow in the first seconds.

*Fig. 4: Average spread diameter after 10, 20, 30 and 120 sec as a function of temperature after mixing. The last value corresponds to the specifications of ISO 1927.*

However, this becomes visible when the flow velocity of the masses is deducted instead of the average diameter. Here it becomes clear that the flow velocity is naturally highest at the beginning (after 10 seconds) and increases with the mass temperature. After 30 seconds, this trend reverses, indicating that

the masses with the highest initial velocity have already lost so much height after 30 seconds that there is no longer enough pressure on the material. The flow velocity at the beginning, i.e. with a high shear rate, therefore has a decisive influence on the further course of the spread flow and correlates here with the dynamic viscosity. As described at the beginning, a coarse grain dispersion was selected here that has a low dynamic viscosity at low shear rates, but which increases exponentially at higher shear rates. This becomes clear when the shear stress is plotted against the shear rate. Figure 6 also shows that the shear thickening property of the coarse grain dispersion decreases with increasing temperature and becomes close to Bingham flow behavior when the mass temperature exceeds 26°C after mixing. The yield stress also decreases systematically with increasing mass temperature (Figure 7).

*Fig. 5: Flow velocity after 10, 20, 30 and 120 sec as a function of temperature after mixing.*

*Fig. 6: Shear rate plotted against the shear stress. The colours indicate the initial temperature prior to mixing. The symbols indicate the mixing time and additionally the initial temperature. In brackets the temperatures after mixing are given. To keep the graph clear, the measurement series was not shown here, where the initial temperature of the mass was 22°C.*

### CONCLUSIONS

First, it is not surprising that the rheological properties are temperature dependent. With increasing mass temperature, the viscosity of the mass decreases and in the present case the masses increasingly show Bingham flow behavior with increasing temperature, while at low temperatures they show shear thickening properties. The yield stress also decreases with increasing temperature. This relationship can already be deduced from the average flow rate, which has values between 218 and 271 and also increases systematically with the material temperature. However, the 3D slump flow measurement system as presented here achieves

a new order of magnitude in the resolution of the rheological processes that take place during the slump flow test.

In the present work, a coarse-grain dispersion with a specific surface area in the matrix grain range of 2.32 m²/g was deliberately selected, which at 20°C exhibits a clearly shear-thickening behavior, which, however, loses significance with increasing temperatures. The coarse grain dispersion is thus already in a range where one can no longer speak of an optimal matrix grain structure. Whether adjustments in the matrix design will lead to less temperature-sensitive dispersions remains open at this point and will be investigated in subsequent work.

*Fig. 7: Dependence of the yield stress on the mass temperature after mixing. Different colours indicate different initial temperatures prior to mixing.*

Basically, however, this work reveals a dilemma. Rheological investigations on coarse grain suspensions and refractory castables must be temperature corrected. Otherwise, even the spreading factor according to ISO 1927 does not lead to reliable results. No indication of the mass temperature after mixing severely limits an objective evaluation of the rheology. Even if the mixing procedure is standardized (1 minute dry and 4 minutes wet, according to ISO 1927), the masses may heat up to different degrees depending on the particle size design. Causing an apparent improvement in material properties to be registered when more heating occurs, which is then falsely attributed to an improvement in particle size distribution. Furthermore, it must be noted here that in the case of cement addition, higher temperatures lead to a higher dissolution rate of the cement particles, which either favors solidification by coagulation due to an increase in the pH value and also leads to a more rapid precipitation of the cement hydrate phases. Then, of course, the flow behavior deteriorates dramatically.

# THERMO–MECHANICAL BEHAVIOR OF ALUMINA–MAGNESIA CASTABLES AND ITS LINING LIFETIME SIMULATION

Yajie Dai[1], Fei Wang[3], Ning Liao[1], Wen Yan[1], Yawei Li[1]

[1]The State Key Laboratory of Refractories and Metallurgy, Wuhan University of Science and Technology, 430081, China
[3]School of Resources and Civil Engineering, Northeaster University, 110819, China

## ABSTRACT

Due to the advantages of high temperature strength, thermal shock resistance and corrosion resistance, the alumina-magnesia castables is considered to be an optimal lining material for sidewall of steel ladles. The castables is installed without pre-sintering, whose thermo-mechanical properties vary with temperature during the pre-heating process and metallurgical service. The castables at different thermal stages shows distinct sensitivity to temperature fluctuation. In this study, the influence of heat treatment temperature and heating/cooling rate on the thermo-mechanical properties as well as fracture behaviour of alumina-magnesia castables is investigated using uniaxial compressive test equipped with a high frequency induction heating system and Brazilian test combined with digital image correlation. Meanwhile, the temperature-dependent Elastic modulus, thermal expansion coefficient and thermal conductivity are measured for alumina-magnesia castables at different thermal stages. The evolution of thermo-mechanical behavior and its dependence on instant thermophysical has been simulated using FLAC3D. It is seen that the brittleness and mechanical strength of alumina-magnesia castables increases with heat treatment temperature due to the better sintering and formation of calcium hexaluminate and spinel phases. Without fully relaxation of residual stresses, the stiffness increases while the strength decreases after fast heating of 200 °C/min. The same castables after different thermal treatments show disparate mechanical responses to cooling rates. Meanwhile, the simulation from pre-heating period to metallurgy operation period using real-time properties provide a more realistic understanding of lifetime thermo-mechanical behavior for castable linings.

Alumina-magnesia castables, thermal stages, calcium hexaluminate, thermo-mechanical behavior, modelling

## INTRODUCTION

Alumina-magnesia castables are adopted as an optimal lining material for sidewalls below the slag line of steel ladles, because of its good high-temperature strength, thermal shock resistance and corrosion resistance [1]. After production, the castables experience curing, drying, pre-heating and service processes (teeming-holding-tapping cycles). Alumina-magnesia castables sustain severe thermal shock during teeming/tapping processes. The thermal shock resistance of castables is often studied by the evolution of residual mechanical parameters after quenching [2]. Besides the quenching process, most thermo-mechanical tests are performed with a slow heating scenario (e.g. 5°C/min). The in-situ mechanical behaviour of castables under high-speed thermal fluctuation and its systematic correlation with service processes should be further studied.

Meanwhile, with the hydration/dehydration, constituents' reactions, phases formation and microstructure evolutions during thermal processes, the thermophysical properties of castables are highly temperature dependent. For typical cement-bonded alumina-magnesia castables, the decomposition of hydrates mainly takes place above 200 °C up to 550-660 °C [3]. The calcium aluminate ($CaO \cdot Al_2O_3$, CA) and calcium dialuminate ($CaO \cdot 2Al_2O_3$, $CA_2$) form at 900 °C and 1000-1200 °C [4]. The in-situ formation of calcium hexaluminate ($CaO \cdot 6Al_2O_3$, $CA_6$) and spinel ($MgAl_2O_4$) take place above 1200 °C [5]. These two ceramic phases contribute to the higher corrosion resistance, high-temperature strength and thermal shock resistance by forming the ceramic bond and strong interlocking. It is apparent that the thermo-mechanical behavior of alumina-magnesia castables varies during firing and service with respected to temperature and time.

The steel ladle consists working lining, safety lining, insulating lining and metallic shell. Besides the lining materials themselves, the thermo-mechanical behavior of steel ladle has also been investigated for reproducing the thermal loss and stress/temperature fields at different thermal processes. For example, the drying stage of castables, which is crucial for the integrality of lining due to the inner vapor pressure, has been simulated to demonstrate the influence of lining geometries and drying scenarios [6]. The thermal modelling has also been performed for pre-heating processes with the consideration of the lid for heat preservation, heat radiation/convection, non-steady state heat conduction and so on [7]. Advanced numerical tool has been developed as well for simulating the thermal evolution in service cycles [8]. However, the effect of castables at different thermal stages with distinct material properties and the continuous evolution of thermo-mechanical behavior for steel ladle from pre-heating to service with temperature-dependent properties are less clarified.

This study analyses the thermo-mechanical behaviour and evolution of thermophysical properties with respected to temperature of alumina-magnesia castables during the pre-heating treatment and the first casting cycle, represented by the specimens after drying, decomposition of hydrates and sintering. The sensitivity of castables to heating and cooling rate is studied via uniaxial compressive tests during fast heating and Brazilian tests afterwards including digital image correlation (DIC) monitoring at room temperature. Besides, the dynamic thermophysical properties are assigned to an axisymmetric numerical model to simulate the thermo-mechanical behavior of castable lining with different properties and evolution of stress/temperature distribution in transient state. The work aims to demonstrate the variation of thermo-mechanical failure pattern of alumina-magnesia castables with the consideration of temperature dependent properties from pre-heating period to metallurgy operation period and provides a basic understanding of the impact of different thermal scenarios.

## MATERIAL AND INVESTIGATION METHODS
### Castables preparation

The composition of alumina-magnesia castables comprises tabular corundum aggregates and powder (98.85wt% $Al_2O_3$), $\alpha$-$Al_2O_3$ powder (99.3 wt% $Al_2O_3$, $d_{50}$=4.1 μm) and fused magnesia powder (98 wt% MgO). The used binder is calcium aluminate cement with the commercial name of "Secar 71"($\leqslant$50 μm, 70.47 wt% $Al_2O_3$, 28.08 wt% CaO). The water-reducing agent is polycarboxylate amphoteric surfactant (FS60, BASF). The dry components were mixed with 4.2 wt% of distilled water. After well mixing, the castables were poured into the steel molds for forming the cylindrical samples with a diameter of 50 mm and height of 100 mm. For better degasification of the samples, the castables were added stepwise during the vibro-molding process. Additionally, some prismatic samples were also molded for basic mechanical tests. All the specimens were cured at 25 °C with 75% humidity for 24 h, and then dried at 110 °C for 24 h in the oven. The cured and dried samples were respectively fired at 1000 °C and 1400 °C for 3 hours. According to different thermal treatment temperatures, the samples were denoted as L, M and H referring to low (110 °C), medium (1000 °C) and high (1400 °C) temperatures. These target temperatures represent the castables at different life stages: i) after drying process, ii) after pre-heating process and iii) at the first service cycle. The applied representative materials at different thermal stages and its application in heating scheme of outer surface of working lining for numerical simulation can also be seen in Fig. 1.

*Fig.1: Representative materials and heating scheme for simulation*
## Mechanical laboratory tests

Usually, high-temperature mechanical tests of refractories are performed with slow heating rates. To measure the high-temperature mechanical properties after fast heating caused by metallurgy thermal operations, the induction heating equipment with a frequency of 20 kHz was coupled with a universal testing machine. An infrared thermometer was placed as monitor and controller for judging heating or temperature maintenance. A target temperature of 1200 °C was applied using two different heating rates: regular (10 °C/min) and high speed (200 °C/min). Both heating scenarios had a dwell time of 30 minutes at target temperature for achieving an uniform temperature distribution across the specimen with diameter of 50 mm under heat flux on the outer surface. The specimens were uniaxially loaded with a loading rate of 0.5 mm/min after reaching homogeneous temperature distribution within the volume.

To study the impact of cooling rate on fracturing process of castables, the disc specimens with geometry of $\phi 50$ mm$\times$20 mm were cooled inside (slow cooling) or outside (fast cooling) the furnace to room temperature after fast heating scenario. Brazilian test was performed for the specimens after cooling. To avoid stress concentrations at the loading points, the arc jaws with radii of 1.5 times the disc specimens were used as loading blocks for a velocity controlled Brazilian tests with a loading rate of 0.05 mm/min. For monitoring the fracture processes, a CCD digital camera with a resolution of 2452 x 2056 pixels$^2$ was positioned in front of the specimens. Surface images are recorded with a frequency of 1 image/second during the whole test. The front face was painted with a white-black random speckle pattern. For both the uniaxial compressive tests and the Brazilian tests, three samples are used for each kind of specimen.

## Numerical methodology

In this study, numerical simulation of thermal analysis was performed by the continuum based Finite Difference code FLAC3D (Itasca, 2020). The variables involved in heat conduction in FLAC3D are related through the energy-balance equation and transport laws derived from Fourier's law. A simplified steel ladle consisting four lining layers was modelled as shown in Fig. 2. The monolithic alumina magnesia castables is applied in working lining and its assigned temperature-dependent thermophysical parameters (Elastic modulus, thermal conductivity and thermal expansion coefficient) are from the laboratory measurements. The rest less sensitive parameters with temperature are adopted from litterature or neglected. The assigned properties of high alumina bricks (Permanent lining, PL), the alumina insulator (Insulation layer, IL) was adopted from the work of Santos et al. [10]. A quarter of the steel ladle was built under the assumption of symmetry conditions.

Since the existing pores and microcracks usually make the refractory materials inhomogeneous, the statistical method using the Weibull distribution was adopted to representing the heterogeneity. The heterogeneity is becoming smaller with increasing shape factor *m*. In this study, *m*=45 was used to characterize the heterogeneity of the WL, PL, and IL, and the steel shell was set as homogeneous material. Afterwards, the

heterogeneous numerical elements were assigned with the temperature-dependent constitutive laws. The Mohr-Coulomb strength criterion with tension cut-off was used as failure criterion and the Mohr-Coulomb model was extended by strain-softening functions to accurately simulate the behavior under/after thermal loading due to the loss of brittleness at high temperatures.

## Results

### Evolution of thermo-physical properties with temperature

The characterizations by X-ray diffraction and scanning electron microscopy show that the corundum and periclase are the fundamental phases of alumina-magnesia castables (Fig. 3). The high-temperature ceramic phases $CA_6$ and spinel are formed in specimen H, while small amount of CA and $CA_2$ phases presents in specimen M. The newly formed phases locate in the matrix due to the in-situ reactions between alumina and calcium oxides as well as with magnesia. The $CA_6$ and spinel phases have similar thermal expansion coefficient as corundum, which results in good thermal compatibility. Meanwhile, the $CA_6$ has a plate-like morphology and contributes to the construction of strong interlocking between $CA_6$ and spinel. Due to the remarkable volume expansion during the formation of high-temperature phases and the ceramic bond, the apparent porosity, strength and ultrasonic velocity increase with the thermal treatment temperature: L<M<H.

*Fig.3: XRD patterns (a) and SEM microstructure (b)*
With different thermal treatment, the alumina-magnesia castables specimens show distinct evolution of thermal expansion coefficient and elastic modulus with temperature (Fig. 4). The stiffness of alumina-magnesia castables (presented by elastic modulus) decrease in order of H>M>L. The ceramic phases and their interlocking favor the high-temperature mechanical resistance. With less microstructure evolution and damage accumulation, the elastic modulus of specimen H decreases slightly with temperature up to 1200 °C and no obvious attenuation exhibits during heating-cooling cycle. The elastic modulus of specimen M and L decrease with temperature and a lessening of the decrease followed by an increase above 1050 °C is observed. Between 200 °C and 350 °C, a strong decrease of elastic modulus of specimen L occurs due to the dehydration of calcium aluminates hydrates. With the microstructure variation, the room temperature elastic moduli of specimen M and L after thermal cycle significantly reduce.

237

The specimen H is quite linearly expanded with temperature as no further phase transformation occurs after fully reaction during material preparation. With the existence of ceramic phases ($CA_6$ and spinel) and strong bonding, the H shows highest thermal expansion below 1100 °C, while that of M is also higher than L with the presence of certain amount CA and $CA_2$ in matrix. The crystallization of CA at this temperature range has slight effect on the thermal expansion, which turns in to high-temperature calcium aluminate phases with further temperature increase. Above 1100 °C, the specimen M and L exhibit high volume expansion because of the accumulated formation of $CA_2$ and spinel. The $CA_2$ reacts afterwards with the alumina for the formation of $CA_6$, which results in the further expansion. Part of the calcium oxide has already reacted with alumina during the firing of specimen M at 1000 °C. Thus, the volume expansion rising of specimen L is the most significant with the high amount of new phases formation. The thermal conductivities of three kinds of specimens also increase with temperature.

*Fig.4: Evolution of elastic modulus (a) and thermal expansion coefficient (b) with respect to temperature*

**Dependence of fracture behaviour on heating and cooling rate**

Fig. 5(a) exhibits the stress-displacement curves of the uniaxial compressed specimens under 1200 °C experienced fast (200 °C/min, denoted as -f and solid lines) and slow (10 °C/min, denoted as -s and dash lines) heating procedures. With the formation of high ceramic phases and better sintering, the uniaxial compressive strengths UCS of H and M exceed 80 MPa. No softening behaviour is observed for fired specimens under this stress level, only some isolated small cracks occur on the surface of H while massive cracks are generated in M. It can be assumed that compressive strength of H is higher than that of M. The UCS of dried specimen L-f is 69.6 MPa and a slight-nonlinear yielding behaviour appears right before reaching the peak load and the brittle failure. The lateral deformation of specimen L-f is small and the specimen shows a clear shear failure, whose inclined fracture surface is rough and loose. The static Young's modulus E can be calculated from the slope of the stress-displacement curves, which is used for characterizing the material stiffness. The static E increases in the order L < M < H. One should be aware that the static E of specimen H-f (40 GPa) is much smaller than the dynamic one, due to the different determination methodology and compliance of the mechanical tests.

The stiffnesses for specimens with slow heating are smaller than those with fast heating. During fast heating, less microstructure relaxation is allowed, which results in higher residual thermal stresses and stiffer mechanical response. With the existence of high-temperature ceramics phases $CA_6$ and spinel, the H has better high-temperature mechanical properties. During slow heating to 1200 °C, further densification and thermal reactions occur in specimens L and M. The maximum load of L-s is higher than for L-f. All three types of loaded specimens have only fine cracks as documented for H without forming significant macro-cracks or ruptures after slow heating, suggesting a smaller degree of damage. The fast heating rate up to 200 °C/min acts as an in-situ thermal shock and results in significant UCS reducations, but a much less difference in stiffness.

The castable lining experiences drying, pre-heating, first operation cycle (teeming-holding-tapping), re-heating and successive operation cycles till repair or service termination. It undergoes severe cold shock during tapping and unexpected shut down. Before a thorough discussion of the difference between H, M and L, the tensile failure of specimen H, which represents the alumina-magnesia castables at the first operation cycle, is firstly investigated. The Brazilian tests are performed at room temperature for three types of H: the original one without further heat treatment as H-O, the one fast heated to 1200 °C and air quenched as H-F and the one slowly cooled in the furnace as H-S. Their force-displacement curves are shown in Fig. 5(b). The forces continuously increase with applied displacement followed by an abrupt failure after reaching the maximum load. The quasi-linear increase and abrupt dropping of forces imply a predominant brittle failure of all specimens of H. The average strengths and their standard deviations are listed in the table. The cold shocked specimens H-F have the lowest strength and reveal some visible nonlinearity (softening) near the peak region. This manifests the generation of primary damage in H-F during fast cooling. It is similar for H-S but with less reduction of strength and non-obvious nonlinearity.

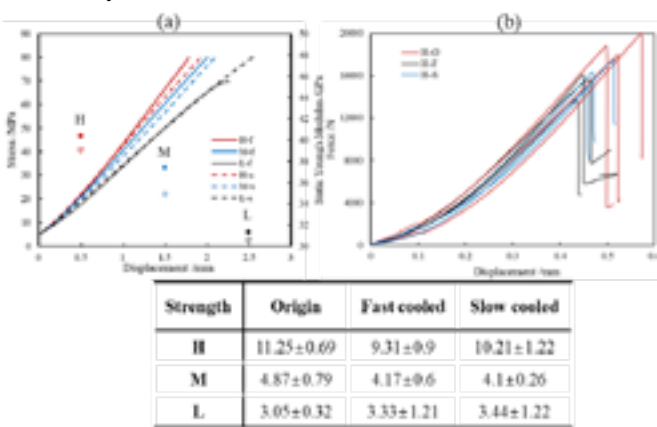
| Strength | Origin | Fast cooled | Slow cooled |
|---|---|---|---|
| **H** | 11.25±0.69 | 9.31±0.9 | 10.21±1.22 |
| **M** | 4.87±0.79 | 4.17±0.6 | 4.1±0.26 |
| **L** | 3.05±0.32 | 3.33±1.21 | 3.44±1.22 |


*Fig.5: Stress-displacement curves under UCS (a) and Brazilian test (b), average tensile strength (table)*

To better illustrate the influence of damage induced by different cooling strategies on tensile failure under Brazilian test, DIC analysis is performed. The strain evolution of specimen H with and without thermal shock is shown in Fig. 6(a). The horizontal strain component $\varepsilon_{xx}$ is adopted as indicator for crack opening in the horizontal direction. Due to the high strength and brittleness, almost no micro-crack development for H-O is observed before reaching the maximum load. With the high amount of elastic energy stored within the bulk of H-O, the disc specimens are split into two halves shortly after the peak load (indicated by the high displacement difference before and after load peak in Fig. 6(b)).

During slow cooling in furnace, some fine micro-cracks are induced in H-S, which cause the earlier damage in the pre-peak region and the development of a more complicated crack network. With the gradual energy release during the fracture process zone development, a milder and narrower crack opening is observed at peak for H-S. H-F shows similar failure behaviour as H-S and H-F. However, with a severe cold shock (fast cooling), a larger initial crack exists in H-F. Instead of forming a fracture process zone like in H-S, a further opening of the initial crack is observed in the pre-peak region. Due to the tensile stress accumulation in the Brazilian disc, the primary crack propagates along the direction of the vertical diameter, which is different from the initial crack path induced by the cold shock. As a consequence, the change of horizontal opening displacement for H-F is stronger than that of H-S, but still much lower than that of H-O due to less stored elastic energy.
*Fig.6: Strain map of specimen H after different heat treatment (a) and variation of crack opening displacement (b) at load peak*

**Simulation of stress and temperature distribution**

To better understand the impact of temperature-dependent thermophysical parameters, a series of sensitivity analysis was conducted. In this case, five parallel models with same geometries were created, with three of them having all parameters inputted as temperature independent except for the parameter being analysed (conductivity, expansion and Young's modulus). The fourth model has all parameter as temperature dependent (model "all" as in Fig. 8), while the fifth model serves as a completely temperature independent reference (model "Noun"). The "stress ratio" and "displacement ratio" are defined as the ratio between values of the target models and that of the reference model. Ratio over 1 means a growth in temperature-induced stress or displacement, ratio between 0 and 1 means a reduction, and negative ratio indicates the change from tensile to compressive stress. The stress and displacement variations are acquired along a scanline, which is the horizontal line drawn from heated surface of WL to shell (Fig. 7).

The temperature-dependent thermal conductivity is the predominant factor of temperature distribution, which is related to the subsequent thermal expansion and deformation. As it is seen, the results of model "cond" are close to that of mode "all". Meanwhile, the stress ratio of model "expan" varies a lot along the scanline, as remarkable volume expansion tends to take place at higher temperature, which is restrained by the surrounding lower temperature region and incurs a great compressive stress to high temperature region. Compared to other two parameters, the model with temperature-dependent Young's modulus has less undulant changes with distance from heated surface. Meanwhile, with the softening at higher temperature, the Young's modulus and thermal expansion have offset each other in the simulation results of stress and deformation. The maximum principal stress and displacement ration in the PL, IL and steel shell are more or less stable.

*Fig.7: Stress (a) and displacement(b) ratios of target models at the end of pre-heating*

Figure 8 shows the plasticity states of the five parallel models after two metallurgy cycles. The outer surface of WL experiences the most severe thermal shock and highest temperature, which could be damaged by the shear stress. The discrete tensile stress can also occur due to the local thermal mismatch related to the heterogeneity. Meanwhile, the most plastic deformation induced by the tensile stress locate in the permanent lining. Compared with the plasticity state of "Noun" model, the damage is much more severe in the model with the temperature-dependent parameters, which implies the necessity to consider the dynamic evolution of

properties with time and temperature for achieving realistic thermos-mechanical investigation.

*Fig.8: Plasticity states for five parallel models at the end of two metallurgy cycles (Legend: s and t: shear and damage, p: failure accumulated in the past, None: no damage )*

**CONCLUSIONS**

By experimental characterization and numerical modelling, the dependence of thermophysical properties on time and temperature and its influence on the thermomechanical behavior of alumina-magnesia castables has been studied. Main conclusions are:

(1) The brittleness and mechanical strength of alumina-magnesia castables increase with heat treatment temperature due to the better sintering and formation of ceramic phases. Without full relaxation of residual stresses, the stiffness increases while the strength decreases after fast heating of 200 °C/min. Meanwhile. the same castables after different thermal treatments show disparate mechanical responses to cooling rates.

(2) The thermophysical parameters evolve with temperature and piecewise change with the thermal processes. The sensitivity analysis of parallel simulations demonstrates that the thermal conductivity is the most influential parameter, as it dominants the temperature distribution and affects the succeeding thermal expansion and deformation. The increase of thermal expansion coefficient and decrease of Young's modulus with temperature counterbalance the deformation of linings.

(3) Compared with the modelling using temperature-independent parameters, the model with temperature-dependent thermophysical parameters exhibits more severe shear damage in the outer surface of working lining and tensile stress induced plasticity in permanent lining.

## ABSTRACT

Appropriate mixing of monolithic materials is inevitable for a proper installation of refractory monolithics. Without in-depth knowledge about this important step refractory installations are prone to premature break down with unwanted and expensive down times. With the help of a 3D-spread flow device it is possible to quantify the effect of inappropriate mixing and how not precisely adjusted grain size distributions may contribute to this. It is still under investigation how the grain size distribution especially in the matrix grain fraction affect the complexity of mixing.

However, at this point of research it already can be stated that the grain size distribution is susceptible to the mixing velocity and mixing time and if not appropriate even susceptible to the ambient conditions. It could be figured out that the ambient conditions affect the dynamic viscosity in certain matrix combinations remarkably. To substantiate this assertion model castables were developed that solely were altered in the proportions of reactive and calcined alumina concentrations and therefore in their specific surface. While the first part describes the method of 3D-spread-flow and the temperature dependence of the rheological properties [1], the second part shows by way of example three coarse-grain dispersions that differ from the real refractory concrete only in that no cement was added to the material. The coarse grain dispersions in turn differ in the specific surface area of the matrix components, whereby a very coarse, a medium and a very fine matrix composition was considered with 2.32 4.06 4.94 m$^2$/g.

## Introduction

Refractory concretes are complex mixtures of granulations of refractory raw materials with grain sizes between approx. 0.1 µm and 6 mm, a binder, and chemical additives [2], [3]. The chemical additives, especially dispersing agents, exert a considerable influence on the rheological properties of refractory concretes.

Refractory castables are homogenised with water in compulsory mixers and then placed in a mould or behind a formwork. This is done by self-flowing, vibration or spraying. Refractory concretes can also be pumped.

Tab. 1: Composition of coarse grain dispersions that vary in the matrix particle compositions leading to specific surface areas that are given in m$^2$/g.

| Raw Materials | all | Raw Materials | CD1 | CD6 | CD10 |
|---|---|---|---|---|---|
| T60 3-6 mm | 19 | NO 725-10 | 10 | 3.5 | 7 |
| T60 1-3 mm | 17 | NO 713-10 RF | 7 | 3.5 | 10 |
| T60 0.5-1 mm | 14 | CT9FG | 0 | 5 | 0 |
| T60 0-0.5 mm | 15 | CT800FG | 0 | 5 | 0 |
| T60 0-0.045mm | 18 | FS60 | 0.1 | 0.1 | 0.1 |
| water | 5,5 | spec. Surf. area | 4.06 | 2.32 | 4.94 |

Each component of refractory castable influences its rheological properties [3]. A differentiation must be made between the individual classifications of the raw materials into fine (0-100 µm), medium (0.1-1 mm) and coarse (> 1 mm) grains. Medium and coarse grains can be summarised as aggregates [4]. The aggregates and their grain size distribution clearly influence the viscosity of refractory concretes. This is due to interlocking, friction and movement of the aggregates during flow. The general consensus is that aggregates exert a considerable influence on the rheology of coarsely dispersed fluids [5], [6], [7], [8], [9], [10].

For this purpose, a cement free coarse grain dispersions were used that differ in the specific surface area of the matrix components, whereby a very coarse, a medium and a very fine matrix composition was considered with 2.32 4.06 4.94 m2/g. The purpose of this article is to show how the rheological properties change with different mixing times (1 minute dry and 2, 3 and 4 minutes wet) and three different mixing speeds (200, 450 and 700 rpm).

## MATERIAL AND METHODS
### Material

The investigations were carried out on three coarse-grain dispersions, CD1, CD6, and CD10 which does not contain any cement, as the initial aim here is to ensure that the rheological behaviour is not influenced by the setting process of the cement phase. In particular, it should be emphasised here that the early formation of cement hydrate phases leads to stiffening, but also that the change in pH due to the solution of $Ca^{2+}$ ions influence the rheological properties. This ensures that only the particle size distribution in combination with the plasticiser, in this case Castament® FS60, determines the rheological properties.

Said coarse grain dispersions, belongs to a development series of a total of 10 formulations that were developed within the framework of a 2-year IGF project, whereby here the matrix components were permuted in their concentration but kept the same in total. The specific surface area varies between 1.29 and 4.93 m$^2$/g. All coarse grain dispersions have been developed to have self-flowing properties.

Fig. 1: Effective dynamic viscosity of the cement-free refractory concretes or coarse dispersions as a function of the mean shear rate. The dynamic viscosity was determined with the lifting sphere rheometer, as developed by Bastian and the shear rate was calculated by means of CFD-FEM simulation.

This paper focus on three coarse grain dispersions, CD1, CD6 and CD10, that cover a distinct range of matrix grain size distribution from coarse to fine with specific surfaces 2.32 (CD6), 4.06 (CD1) 4.94 m2/g (CD10).

All coarse grain dispersions consist of different grades of tabular alumina T60 (from 6 mm to 45 µm, Almatis, Germany). The matrix components contain four grades of calcined alumina that allow to adjust a variety of matrix compositions, namely CT 9 FG, CT 800 FG, (Almatis, Germany) NO 725 10, and NO 713 10 RF (Nabaltec, Germany) were used in different proportions over the entire set of coarse grain dispersions (table 1).

Figure 1 describes the shear rate dependent dynamic viscosity of these three coarse grain dispersions as there were recorded by Bastian et al. by using the lifting sphere rheometer which is described in [11], [12]. The shear rate-dependent dynamic viscosity of these coarse grain dispersions varies massively with the composition of the slurry phase. The medium-fine matrix of the coarse grain dispersion (GD1) results in a medium dynamic viscosity at low shear rates and a lower dilatancy, if any, at higher shear rates. The coarse grain dispersion with the coarse matrix (GD6) has a low dynamic viscosity at low shear rates. This increases exponentially with increasing shear rate. This reflects a pronounced dilatant rheological behaviour. If the matrix of the refractory concrete (GD10) is very fine, a high viscosity is pronounced at low shear rates. As the shear rate increases, the dynamic viscosity decreases and remains at a low level.

Fig. 2: Temperature after mixing correlated with the work of mixing, which is defined in simplified terms as the product of the mixing speed and the mixing time. With increased work of mixing the temperatures after mixing increase almost linearly.

Fig. 3: The mean diameter of the spread flow after 10 seconds is plotted against the mixing work.

### Methods

*Preparation of coarse grain dispersions*

To ensure a proper mixing, an intensive mixer (type R02, Eirich GmbH & Co. KG, Germany) was used with a stick agitator and simultaneous rotation with a rotation speed of 200, 450 and 700 rpm. 200 rpm corresponds approximately to the energy input of a planetary mixer as recommended by ISO 1927. All mixtures were premixed dry for 1 minute and then homogenised for 2, 3 or 4 minutes after adding water. A total of 9 mixtures of 5 kg each were produced for every coarse grain dispersion.

*Measurement procedure and device for 3D-slump flow*

The recording of the 3D-slumpflow is realised with an image processing platform and integrated area camera with a projection field size of 250 x 250mm. Here, a 3D point cloud is generated by means of fringe projection, the combination of high-speed camera and structured light from eight projectors, included in model CV-H1X, provided by Keyence Cooperation as described in part one of this contribution [1].

Fig. 4: The mean diameter of the spread flow after 120 seconds is plotted against the mixing work.

### RESULTS AND DISCUSSION

While the first part of this article dealt with the temperature influence of the rheological properties of coarse-grained dispersions, the dependence of the rheological properties on the mixing energy input and on the grain structure of the matrix is investigated here on the basis of three selected compositions.

Since all 27 tests carried out (9 for each coarse grain dispersion) differ individually in their production before the spread-flow is recorded, namely in the mixing energy input, it is first important to take a closer look at the heat absorbed by friction of the particles. Figure 2 therefore relates the temperature after mixing to the mixing work. The mixing work is assumed to be a very simplified product of the mixing time and the mixing speed, which at least means that the mixing energy input can be used as a value without being quantified exactly. Figure 2 then shows a near linear correlation of the work of mixing with the temperature after mixing. This is not particularly surprising at first, since the energy input is controlled by the mixing time and the mixing speed. However, it is remarkable that the coarse-grain dispersion, CD6, absorbs significantly more friction heat, although CD1 absorbs more heat with less mixing work. However, DC1 and CD10 basically react similarly to the increasing mixing energy input. The deviating heat absorption of the coarse grain dispersion, CD6 can be attributed to the significantly higher viscosity at high shear rates, as described above. It is still important to mention here that the absolute temperatures are less important than the linear increase with the mixing energy input, the slope of which differs significantly in the case of CD6. The final temperature depends strongly on the raw material temperature before mixing. The results imply that CD1 were processed at higher ambient conditions.

If the spread flow after 10 and 120 seconds is plotted against the work of mixing, the positive trend shows that the result is also influenced by the heat absorption due to mixing. If one takes a closer look at both diagrams, it becomes clear with a little effort that CD 6 after 10 seconds hardly differs from the other two coarse-grain dispersions, but after 120 seconds it tends to lead the others resulting in larger average diameters in the spread flow. Since there is also quite a high scatter of results within the coarse grain dispersions, it is not really opportune to enter trend lines. However, they do open up the possibility of guiding the eye a little. Except for CD10, the finest variant, a positive trend generally implies the temperature dependence of the flow. In general, CD10 is cooler during processing, so that at least the lower spread flow can be

explained by this. However, the almost linear temperature increase with different mixing work should also lead to a positive correlation for CD10, if non-matrix-dependent influences must be taken into account more strongly here. In principle, further investigations must be carried out in the future to gain a better understanding.

In order to make the large amount of data somewhat clearer, only one mixing time (4 minutes wet) and two different mixing speeds are considered in figure 5. If the shear rate is plotted against the shear stress, it is immediately apparent that the yield stress value, $\tau_0$, is dependent on the mixing speed. The lowest values are measurable for the coarse grain dispersion, CD6, whereby a higher mixing speed significantly reduces $\tau_0$. The high mixing speed also leads to a moderate increase in shear stress with increasing shear rate. The mass becomes less viscous, which in turn is primarily due to the influence of temperature. The mass is about 14°C warmer after mixing at 700 rpm (compare table 2). CD1, on the other hand, shows a comparable yield stress at both mixing speeds, whereby the temperature difference here is only 7.7 K. The yield stress, however, is significantly higher than that of the CD1. However, the yield stress is remarkably higher than for CD6. Again, it can be seen that the high mixing speed leads to a moderate increase in shear stress with increasing shear rate. The slopes are comparable for both coarse grain dispersions depending on the mixing energy. The coarse grain dispersion, CD10, behaves somewhat differently.

First of all, it should be noted that CD10 has a significantly higher yield stress than CD1 and CD6, although the temperatures for both mixtures are at least comparable to GD10. In addition, it should be noted that less mixing energy leads to a lower yield stress and therefore behaves differently to CD1 and CD6. Furthermore, the mass mixed at 700 rpm shows no significant dependence on the shear rate in shear stress.

If we compare this result with figure 1 and the corresponding description, it becomes clear that both results can be linked to each other. As described, CD6 exhibits negligible dynamic viscosity at low shear rates, while CD1 and CD10 show a shear thinning behavior, although this is more pronounced for CD10. This also explains why the yield stress is noticeably higher for CD1 and very clearly higher for DC10.

Basically, it is not surprising that the viscosity decreases with increasing temperature after mixing. Nevertheless, one can recognize differences between the coarse-grain dispersions presented here that relate to the mass structure of the matrix. Figure 6 again extends the consideration to the different mixing times (1+2 and 1+4 minutes) and all mixing speeds are considered (200, 450 and 700 rpm). While an almost linear relationship can be observed for CD6, this appears to be more complex for CD1 and CD10. There is no linear relationship here. On the one hand, this can be attributed to the more complex behavior of both masses at low shear rates (fig. 1), on the other hand, more work needs to be invested in the 3D-spread flow method in order to better substantiate the significance of the measurement results.

Tab. 2: Temperatures after mixing for 1 minute dry and 4 minutes wet at velocities of 200 and 700 rpm.

| Disspersion | Mixing velocity | Temperature after mixing in °C |
|---|---|---|
| CD 1 | 200 rpm | 36.0 |
|  | 700 rpm | 43.7 |
| CD6 | 200 rpm | 29.7 |
|  | 700 rpm | 47.5 |
| CD10 | 200 rpm | 29.7 |
|  | 700 rpm | 36.5 |

## CONCLUSIONS

Within the framework of a two-year research project, a total of 10 coarse grain dispersions were developed, which differ only in the grain structure of the matrix. From these 10, three were selected for this work, which cover a representative range from coarse to fine with specific surface areas of 2.32 (CD6), 4.06 (CD1) and 4.94 m2/g (CD10).

In general, it can be stated that the 3D spreading flow provides significantly more information about the rheological behavior of coarse-grained dispersions than simply an average spread-flow after a given time. By constantly measuring the slump flow, practically from the first second to the end (here 150 seconds), the change in height and diameter over time can be documented. This makes it possible to determine shear rates and evaluate them. Even the shear stress can be calculated, although, as already described in part 1 [1], a suitable model must still be developed that dynamically simulates the hydrostatic pressure over the entire test period. Shear stress values as reported in this paper are unrealistically high and do not match the results obtained with the lifting sphere rheometer. Nevertheless, the results are suitable to show differences in a direct comparison.

*Fig. 5: Shear rate plotted against the shear stress. The colours indicate the nature of the coarse grain dispesion, CD1, 6 and 10. The number of results is reduced to two mixing velocities, 200 and 700 at a single mixing time of 4 minutes wet mixing. The calculation of shear rate and shear stress is reported in part 1 of this contribution [1]*

*Fig. 6: Yield stress plotted against the temperature after mixing. The colours indicate the nature of the coarse grain dispersion. The symbols indicate the mixing time, 1+2 and 1+4 (1 minute dry, x minutes wet). For every kind of symbol three values are shown, that could be distinguished from left to right by the mixing energy input (200, 450 and 700 rpm)*

Differences within individual coarse-grain dispersions are mainly due to the temperature of the masses, which is caused by different mixing energy input.

Nevertheless, the results show that the coarse grain dispersions behave differently, which was already described by Bastian using the lifting sphere rheometer [11], [12]. In particular, CD1 and CD10 show a high viscosity at low shear rates, which could also be confirmed with the 3D spread flow (fig. 5). However, the temperature-dependent relationship to viscosity is less clear for both coarse grain suspensions (fig. 6). Sometimes the yield stress even increases, which is particularly true for GD10. Since this is especially true for long mixing times (1+4), it could also be that water evaporates during mixing, to which the fine-grain dispersions react more sensitively, since they have a larger grain surface and thus require more water for wetting. In addition, it can be shown that differences in the particle size distribution of the matrix obviously have different capacities to absorb heat through qualitatively different friction and thus show clear differences in the mass temperature after mixing. It can be stated that coarser particles may generate more friction than fine particles.

The results presented here show that the relationships are complex and have not yet been understood in depth and require further research. In the following investigations, the seven coarse-grain dispersions will also be included in order to obtain a clearer picture of the interaction of the matrix composition with the flow behavior.

In principle, however, it can be stated that a higher mixing energy input reduces the viscosity of the coarse-grain dispersions, whereby the temperature increase plays a decisive role. It should be noted, however, that the addition of cement only allows a moderate temperature increase without provoking too early stiffening.

The project will be continued within the framework of a new IGF project, which will make it possible, for example, to keep the temperature comparable after mixing.

Finally, it should be mentioned that with relatively little additional effort, considerably more information can be extracted from a routine test, which is practically always carried out as part of the refractory castable development. So far, tests have only been carried out on self-flow castables, but a transfer to vibratory concretes is possible without any problems, if not even easier, since with self-flow castables the flow begins immediately after the cone is pulled and measurement data cannot be obtained until the cone and hand are out of the picture.

# 3 REFRACTORIES FOR IRON- AND STEELMAKING

# END OF PETROLEUM TAR BINDER, NEW GENERATION OF TAP-HOLE CLAY. FORMALDEHYDE AND PAH FREE TECHNOLOGY

Thierry Joly, VESUVIUS EUROPE – Advanced Refractories, Lyon, France
Roger Isenbarger, Stephen Draper, VESUVIUS USA – Advanced Refractories, Pittsburgh, USA

**ABSTRACT**
Taphole clay (THC) is used to control the iron tapping stream and hearth liquid levels in the blast furnace. THC consists of a solid part and a binder phase. Vesuvius has launched a major program to develop THCs that are safe for health and the environment. In a previous publication [1], the study carried out on the substitution of phenolic resins led to the development of a phenol-free, formaldehyde-free, and PAH-free material for the European market. The study presented here concerns the substitution of tars (coal or petroleum) used in NAFTA and the development of a Formaldehyde-free and PAH-free material.

**INTRODUCTION**
THC needs to fulfill functions as described [2] and [3]:
1) The plasticity should be compatible with the mud gun characteristics. The THC should exhibit high density after plugging. The shelf life is also an important parameter.
2) The degree of sintering must be balanced between being sufficient to resist to the top gas pressure and have no deterioration of the mushroom, against not being excessive to allow taphole opening without difficulties.
3) The THC should have high resistance to erosion by hot metal and slag then corrosion by slag. The THC should allow proper hole enlargement at the time of tapping to ensure removal of slag and manage the level of the liquid inside the blast furnace.
4) To ensure the THC volume stability at all temperatures of usage (in the taphole sleeve during curing, at high temperature during tapping), change in volume must be expansile.
5) Close adhesion of newly injected taphole clay to the residual THC applied previously is essential.
6) During the design processing, the THC must consider the environment and taking care of the health of the users.

In NAFTA, the legislation does not prohibit the use of coal tar, the choice of clean or dirty solutions depends on the environmental policy applied in each company.

## 1. CHOICE OF THE BINDER
The choice of binder consists in proscribing coal or petroleum tar, which contains PAHs (Table 1) harmful to human health [4]

| PAH | Carcino genicity | Coal Tar (ppm) | Petroleum Tar (ppm) |
|---|---|---|---|
| Naphthalene | D | $8.2 \times 10^3$ | $1 \times 10^3$ |
| Acenaphthylene | D | | |
| Acenaphthene | NA | $3.9 \times 10^3$ | $2.8 \times 10^2$ |
| Fluorene | D | $2.1 \times 10^3$ | $1.6 \times 10^2$ |
| Phenanthrene | D | $6.6 \times 10^3$ | $7.4 \times 10^2$ |
| Anthracene | D | $1.7 \times 10^3$ | $2.1 \times 10^2$ |
| Fluoranthene | D | $4.2 \times 10^3$ | $2.3 \times 10^2$ |
| Pyrene | NA | $3.3 \times 10^3$ | $5 \times 10^2$ |
| Benzo[a] anthracene | B2 | $1.4 \times 10^3$ | $2.6 \times 10^2$ |
| Chrysene | B2 | $1.3 \times 10^3$ | $2.7 \times 10^2$ |
| Benzo[b] Fluoranthene | B2 | $1.3 \times 10^3$ | |
| Benzo[k] Fluoranthene | B2 | $5.5 \times 10^2$ | |
| Benzo(a)pyrene | B2 | $1.2 \times 10^3$ | $1.9 \times 10^2$ |
| Indeno[1,2,3-cd] pyrene | B2 | $5.9 \times 10^2$ | |
| Dibenzo[a,h] anthracene | B2 | $2.1 \times 10^2$ | |
| Benzo[g,h,i] perylene | D | $6 \times 10^2$ | |
| Sum | | $3.7 \times 10^4$ | $3.9 \times 10^3$ |

*Table 1: PAH in coal and petroleum tars. B2 "possibly carcinogenic to humans"; D "unclassifiable as to carcinogenicity"; NA Not Available*

Similarly, the use of phenolic resins containing volatile organic compounds such as phenol or formaldehyde is undesirable. The new generation of binder system contains no PAHs or formaldehyde, making it the cleanest solution on the market. To select the adequate binder, constraints are divided in three main categories: raw materials that are not REACH or GHS regulation sensitive; production orientation by providing a solution which is

not impacting the manufacturing speed or reliability, then customer oriented by providing a solution which is fitting the current protocols used with the standard systems.

## 2. EXPERIMENTAL PROCEDURE
The experimental approach was carried out in four stages:
1) The study followed the development of the European New Generation [1] duplicated the solution in NAFTA.
2) Rheology study performed in comparison with the petroleum tar product (Anton Paar MCR 302 Rheometer).
3) Thermogravimetric analysis launched to search for a behavior close to that of petroleum tar (STA 409 Netzsch).
4) Selected binder tested during several field trial to assess the real situation.

## 3. RESULT and DISCUSSION
### 3.1 Rheological study
A series of samples was tested by a rheology approach, only the retained solution compared to petroleum tar is presented. The concept is to present a close match for the viscosity in regard with the petroleum tar. The retained solutions has carbon adjustments to keep an equivalent fixed carbon rate between the petroleum tar and Eco-Friendly binder change. This addition of carbon impacts the rheological behavior of the selected solution.

Viscosities of the blends were determined at three different temperatures (25, 45 and 65 ºC).

Figure 2 and Figure 3 are respectively showing the viscosity evolution of petroleum tar then Eco-Friendly binders at different temperature and share rate (1 s$^{-1}$ and 100 s$^{-1}$).

*Fig. 2: Evolution of petroleum tar viscosity in regards with temperatures.*

*Fig. 3: Evolution of Eco-Friendly binder viscosity in regards with temperatures.*

Although the viscosity values differ between the two systems, they are very close and indicate compatibility of the Eco-Friendly binder with the THC mix.

This was also supported by the Hershel-Bulkley Index [5] as described in the Figure 4. Parameter p which is the Hershel-Bulkley index, is indicated for describing the behavior of the flow for both systems:

- p < 1: shear thinning.
- p > 1: shear thickening.
- p = 1: Bingham behavior.

*Fig. 4: Hershel-Bulkley Index (p) at different temperature (25, 45, 65°C) show the shear-thinning behavior of the binders.*

Both systems have the same behavior as illustrated by the Herschel-Bulkley index with p < 1.

The binders were also evaluated as a function of viscosity (fig. 5).

*Fig. 5: viscosity in function of temperature between Petroleum tar binder (curve in black) and Eco-Friendly binder (curve in green).*

Up to 90 °C, both binders behave equally well; viscosity gradually decreases with temperature. Around 90 °C, petroleum tar begins to stabilize its behavior while the Eco-Friendly continues to decrease in viscosity until approximatively 130 °C, when it begins to stiffen. At this level, the carbonaceous additions of the Eco-Friendly binder governs the rheological behavior.

In conclusion of the study for the rheology part, one solution was selected. Indeed, the Eco-Friendly system is presenting the closest behavior to the petroleum tar from all the first possibilities.

### 3.2 Thermogravimetric study

To further characterise the binder blends, TGA under non-oxidizing atmosphere based on argon was conducted. The experimental conditions are a progressive rise in temperature (without thermal pre-treatment) up to 1450 °C at 5 °C per minute, without step and under argon atmosphere (Figure 6).

*Fig. 6: TGA of Petroleum tar binder (black curve) and Eco-friendly binder (green curve).*

As explained in the section 3.1, the Eco-Friendly binder consists in a blend of a liquid and some carbon. We observe a rapid loss of mass at low temperatures and a stabilization between 200 and 400 °C (effect of added carbon). The new system of binder degasses more quickly than the petroleum tar at low temperatures. This allows to consider a short dwell time but also indicates a THC which will have sufficiently evacuated its volatile matters not to generate splashing by outgassing at the time of the taphole opening and reduces wet taphole conditions.

### 3.3 Extrusion Pressure

The evolution of the extrusion pressure by a Marshall Test as a function of the sample' temperature is provided (Figure 7).

*Fig. 7: Extrusion pressure given by a Marshall test of Petroleum tar binder (black curve) and Eco-friendly binder (green curve).*

The stable extrusion pressure as a function of the temperature allows an easy use of the developed THC mix, it is possible to initiate the cure as early around 130°C. This reduces the holding time of the mudgun on the taphole face compared to the petroleum tar bonding system.

### 3.4 Physical properties of THC

Table 3, shows the main physical characteristics of the two THC after firing at 1093 °C (2000 °F) in a reducing atmosphere for 5 hours. The Eco-Friendly binder is presenting a higher mechanical strength for a lower open porosity in comparison with the petroleum tar bonded system, this is aligned with an improved performance on customer site.

| THC product | Rammed Density (k.gm$^{-3}$) | Fired Density (k.gm$^{-3}$) | CCS (N.mm$^{-2}$) | Apparent Porosity (%) | Volatile Loss (%) |
|---|---|---|---|---|---|
| Petro. tar | 2400 | 2130 | 8.3 | 30.5 | 8.6 |
| Eco-F. Binder | 2370 | 2100 | 13.9 | 24.0 | 9.7 |

*Table 3: Main characteristics of a taphole mixes made with Petro Tar and Eco-Friendly binder.*

### 3.5 Field Trial

In NAFTA, Eco-Friendly binder has replaced petroleum tar bonded system in all Vesuvius formulations. The new materials perform better in the mud gun with better injection stability, an easy cleaning and limited loss of THC per plugging. The tapping performance is at least equivalent to the petroleum tar system. Customers noticed the decreasing of organic smell and black smoke. Opening is easy, typical drill duration took between 60 and 90 seconds. A fast firing rate with a faster release of volatiles than the petroleum tar leads to limited spatter at the beginning of the tap. The taphole length is consistently at the top of the range. At one of our main customers the quantity injected is reduced and cuts specific consumption by at least 17%.

### 4. CONCLUSION

The Eco-Friendly Binder has zero formaldehyde and zero PAH contents. Application in the field shows equivalent or increased performance. Eco-Friendly Binder does not require any reworking of the THC formulation, so it can be easily substituted for conventional binder for all currently supplied materials.

# COMPARATIVE STUDY BETWEEN COAL TAR PITCH AND LOWER POLYCYCLIC AROMATIC HYDROCARBON (PAH) ALTERNATIVE BINDERS FOR USE IN TAPHOLE CLAYS

I.J. Cameron[a], S. Ramjee[b], A.M. Garbers-Craig*[a], [a,b]University of Pretoria, South-Africa

## ABSTRACT

The conventional binder used in taphole clay is high volatile coal tar pitch (CTPht) or a similar low softening point pitch which poses great health and environmental risks due to the polycyclic aromatic hydrocarbon (PAH) present in the binder. Less toxic or non-toxic (lower PAH content) alternatives that have been identified as substitutions are distilled coal tar, petroleum-based phenolic pitch, waxy (paraffin) crude oil, and wood-based tars which are derived from the Kraft process. The behaviour of the CTPht was evaluated with respect to its rheological properties (Newtonian behaviour, thermal stability), its thermal behaviour (using thermogravimetric analysis, TGA-DTG) as well as its chemical composition (using gas chromatography mass spectroscopy, GC-MS) to identify critical binder properties. The proposed alternative binders were then evaluated against the critical binder properties of the CTPht and the most suitable alternative proposed.

## INTRODUCTION

The binder systems conventionally used in taphole clays are either pitch bonded (high-temperature coal tar pitch, CTPht), resin bonded (phenolic resole resin) or a combination binder that contains both coal tar pitch and phenolic resin [1] [2] [3]. The CTPht has unique fluid properties that make it a favourable binder for taphole clays. These properties include viscoelasticity, which ensures mixing of the binder with the aggregate and matrix at low temperatures (<50 °C) during the manufacturing process. The binder also allows for good plastic behaviour during ageing of the clay. The use of CTPht in taphole clays allows for a thermoplastic clay to be formed that ensures a transition-free sintering zone between the new clay that is rammed into the tap hole and the previously sintered clay in the tap hole [1] [4] [5].

The major disadvantage of CTPht is the toxicity due to the presence of polycyclic aromatic hydrocarbons (PAH) in the fluid of which the 16-EPA-PAH species are identified Group I carcinogens [6]. The permissible exposure limit (PEL) identified by the US environmental protection agency (EPA) for the 16-PAH species in air is 0.2 mg/m$^3$ during an 8-hour period [7]. In order to eliminate this exposre to humans in contact with the material, alternative binders are evaluated which include processed and synthetic coal tar pitch with lower PAH content, petroleum-based mesophase-forming pitch, and waxy oil, as well as wood-based tars from three different sources, i.e., beechwood, pinewood and a vegetable source. The work in this paper describes the characteristics and behaviour of the model taphole clay binder, CTPht, and compares the alternative bidners with lower PAH content to it.

## MATERIALS & METHODS

The binders that were selected for evaluation with their respective designation and origin are shown in Table 1.

*Tab.1: Alternative binders identified for comparison evaluation to coal tar pitch (CTPht)*

| Binder name | Group |
|---|---|
| CTPht, 20P, EcoP | Coal tar |
| CWO, PCWO, MP | Petroleum |
| Tar-BW, Tar-PW | Wood-based |
| Tar-Veg | Vegetable |

## Gas chromatography mass spectroscopy (GC-MS)

The volatile species in each of the samples were evaluated by gas-analysis using GC-MS. Both targeted and untargeted analyses were done to (1) determine the concentration of each of the 16-EPA-PAH species in the sample (targeted), and (2) determine the remainder of the species in the sample (pseudo-quantitatively, untargeted). The samples were prepared in both hexane and toluene, and the results reported are for the toluene solvent. For the targeted analysis a pesticide standard containing the 16-EPA-PAH was used to construct concentration diagrams, which were then used to determine the concentrations in the samples. The same procedure was used for the untargeted analysis however, concentration diagrams were not constructed but only used for identification. The pseudo-quantification was done on the chromatographs. An 6890N Agilent with inert XL EI/CI mass selective detector, coupled with e CTC Analytics PAL auto-sampler, was used. A non-polar Rxi-5Sil MS capillary column was used for the samples.

## Thermogravimetric analysis (TGA)

The volatilization study on each of the samples was done using a Hitachi STA 7300 TGA coupled with a differential scanning calorimeter (DSC), using TA 7000 interpretation and measuring software. 30μL alumina crucibles were used, with sample size 5-10 mg. The samples were heated from 50-800 °C in a nitrogen atmosphere (flow rate = 20mL/min) at a rate of 10°C/min.

## Rheology

For the rheology evaluations the binders were tested for (1) isothermal rotation at 45 °C (Newtonian fluid behaviour), (2) temperature sweep in rotation to determine thermal stability from 30-150 °C at a heat rate of 5 °C/min. The rheometer used was an Anton Paar Physica MCR 501 equipped with both a cone-plate measuring system and a Peltier 200 temperature control system. For the cone-plate system, a 0,5°, 50 mm diameter sized spindle was used, and the samples were heated in air. For interpretation, RheoCompassRM software was used.

## RESULTS AND DISCUSSION

### Gas chromatography mass spectroscopy

The targeted analysis results of each of the binders were used to determine the total PAH content (16-EPA-PAH) species and calculate the benzene equivalent [8]. The results from the GC-MS targeted analysis are shown in Table 2. The beechwood and pinewood tar sample results are not shown in Table 2 due to the samples not containing any of the 16-EPA-PAH species. The coal-based binders, especially 20P, showed the highest toxicity with respect to total PAH. The EcoP had the lowest PAH content and BE-value among the coal-based binders. The petroleum binders all had PAH contents an order of magnitude lower than the coal-based ones. The processed crude wax oil was the least toxic binder of the petroleum binders. The wood-based binders showed to lowest toxicity with both beechwood and pinewood tars not containing any carcinogenic 16-EPA-PAH species.

### Thermal analysis (TGA)

Thermal analysis was used to determine the average mass loss during a specific temperature range in order to compare the degree of volatile release and how suddenly it occurs. The reference binder had the lowest average mass loss (0,28 g / °C) over a temperature range of ΔT ~ 310 °C. The closest alternative was the EcoP, with an average mass loss of 0,21g / °C at ΔT ~ 398 °C compared to the reference. The 20P had a higher average mass loss over a shorter temperature range. The pinewood and vegetable tar had similar average mass losses to the 20P over a comparable temperature range (ΔT ~200). The petroleum-based binders had the highest

average mass losses, ranging from 0,96-0,97 g / °C over a short temperature range (ΔT ~ 100 °C).

*Tab.2: Targeted analysis results showing calculated total PAH and BE-value*

| Binder | Total PAH (ppm) | Benzene equivalent, BE (%) |
|--------|-----------------|----------------------------|
| CTPht | 13737,1 | 1,67 |
| 20P | 19918 | 1,80 |
| EcoP | 8491 | 0,18 |
| CWO | 906,8 | 0,03 |
| PCWO | 43,02 | 0,03 |
| MP | 1525,1 | 0,30 |
| Tar-Veg | 126,16 | 0,02 |

**Rheology**

All binders were evaluated for their Newtonian behaviour, and all binders, except for CWO, showed Newtonian behaviour. The shear-thinning behaviour of the CWO is probably due to the presence of residual moisture in the sample, as it is an unrefined version of the wax oil. The thermal stability of the binders is shown in Figure 1. The results show that, except for Tar-Veg and Ta-PW, the binders are homogeneous mixtures that maintain their molecular structure during heating. There is a correlation between extrusion pressure and workability, wherein binders with higher viscosities require higher extrusion pressures to extrude the clay [9]. The Tar-BW has the closest thermal stability and change in viscosity with temperature compared to the reference binder. It has a slightly higher starting viscosity, which can be mitigated by incorporating a lower viscosity liquid as a plasticizer to slightly lower the viscosity. The MP binder has the highest decrease in viscosity during heating while still maintaining its molecular structure at higher temperatures. The Tar-PW and Tar-Veg binders did not maintain thermal stability and are not considered favourable alternatives to CTPht, as thermal stability is a critical property of binders.

*Fig. 1: Rheological thermal stability of various binders*

**Overall ranking of binders**

The analytical evaluations were used to rank the alternative binders according to their suitability to replace CTPht as a binder in taphole clay. Table 3 shows the binders and their rankings, based on composition, thermal analysis, and rheology.

*Tab.3: Overall ranking of alternative binders based on the compositional, thermal, and rheological evaluations*

| Position | Overall rank |
|----------|--------------|
| 1 | Tar-BW |
| 2 | CWO |
| 3 | MP |
| 4 | PCWO |
| 5 | EcoP |
| 6 | 20P |
| 7 | Tar-PW |
| 8 | Tar-Veg |

The rankings are listed from top to bottom, with the most suitable binders at the top and the least suitable at the end. The selection criterion for ranking was a combination of lowest total PAH value, and good dynamic viscosity and thermal stability for manufacturing and green strength development. The most suitable binder to replace CTPht is the beechwood tar (Tar-BW). The other bio-based binders were ranked lowest due to limited dynamic viscosity thermal stability. The coal-based binders were also ranked low due to their high toxicity levels. The petroleum-based binders were the closest alternatives, besides the Tar-BW, to replace the CTPht, with the CWO and MP ranking as the second and third alternatives, respectively.

**CONCLUSIONS**

The selection of alternative binders to CTPht was carried out by using compositional and toxicity measurements (GC-MS), thermal behavior (TGA) and rotational rheology to evaluate the flow characteristics, and dynamic viscosity thermal stability of each binder. The GC-MS targeted analysis showed that the binder with the highest total PAH content to be 20P, while Tar-PW and Tar-BW exhibited the lowest toxicity among the binders. Some of the petroleum-based binders (CWO, PCWO) also exhibit low toxicity compared to the coal-based alternatives. The variation in thermal stability between the binders was 0,21-0,96 g / °C. The petroleum wax-based binders having the highest mass loss over a short temperature range, while the coal-based binders exhibited the lowest mass loss over a wide temperature range. This behavior is similar to that of the reference binder. The dynamic thermal stability assessment indicated that all binders, except for Tar-PW and Tar-Veg, had good thermal stability and have the potential to replace CTPht. From the analytical evaluations and comparison to the behavior of the reference binder, Tar-BW has shown to be the most favorable binder for replacing CTPht in taphole clay.

# DEVELOPMENT OF HIGH PERFORMANCE TAP HOLE CLAY

Tuhin Patranabish, Kazi Asif Ahmed, Saumen Sinha and Indra Nath Chakraborty
Calderys India Refractories Limited

**ABSTRACT:**

Taphole Clay (THC) related challenges increase with the increased BF productivity, quality variation of iron ore and cost of refractory raw materials**.** Addressing these issues has all along been a problem since the changes THC undergoes, after injection, inside a Blast Furnace (BF) is never known. Decisions regarding THC formulation design are always based on speculation. In this paper we report the development of THC, for big and jumbo furnaces, following a thermodynamic approach. Influences of THC raw materials were evident in thermodynamic calculation results as well as corrosion of the refractory, by a representative BF slag, during laboratory Induction furnace corrosion study. Corrosion of the THC, observed during induction furnace interaction study, was correlated with the quantum of liquid as well as the minerals formed during THC - Slag interaction and viscosity of the liquid formed.

The THC formulations were optimized based on thermodynamic results and the same has been used successfully in Big and Jumbo BF.

**INTRODUCTION:**

Colloquially Big and Jumbo Blast Furnaces (JBF) are defined as those with capacities in the range of 6000 - 9500 and > 9500 Ton/Day, respectively. Good health and reliable operation of the tap hole are essential for smooth functioning as well as achieving the desired lifespan of BF. Nowadays Jumbo BF operations are very challenging due to the high productivity target, deterioration of the input raw material quality, especially iron ore and cost reduction target.

The expectation of BF operators, from THC, are plugging without any leakage and back flushing, smooth TH opening, i. e. only with drill bit without hammering or oxygen lancing, no increase in TH diameter during slag as well as metal casting, consistent TH Length, no slag delay and no spitting during casting. Achieving these targets requires correct THC formulation as well as its quality consistency. Controlled drainage rate, with required Cast Duration (CD), depends on the stability of the Mushroom and controlled erosion of TH pipe formed by the THC used for closing after the completion of slag - metal tapping operation.

CD is defined as the total drainage time of Metal and Slag after opening of TH. The same, depends on the mushroom stability and TH Pipe erosion rate during drainage of metal and slag. Mushroom stability depends on several factors, e. g. THC formulation, THC binder system as well as mixing process during its production and THC workability / plasticity. BF operation practice, including plugging, also plays a significant role in THC performance. In today's context the designed THC should not get corroded under high slag rate, high slag basicity and slag with >1.0% MnO.

In general, Ferro silicon nitride (FSN) and silicon carbide (SiC) are seen as essential constituents of THC for its acceptable performance, e. g. desired CD. [1] Concentration optimization of these constituents is vital for attaining the targeted THC performance parameters. During this work, FactSage 8.2, a chemical thermodynamic software and database [2], has been utilized to optimize the characteristics as well as minimize the quantum of liquid formed during THC - slag interaction, at lower FSN and SiC concentrations in THC formulation. The FactSage THC - slag interaction results have been verified in the laboratory by Induction furnace Finger Test (FT). The optimized THC formulation has been tried in a 12000 TPD BF. This paper reports the THC formulation optimisation process using FactSage, laboratory induction furnace and field trial results

**EXPERIMENTAL:**

Conventional THC constituents were used for calculation of THC - slag / metal interaction by FactSage equilibrium phase proportion as well as laboratory induction furnace THC - slag interaction. Numerous THC - slag interaction data were generated, by using FactSage, for THCs with varied (SiC + FSN) concentrations and Alumina to silica ratios. The chemistry of shortlisted THC compositions, used for the FactSage calculation, are reported in Table I.

Primary focus has been given on (SiC + FSN) concentration. THC A is the conventional formulation for JBF. The process adopted for formulation adjustment is reported in Table II.

FactSage was used to see the impact of temperature on 70% THC and 30% JBF slag mix as well as 70% THC and 30% JBF Hot Metal (HM) mix. FactPS, FToxide, FTmisc, FTOxCN (only for solid phases) was used to do the calculation for this subject topic. Calculations were done for an interaction temperature of 1500 $^0$C.FactSage predicts the concentrations as well as compositions of gas, liquid and solid of the aforementioned interactions.

**Table** Ⅰ Chemistry of THC formulae

| Formula | Al2O3+SiO2+C | SiC+FSN |
|---|---|---|
| THC A | X | Y |
| THC B | X+Δx1 | Y-Δy1 |
| THC C | X+Δx2 | Y-Δy2 |

**Table** Ⅱ THC Formulae Chemistry Balance

| Product | Chemistry balance |
|---|---|
| THC B | Δx1=Δy1 |
| THC C | Δx2=Δy2 |

Typical slag chemistry of JBF, where the field trial was conducted, are reported in Tables III.

Table IV reports the typical HM chemistry of the aforementioned JBF. The accuracy of factsage equilibrium prediction for this type of mix was verified by laboratory induction furnace FT. For FactSage calculation as well as laboratory induction furnace FT, the slag and HM, reported in Table III and IV, respectively, were used.

The test specimens, for induction furnace FT, were of cylindrical shape for avoidance of corner breakage. 70% metal and 30% Slag, on weight basis, were used for the test. The molten liquid temperature was maintained between 1498°C to 1520°C. Samples were dipped partially into the molten liquid. The sample holder was rotated from a control panel at a speed of 5 rpm. After the completion of the test, samples were cooled down. The corrosion was measured along the diameter of the cylinders. The reduction in diameter, in comparison to the initial specimen diameter, has been reported as refractory wear.

**Table III** Jumbo BF Slag

| Constituent Concentration, % | | | | | | | | |
|---|---|---|---|---|---|---|---|---|
| $SiO_2$ | $Al_2O_3$ | CaO | MgO | MnO | FeO | $TiO_2$ | $Na_2O$ | S |
| 35.07 | 18.26 | 35.84 | 6.82 | 1.32 | 0.37 | 0.82 | 0.33 | 0.59 |

**Table I**V Hot metal chemistry in %

| Fe | Mn | Si | C |
|---|---|---|---|
| 94.5 | 0.5 | 1.0 | 4.0 |

The Green and 1300 $^0$C / 3 hrs coked bulk density data were generated for THC A,THC B and THC C. The apparent porosity (AP), volatile matter (VM) and cold crushing strength (CCS) were measured after curing the test specimens in reducing atmosphere at 1300 $^0$C for 3 hrs. All the data were generated using internal test procedures.

**RESULTS AND DISCUSSION:**
Figure 1 shows FactSage predicted mineral, liquid and gas concentrations of 70% THC - 30% JBF slag interaction at 1500 $^0$C . Apart from gas and liquid, the major constituents of the predicted solid phases are SiC, $CM_2A_8$ [3] and $CA_2$ where C, M and A are CaO, MgO and $Al_2O_3$, respectively. $CA_2$ is a refractory phase. The formation of $CM_2A_8$ is significant, which is a solid solution of $CA_6$ and MA(spinel) [3]. $CA_6$, like spinel, can accommodate a varied range of atoms in its crystal structure.[4] As a result $CA_6$ also can modify the slag characteristics as well as the slag corrosion behavior. The $CM_2A_8$ concentration follows the following trend.

THC C > THC B > THC A

THC C is expected to offer greater resistance to the slag attack owing to higher $CM_2A_8$ concentration. The concentration of in situ formed (secondary) SiC, after interaction with slag, also follows the same trend. In situ SiC formation has been explained in greater detail in one of the following sections.

It is prudent to mention that THC A had the highest concentration of (SiC + FSN) whereas the same for THC C was the lowest (Table I). The predicted liquid phase follows a trend reverse to that for SiC phase, i. e. least for THC C and is highest for THC A, though THC C has the highest oxide concentrations (Table I). The liquid concentration, thus, is controlled by the amount as well as ratios of the THC oxide constituents.

Figure 1 also illustrates the concentrations of the THC - slag interacted gas phase. Concentrations of gas formed after interactions are comparable for all the three formulations.

Carbon monoxide (CO) and Nitrogen ($N_2$) are the major gas constituents. CO originates from the oxidation of carbonaceous constituents of the THC formulation. $N_2$ originates from the dissociation of FSN as per reaction 1. [1]

$$3Fe + Si_3N_4 \longrightarrow 3FeSi + 2N_2 (g) \qquad (1)$$

***Fig 1*** *FactSage results of THC - Slag Interaction at 1500 $^0$C*

Figure 2 illustrates the yields of 70% THC - 30% HM interaction at 1500 $^0$C. The yields are fairly similar to those observed for THC - slag interactions. Like THC - slag interaction, the constituents of the gas yields are $N_2$ and CO. The solid yields of the interaction are the constituents of the virgin THC, except for the $Al_2OC$ - AlN phase. Apart from slag, THC - HM interaction at 1500°C also yields an iron rich liquid termed as Fe- liquid. The concentration of Fe - liquid varies in a narrow range, viz. between 34.64 to 34.87 %.

***Fig 2*** *FactSage results of THC-HM Interaction at 1500 $^0$C*

Figure 3 shows the viscosity of liquid, formed during THC - slag interaction, has been calculated based on the liquid chemistry predicted by FactSage. In reality viscosity of the solid - liquid mix should have been considered. [4] The liquid yield of THC - slag interaction, however, is too low for accurate determination of Solid - Liquid mix viscosity. Only liquid viscosity, hence, has been considered for discussion of the results. The viscosity of the liquid formed by virtue of interaction follows the following trend.

THC C > THC B > THC A

It is evident that the viscosity variation of the liquid formed during slag interaction with different THC, however, is marginal. In the interaction equilibrium phase proportion, liquid concentration for THC C is significantly lower. As a result, the effective viscosity of Solid - liquid mix would be significantly higher for THC C - slag interaction equilibrium phase proportion. These aspects of THC C are expected to play a significant role in determining the resistance to slag attack.

251
**Fig 3** *Viscosity of the liquid formed during THC - Slag Interaction at 1500 $^0C$*

Figure 3 also illustrates the concentration of $CM_2A_8$ during interaction with slag.

When the SiC content of the THC - slag interaction equilibrium phase proportion is higher than that in the starting THC - slag mix, it is obvious that SiC had formed during the aforementioned interaction. The increased SiC concentration has been defined as secondary / in situ formed SiC. In situ SiC formation occurs by virtue of the reaction 2. [1] FeSi of equation 2 originates from reaction 1.

$$FeSi + C \longrightarrow SiC + Fe \qquad (2)$$

Secondary SiC formation has also been observed for THC - HM interaction. The quantum of secondary SiC formation, however, is lower compared to THC - slag interaction. It may, thus, be speculated that part of the SiC of THC is dissolved in the HM during the interaction.

Figure 4 illustrates the impact of Alumina to Silica (A to S) ratio of THC formulation on the quantum and viscosity of the liquid formed during interaction with slag at 1500 $^0C$. It is evident from the results that increased A to S ratio lowers the concentration of the liquid formed as well as increases the viscosity of the liquid. Additionally, increased A to S ratio also increases the secondary SiC formation. The combined effect of all these aspects is expected to improve slag attack resistance of THC.

It is also obvious from Figure 4 that the increase of A to S ratio also enhances $CM_2A_8$ formation as well as slag corrosion resistance. The combined effect of A to S modification on liquid concentration as well as its viscosity, $CM_2A_8$ formation and secondary SiC formation, is reflected on the slag resistance.

**Fig 4** *$Al_2O_3$ / $SiO_2$ ratio impact on liquid characteristics formed during THC - Slag interaction at 1500 $^0C$*

**Fig 5** Appearance of Finger Test Specimens after Interaction with slag - HM mix at 1500 $^0C$

It is apparent from Figure 5 that THC C, which has the least concentration of (SiC + FSN), offers the best resistance to slag attack. Apart from the aforementioned ingredients of THC formulations, adjustment of A to S ratio, thus, also influences THC slag resistance.

Figure 6 illustrates the Green BD and 1300 $^0C$ / 3 hrs cured BD of the THC formulations (A,B,C) which were shortlisted based on FactSage calculations. The results show that the change in the composition, in terms of ingredient concentrations as well as their type, does not alter the product density.

Figure 7 illustrates the VM, AP and CCS of the shortlisted compositions. Here again the differences in these properties are marginal.

**FIELD TRIAL APPLICATION RESULTS :**

All three FactSage result based shortlisted THC formulations were manufactured through the same manufacturing process. After aging, all the three THCs were used in a JBF. Table V reports the observations made during the field trial of THCs. During this study, the quantity of THC used for plugging and CD were the primary performance determining parameters. The quantity used for plugging was lowest for THC C, whereas CD for this formulation, however, was the highest compared to the other trial formulations. Higher CD indicates that the wear of the mushroom formed by THC C is minimal. This fact corroborates with the observation made during laboratory induction furnace corrosion tests.

**Fig 6** *Green Bulk density and 1300 $^0C$ / 3 hrs Coked Bulk density*
***Fig 7*** *Apparent Porosity (AP),Volatile Matter (VM) and 1300 ⁰C / 3 hrs Cured Cold Crushing Strength (CCS)*

It is evident from the field trial results that for THC C, the average HM temperature was higher by ~ 15 ⁰C. It also is well known that the chemical reaction rate accelerates exponentially with increasing temperature. Even with such adverse operating conditions, i. e. higher BF operating temperature, THC C, which had the lowest (SiC + FSN) concentrations, has yielded the best performance. It also is evident that the liquid phase concentration and the liquid viscosity predicted by FactSage, for THC - slag interaction, as well as laboratory induction furnace FT results can be taken as a good indicator for the resistance of THC to slag attack during their usage in the field. The role of evolved gasses, viz. $N_2$ and CO, on the slag attack resistance, however, is not very clear. It is speculated that the evolved gasses form a barrier between THC and slag and thus, the interaction between THC and slag is reduced. The other plausible role of evolved gasses could be that they get generated within the THC pores and thus, the slag penetration is reduced.

**Table** V **Corrosion Test and site performance data**

| Product | HM Temperature Range, ℃ | Plugging Quantity, Liter | Average (minutes) | Finger Test Corrosion, % |
|---|---|---|---|---|
| THC A | 1486 - 1523 | 180 | 146 | 19.5 |
| THC B | 1475 - 1522 | 185 | 178 | 14.5 |
| THC C | 1500 - 1532 | 176 | 181 | 12.3 |

**CONCLUSION:**
FactSage thermodynamic software predicted THC - slag interacted liquid characteristics, viz. its quantum and viscosity, is a good indicator for the field performance of THC. Usage of FactSage software, for THC formulation optimisation, virtually eliminates time consuming as well as expensive conventional route for formulation optimisation. It appears that the THC formulation should be so adjusted that THC - slag interaction yields lowest liquid concentration, highest liquid viscosity at highest possible A to S ratio of the THC formulation. It is obvious from this work that FactSage can be used for generation of these data without carrying out any laboratory experiment. Laboratory induction furnace FT also reveals that control of these parameters reduces the THC wear by slag. Lesser THC corrosion, during its interaction with slag, is reflected in longer CDs during BF tapping.
The work also reveals that the concentrations of (SiC + FSN) can be optimized by using the FactSage software. Apart from the concentrations of these critical constituents, A to S ratio of THC formulations play a significant role, by influencing secondary SiC

formation, in controlling the THC wear in JBF and as a result increases the CD. The calculation reveals that $N_2$ and CO gases evolve during interaction of THC with slag as well as HM. The impact of these evolved gasses on the THC wear, however, could not be deciphered during this work.

# BEHAVIOR OF CARBON-BASED BINDERS FOR BLAST FURNACE TAPHOLE CLAYS FOCUSED ON ENVIRONMENT, SAFETY, AND PERFORMANCE

Tomás Moreira de Oliveira, Aloísio Simões Ribeiro, Paschoal Bonadia Neto
RHI Magnesita, Contagem, Brazil

Eduardo Henrique Martins Nunes
Universidade Federal de Minas Gerais, Belo Horizonte, Brazil

**ABSTRACT**

The liquid binder plays an essential role in taphole clay composition to guarantee its properties such as plasticity, adhesion, corrosion/erosion resistance, and ease of drilling during use in blast furnaces. Additionally, the binder also has a major role concerning environmental and safety aspects. Several studies have been carried out on taphole clay binders, but it is not common to find an in-depth comparative analysis between the different existing types. In this study, four commercially available carbon-based binders were investigated, namely a traditional coal tar pitch, a novolak phenolic resin, a low benzopyrene coal tar pitch, and a petroleum-based binder. This study aimed to understand the key properties of each taphole clay binder and how they affect the refractory mix regarding environmental, safety, and performance aspects. Specific tests to evaluate binders were carried out and associated with taphole clay properties.

## 1 INTRODUCTION

Taphole clays are plastic refractory materials used to seal blast furnace tapholes at the end of the tapping operation. They are made from various solid raw materials in different grain sizes, which are agglomerated by the addition of a liquid binder. This liquid material is very important for taphole clays to obtain their properties such as plasticity, adhesion, corrosion/erosion resistance and ease of drilling. Additionally, the binder has a major role concerning environmental and safety aspects. For this reason, taphole clay binders have been the subject of several recent studies[1-4].

One of the main binders in used is coal tar pitch, but it is a toxic material. Due to the high presence of polycyclic aromatic hydrocarbons (PAHs), especially benzopyrene (BaP), coal tar pitch is carcinogenic[5-7], which has motivated the development of alternative binders. These include phenolic resins, coal tar pitches with low benzopyrene content and petroleum-based binders.

Although taphole clay binders are an important topic, it is not common to find an in-depth comparative analysis of the different types available. In addition, there is no adequate reference about key properties to be evaluated in binders for taphole clays. In this study, four types of binders available on the market were characterized: traditional coal tar pitch, novolac phenolic resin, low benzopyrene coal tar pitch, and a petroleum-based binder.

## 2 OBJECTIVES

Understand the key properties of each taphole clay binder and how they affect the performance of the refractory mix.

## 3 MATERIALS AND METHODS

### 3.1 Materials

Table 1 shows the identification and description of each product evaluated in this study. The selected binders were a conventional coal tar pitch, a low-benzopyrene coal tar pitch, a petroleum-based binder, and a phenolic novolac resin.

Tab. 1: Identification and description of the analyzed binders.

| Identification | Description |
|---|---|
| CTP | Traditional coal tar pitch |
| ECTP | Eco coal tar pitch with low benzopyrene |
| PNR | Phenolic novolac resin |
| PBB | Petroleum-based binder |

### 3.2 Brookfield viscosity

The Brookfield viscometer measures fluid viscosity at given shear rates and temperatures, which is a measure of a fluid's resistance to flow. The viscometer rotates a sensing element (spindle) in a fluid and measures the torque required to overcome the viscous resistance to the induced motion. In this test, spindle number 21 was used, and viscosity was measured at 30, 40, 50, 60, 70, 80, and 90 °C.

### 3.3 Curing test with parallel plate rheometer

The equipment used for this analysis was an Anton Paar / MCR 102 parallel plate rheometer. In this test, the viscosity of the binder was measured as the sample was heated to evaluate the curing behavior of the binder. The measuring system used for the curing test was a 25 mm disposable plate. The deformation used was 0.1% with a 1 Hz frequency. The samples were heated from 40°C to 400°C at a rate of 3 °C/min.

### 3.4 Thermogravimetric analysis

Thermogravimetric analysis (TGA) was performed using a TGA Discovery thermobalance. The binders were heated from room temperature to 800 °C at a rate of 10 °C/min. Nitrogen was used as the purge gas at a flow rate of 25 mL/min to avoid oxidation. TGA was used to determine mass loss as a function of temperature, examining the release of volatiles and residual carbon from the binders.

### 3.5 Gas chromatography coupled with mass spectrometry and a flame ionization detector

The equipment used for this analysis was a Thermo Scientific Trace 1310 GC with a TSQ 8000 Evo Triple Quadrupole Mass Spectrometer and Ionization Flame. This test was used to analyze PAHs from CTP, ECTP, and PBB, and free phenol and formaldehyde from PNR, which according to the literature[5-11] are the most common compounds analyzed in this type of binders to check their hazardousness.

For the determination of the content of PAHs, about 100 mg of the binder samples were extracted with a mixture of tetrahydrofuran/toluene (4: 6 ratio) using bath ultrasonics. The samples were then filtered, and an aliquot was taken for purification by solid phase extraction (SPE) using the dichloromethane/pentane mixture (4: 6 ratio). After the extraction step, the extracts obtained were subjected to analysis by gas chromatography with mass spectrometry (GC/MS) and flame ionization (FID) detectors. The following analytical standards were used for quantification of PHAs and process control: PAH standard solution, deuterated PAH internal standard solution (mixture of naphthalene d8 (NAP d8), acenaphthene d10 (ACE d10), phenanthrene d10 (PHE d12), chrysene d12 (CHR d12) and perylene d12 (PER d12)) and decafluorobiphenyl (DBF) injection standard solution.

For the determination of the content of free phenol and formaldehyde, about 10g of the phenolic resin was extracted with diethyl ether after neutralization with concentrated sulfuric acid. After the extraction step, the extract obtained was subjected to analysis by GC/MS and FID. Phenol and formaldehyde standard solutions were used to quantify free phenol and formaldehyde in the sample.

# 4 RESULTS AND DISCUSSION

## 4.1 Brookfield viscosity

Table 2 gives the Brookfield viscosity of each binder analyzed in this study in mPa.s and % relative to the value at 30 °C. Some values could not be measured, because the viscosity was too low to be detected by the equipment. ECTP is the material with higher values and PBB with lower. Binders with higher viscosity have been reported for improving the plasticity of taphole clays, which gives longer and good texture inside the taphole under hot conditions, resulting in a stable mushroom (taphole clay wall formed inside the blast furnace hearth)[12]. However, it is well known that the viscosity is something that can easily be adjusted during the production of the binder according to the needs of the taphole clay producer.

Another important feature is that PNR showed a lower decrease in viscosity relative to the initial value measured at 30°C compared to the other binders. This behavior suggests that the plasticity of taphole clays produced with PNR should be less sensitive to temperature variations within the mudgun for this temperature range (30-90°C), which would increase plasticity stability over injections at different temperatures.

Tab. 2: Brookfield viscosity as a function of temperature of each binder in mPa.s and % relative to the value at 30 °C.

| Temperature (°C) | Brookfield viscosity (mPa.s) | | | |
|---|---|---|---|---|

## 4.2 Curing test with parallel plate rheometer

The results from the curing test with a parallel plate rheometer can be seen in Figure 1. PNR presented a behavior that is significantly different from the other binders. Due to the curing of the novolac resin, there is a sharp increase in its viscosity at 128°C, whereas all other binders only show a significant increase in viscosity at temperatures above 300°C. This increase in viscosity is related to the curing of the binder and explains why resin-bonded taphole clays cure faster than tar-bonded clays, as reported by some authors[2, 12, 13].

ECTP presented an increase in viscosity in two steps. At 280°C the viscosity starts to increase, but at 313°C the values decrease and do not increase again until 343°C. The first complex viscosity increase (280 °C) is believed to be related to the release of volatiles from the solvents of the binder, while the decrease at 313 °C is probably related to the softening point of the pitch, which has been combined with the solvents to produce the binder. Pitch passes through a thermoplastic phase when heated to pyrolysis temperature[10, 14-16]. The increase in viscosity at 343 °C represents the final consolidation of ECTP in the solid state.

CTP and PBB showed an increase in viscosity in one step, starting at 367 °C for CTP and 316 °C for PBB. The petroleum based-binder starts its hardening process at a lower temperature when compared to the coal tar-based material, but it shows an improvement in hot plasticity when compared to the resin-based binder.

CTP is the binder that can keep its liquid form for a longer time and comparing its behavior with PNR, the differences in the properties of the taphole clays with these two binders are better understood. During and after plugging, pitch-bonded taphole clays are able to maintain plasticity for a longer period of time as they are heated (slow curing process), while resin-bonded mixes have a faster curing process that leads to a rapid loss of plasticity[2, 12, 13]. These characteristics improve injectability of pitch-bonded material, but at the same time increase the chance of having gas pocket over drilling and unstable flow of hot metal and slag from the blast furnace over tapping if time between taps is short[13, 17].

Fig. 1: Curing test with parallel plate rheometer results with each binder.

## 4.3 Thermogravimetric analysis

Figure 2 shows the results for TGA of each binder sample over heating in a non-oxidizing atmosphere. The most important information analyzed from the graph was the final residual carbon at 800 °C and the way that volatiles were released for each binder.

With greater residual carbon, higher corrosion resistance is expected, as higher amount of carbon that has low slag wettability[18] fills the porous of the refractory. The order of products that had more residual carbon from highest to lowest is PNR (38.0 %), ECTP (26.0 %), CTP (18.0 %) and PBB (11.2 %). Thus, although this is not the only binder property to affect corrosion resistance, higher resistance to hot metal and slag attack is expected for the taphole clays produced with the binders containing higher residual carbon. The lower capacity of carbon fixation of petroleum-based binders that was reported by some authors[10] was also seen in this TGA analysis.

Fig. 2: TGA results for each binder analyzed in a non-oxidizing atmosphere.

255

Regarding volatiles release behavior, it is known that the release of these gases in lower temperatures together with fast curing favors crack formation in taphole clay mushroom[2]. Figure 3 shows the derivative of the curves from the TGA test, and PNR, as expected, was the binder that showed the first peak of weight loss at a lower temperature (103 °C), followed by ECTP (152 °C), PBB (175 °C) and CTP (216 °C). Since PNR also has fast curing, a taphole clay with this resin would be more subjected to crack formation due to gas release pressure in a structure that is already solid.

*Fig. 3: Derivative from TGA results with each binder analyzed in a non-oxidizing atmosphere.*

### 4.4 Gas chromatography coupled with mass spectrometry and a flame ionization detector

The results from GC/MS are presented in Table 3 and Table 4. PAHs were analyzed for CTP, ECTP and PBB and free-phenol and formaldehyde were analyzed for PNR. As expected, CTP is the binder with the highest amount of BaP (611 ppm) associated with a high level of total PAHs (38428 ppm), which makes it more harmful to human health. Although BaP from CTP is much lower than what has been found in the literature (10000-15000 ppm[10]), it is still higher than 50 ppm, which is the limit for not being considered a dangerous working material according to TRGS 551[7].

Tab. 3: PAHs of CTP, ECTP and PBB analyzed by GC/MS.

| PAH (ppm) | CTP | ECTP | PBB |
|---|---|---|---|
| Naphthalene (NAP) | 9771 | 7708 | 0 |
| Acenaphthylene (ACY) | 66 | 296 | 44 |
| Acenaphthene (ACE) | 5707 | 13141 | 32 |
| Fluorene (FLU) | 2594 | 3242 | 10 |
| Phenanthrene (PHE) | 7707 | 3300 | 157 |
| Anthracene (ANT) | 1289 | 503 | 275 |
| Fluoranthene (FTL) | 3971 | 5801 | 7 |
| Pyrene (PYR) | 3104 | 4115 | 42 |
| Chrysene (CHR) | 577 | 425 | 27 |
| Benzo[a]anthracene (BaA) | 628 | 462 | 25 |
| Benzo[j]fluoranthene (BjF) | 788 | 367 | 12 |

| **Total** | 38428 | 40475 | 739 |

Tab. 4: Free-phenol and formaldehyde of PNR analyzed by GC/MS.

| Compound (%) | PNR |
|---|---|
| Phenol | 0.82 |
| Formaldehyde | N.D. |
| ***N.D.: Not detected*** | |

ECTP showed better values for BaP (289 ppm), but was still higher than 50 ppm. Besides that, the total PAHs of ECTP (40475 ppm) was the highest, which makes it a reasonably hazardous material. The only binder with less than 50 ppm BaP and low total PAHs was PBB, which had 16 ppm BaP and 739 ppm total PAHs. As expected, based on literature review[10-11], PBB contains much lower levels of PAHs than conventional coal tar pitch.

Similar to PBB, PNR showed GC/MS results (Table 4) of a binder with a lower risk to human health. Some standards classify the resins containing more than 5 wt. % of free-phenol as toxic[19], and PNR contains only 0.8 % of free-phenol, with no amount of formaldehyde detected by the equipment.

### 4.5 Key binder properties for taphole clay application

With all results that were presented and discussed for binder characterization it was possible to define some parameters that would be important to evaluate in binders for taphole clays and the expected taphole clay properties that would be influenced by these binder characteristics. Table 5 shows the description of each of these parameters and the influenced taphole clay properties. It is always important to check the behavior of the binder mixed in the taphole clays, but a first analysis of the pure binder can already show important information about the expected behavior in the final refractory, which could be useful e.g., when searching for new binders to be used in taphole clays.

Table 6 presents a summary of the results obtained for each studied binder and can be used as a reference for future studies. When thinking about substituting CPT for more eco-friendly options, ECTP is the most similar binder. PNR has much faster curing, which means that a taphole clay produced with it should require much more care over taphole plugging to avoid difficulties over injection and crack formation in the mushroom. On the other hand, PBB has low residual and for that reason less erosion and corrosion resistance are to be expected from the taphole clay produced with it.

Tab. 5: Important characteristics of binders for taphole clays.

| Property | Description | Influenced taphole clay properties |
|---|---|---|
| Viscosity at 50 °C | Brookfield viscosity measured at 50 °C. | Plasticity and texture inside the taphole. |
| Viscosity variation over temperature | Level of Brookfield viscosity variation measured from 30 to 90 °C. | Plasticity sensitivity to temperature variation within the mudgun. |
| Curing temperature | Binder hardening temperature during curing test with parallel plate rheometer. | Hardening speed during heating. |
| Residual carbon | Residue from TGA. | Erosion and corrosion resistance. |
| Beginning of weight loss | Temperature of the first peak of TGA derivative curve. | Tendency to crack formation inside the taphole. |

## 5 CONCLUSIONS

The conclusions are as follows:

(1) The analysis of the pure binders already contains significant amount of information regarding their expected behavior when added to taphole clays. With all results that were presented and discussed it was possible to define some parameters that would be important to evaluate in binders for taphole clays (viscosity at 50 °C, viscosity variation over temperature, curing temperature, residual carbon, beginning of weight loss, total PAH's, BaP, free phenol and free formaldehyde) and the expected taphole clay properties that would be influenced by these binder characteristics.

(2) Based on the results and discussion from binder characterization, ECTP is the material most similar to CTP. PNR has much faster curing, which means that a taphole clay produced with it should require much more care over taphole plugging to avoid difficulties over injection and crack formation in the mushroom. On the other hand, PBB has low residual and for that reason less erosion and corrosion resistance are to be expected from the taphole clay produced with it.

# IMPROVEMENT OF AL$_2$O$_3$–SIC–C BRICKS OF THE HOT METAL LADLE

Kazuma Hashimoto, Koji Yamada, Yasuhiro Yamada
Nippon Steel Corporation, Tokyo, Japan

Shinsaku Takahara and Katsuhiro Ishimoto
Krosaki Harima Corporation, Fukuoka, Japan

## ABSTRACT

The life of hot metal ladles was short at Nagoya Works, Nippon Steel, because Al$_2$O$_3$–SiC–C bricks at the ladle sidewall fell in the last stage of operation. The falling of the bricks was caused by the damage to the joints of the bricks, whereas parts other than the joints were not damaged. We investigated used sidewall bricks to understand the mechanism of joint damage. We developed a new Al$_2$O$_3$–SiC–C brick. The investigation of the used bricks revealed that the molten slag infiltrated the joint mortar and corroded the mortar and brick. Furthermore, the molten slag infiltrated through the cracks caused by the lack of residual expansion of the bricks. Therefore, we applied a new expansible raw material to the Al$_2$O$_3$–SiC–C brick to control residual expansion. Laboratory evaluation confirmed that the developed brick exceeded conventional bricks in terms of residual expansion and corrosion resistance. We adopted the developed brick to hot metal ladle sidewall. Consequently, the life of hot metal ladle was increased by 20%, and the refractory cost was reduced by 17 %.

## BACKGROUND AND PURPOSES OF IMPROVEMENT ACTIVITIES

### Role of hot metal ladle in Nagoya Works

Hot metal transported from a blast furnace by a torpedo car is poured into a hot metal ladle along with a small amount of blast furnace slag. After charging the hot metal into the optimizing refining process (ORP) converter furnace, the Si, P, and S components are removed. Subsequently, the hot metal is recharged into another convert furnace for decarburization. In this steel refining process, a hot metal ladle is used as a transport vessel for hot metal from a torpedo car to an ORP converter furnace.

### Refractory relining specifications and repair pattern of hot metal ladle

The specifications of the hot metal ladle refractory relining are shown in figure 1. The free board and slag line portions of the hot metal ladle wall are relined with Roseki (pyrophyllite)–SiC bricks that are characterized by high durability against the mechanical impact caused by the demolishing work of the adhering metal. The metal line portion of the hot metal ladle is relined with Al$_2$O$_3$–SiC–C bricks (hereinafter referred to as ASC bricks) with superior erosion resistance against blast furnace slag. Among the five (5) hot metal ladles, three (3) ladles are generally operated, with one (1) ladle on stand-by and another one (1) ladle under refractory maintenance repair. In refractory maintenance repair, all wear bricks are newly relined after approximately 2000 heats of operation at the end of their service life without any intermediate repair work.

*Fig. 1: Hot metal ladle relining specifications.*

### Confronting issues of hot metal ladle refractory

Figure 2 shows the surface appearance of the wear bricks in a hot metal ladle that was scheduled for the entire refractory repair work after 2060 heats of operation. Localized wear at the brick joints is clearly observable. When the localized wear at the brick joints is further advanced, the worn bricks drop off owing to the deficiency of mutual support by wedges. Because of this wear pattern, worn bricks must be relined before they are completely outworn; in other words, under the condition in which a relatively large amount of thickness remains in their major portion, the service life of hot metal ladles is insufficient. In addition, irregularities in the surface appearance of worn bricks because of this wearing pattern make it difficult to detect the exposure of permanent bricks caused by the dropping off of worn bricks that may lead to a possible risk of hot metal leakage. Under the aforementioned circumstances, a series of improvement activities is performed to achieve cost reduction of a hot metal ladle refractory by suppressing localized wear at brick joints and minimizing hot metal leakage incidents by introducing a temperature monitoring system on the hot metal ladle steel shell.

*Fig. 2: Surface appearance of wear bricks at 2060 heats of service life.*

## SERVICE LIFE EXTENSION OF HOT METAL LADLE

### Quantitative wear measurement with 3D profile meter

As a first step in the investigation of the wear mechanism, a quantitative measurement of the wear amount of the wear bricks at various relining positions was performed. In the past, the remaining thickness was measured using a rule on used worn bricks retrieved from several relining positions of a hot metal ladle when its refractory maintenance work was scheduled. Because this manual measurement was time-consuming and measuring all relined wear bricks was difficult, three-dimensional (3D) profile meter (hereinafter referred to as PFM) using a lazar ray was introduced. The major specifications of the introduced PFM are listed in table 1. The PFM was set in a refractory maintenance yard for the profile

Tab. 1: Specifications of 3D profile meter system (PFM) for hot metal ladle refractory.

| Item | General Specification |
|---|---|
| Type | Mobile |
| Scannning time | 15 min |
| Range | 35 m (max.) |
| Measurement accuracy | ±5 mm |

measurement of hot metal ladles and other hot metal and molten steel transport vessels under cooled down conditions. The profile measurement of one transport vessel with $+/-$ 5 mm of measurement accuracy took 15 min. With prior profile measurements of the permanent brick surface of the transport vessel, measurement errors caused by steel shell deformation can be cancelled and corrected. In short, the introduced PFM enabled quick quantitative profile measurements of wear bricks relined in all transport vessels for hot metal and molten steel.

**Investigation study on wear mechanism**
First, the wear pattern of wear bricks, that is, the influence of the relined position on the wear amount, was investigated on a hot metal ladle whose refractory maintenance was scheduled after 2060 heats of operation. A vertical wear pattern profile of the hot metal ladle refractory measured with the PFM is shown in figure 3, along with the typical remaining thicknesses of the wear bricks and the calculated wear rate at major portions. The thinnest remaining

*Fig. 3: Vertical wear profile of hot metal ladle refractory at 2060 heats of service life.*

thickness of the wear bricks was observed at the metal line in the lower part of the side wall with 46 mm of remining thickness. Notably, owing to the smallest remaining thickness, wear bricks relined at the metal line in the lower part of the side wall tended to drop off and regulate the service life of the entire hot metal ladle refractory. The most severe wear rate was observed at the ladle bottom, followed by at the lower part of the side wall, where wear bricks were subjected to a relatively strong impact by hot metal discharged from the torpedo car along with the blast furnace slag. The lowest wear rate was observed at the slag line. Second, used wear bricks relined at the metal line in the lower part of the side wall, by the wear amount at which the service life of the hot metal ladle refractory is generally regulated, were closely observed. The cross section of a wear brick retrieved from the lower part of the side wall is shown in figure 4. The sampled wear brick exhibited a smooth hot

*Fig. 4: Cross section of a used conventional wear brick.*

surface without internal cracks or peel-off damage. However, localized wear was clearly observed on both sides of the brick, namely, at both brick joints, with a considerably larger wear amount than that at the center position by 29 mm. Therefore, the symmetrical localized appearance of brick wear at both brick joints was not caused by corner cracks initiated by the wedge effect between adjacent relined bricks. Figure 5 shows a microstructure image obtained by electron probe micro analyzer (EPMA), and element distribution mapping of the brick joint area. The hot face of the wear brick corner was eroded by the slag, and the erosion depth at the left-side brick corner was greater than that of the mortar adhering to the

*Fig. 5: Microstructure of a wear brick near the joint area.*
*(a) Optical reflecting micrograph.*
*(b) EPMA analysis.*

right-side brick. Slag penetration into the gap generated between the mortar and wear brick was observed with Ca element mapping. This slag penetration inferred that joint breakage occurred during the hot metal receiving operation. Based on the aforementioned results, the wear mechanism schematically illustrated in figure 6 can be inferred. First, the mortar was forcibly shrunken by expanding the wear bricks during the hot metal receiving operation. When the temperature was reduced after hot metal discharge, joint breakage occurred because of the insufficient permanent linear expansion of the wear bricks to compensate for the forcibly shrunken mortar. During subsequent hot metal reception, the slag could penetrate the gaps generated by mortar breakage. In association with the deepening of depressions at localized eroded brick joints, turbulence in hot metal and/or slag flow at brick joints became increasingly prominent, accelerating localized erosion. This inferred wear mechanism concluded that imparting sufficient permanent linear expansion to wear bricks and improving their erosion resistance were effective. Precedent studies [1–3] reported that localized wear at brick joints was suppressed by improvement of permanent linear expansion of bricks. Focusing on the aforementioned two characteristics of hot metal ladle wear bricks, improved wear brick materials were developed.

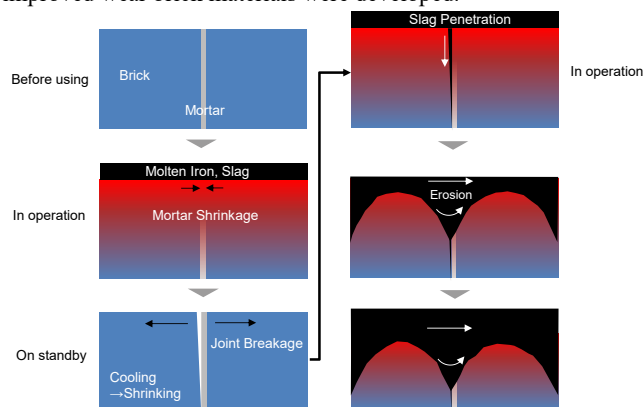

*Fig. 6: Presumed mechanism for localized wear at the brick joint.*

**Development of a new wear brick material**
The specific value of permanent linear expansion at which localized wear at the brick joints was sufficiently suppressed was examined. The specific value of permanent linear expansion of the wear brick at which joint breakage can be prevented can be calculated using Equation (1).

Permanent linear expansion [%] >100×(Joint thickness [mm]×Permanent linear expansion of mortar [%]/100)/Wear brick dimension [mm]                    (1)

When inserting specific figures for a practical operation, namely, 2 mm of mortar thickness, 66 mm of short side dimension of wear brick, and 30 % of permanent linear expansion of mortar, into equation (1), 0.91 % of critical value for permanent linear expansion of wear brick is calculated. To achieve this specific value of

259

permanent linear expansion, new wear brick materials were developed. Two types of wear brick materials, sample materials 1 and 2, onto which sufficient permanent linear expansion and improved erosion resistance were imparted, were developed. The

Tab. 2: Blending compositions of new ASC sample materials.

| | | Conventional | Sample1 | Sample2 |
|---|---|---|---|---|
| Chemical composition / mass% | Al$_2$O$_3$ | 55 | 47 | 56 |
| | SiO$_2$ | 19 | 27 | 18 |
| | SiC | 8 | 8 | 8 |
| | C | 15 | 15 | 15 |
| Expansible material index / - | A | a | 1.5a | - |
| | B | - | - | b |

blend compositions of sample materials 1 and 2 are summarized in table 2. An increase in the permanent linear expansion of sample material 1 was intended by increasing the added amount of expansive raw material A. However, another expansive raw material, B, was applied for sample material 2. To ensure the oxidation resistances of the brick material, blend compositions of SiC and C applied to conventional wear bricks were adopted for the two types of sample materials. The permanent linear expansion, thermal spalling resistance, and erosion resistance of the sample materials were evaluated, along with those of conventional wear bricks. The permanent linear expansions of the three types of refractory materials were measured with differential refractoriness under a load test. Sample specimens under 0.2 MPa of constant load were heated up to and maintained at 1400 °C for 3 h, and to prevent oxidation, internal atmosphere of the furnace was substituted with Ar gas on a steady basis, followed by gradual cooling. After complete cooling, the dimensions of the sample specimens were measured to calculate the permanent linear expansion. The comparative test results are shown in figure 7. Compared with the target value of 0.91 %, the

Fig. 7: Comparison of permanent linear expansion.

conventional wear brick exhibited a permanent linear expansion of 0.86 %. In contrast, sample materials 1 and 2 exhibited permanent linear expansions of 1.42 % and 1.99 %, respectively, that were sufficiently larger than the target value.

The erosion resistances of three types of refractory materials were evaluated with a rotary erosion test, in which sample specimens were eroded by an erosive agent with 1.1 basicity (C/S) at 1500 °C for 1 h. After repeating the erosion test five times, the amount of erosion was measured to calculate the erosion index. The erosion test results are shown in figure 8, where an erosion index of 100 represents the conventional wear brick. Compared with the conventional wear

Fig. 8: Comparison of the erosion index observed in the erosion.

brick, sample material 1 exhibited a worse erosion index of 121, whereas sample material 2 exhibited a better erosion index of 76.

Thermal spalling resistances of three types of refractory materials were evaluated by repeating a spalling test 10 times. In that test, cubic sample specimens, with 50 mm on a side, were rapidly heated by inserting into an electric furnace whose inner temperature was maintained at 1200 °C for 15 min, followed by water cooling for 5 min. After a series of thermal spalling tests, the total length of the cracks initiated in the sample specimen was measured to calculate the crack length index that was normalized with 50 mm of a side length. Figure 9 presents a comparison of the crack length indices of the sample specimens. Both sample materials 1 and 2 exhibited superior thermal spalling resistance to the conventional wear brick. In conclusion, sample material 2 was definitely superior to the conventional wear brick in all the characteristics required for hot metal ladle relining. Based on this conclusion, a practical application of the wear brick made of sample material 2 was conducted.

Fig. 9: Comparison of the crack length index observed in the thermal spalling test.

**Practical application of the newly developed wear brick**

Wear bricks made of sample material 2 were relined in the lower part of the side wall in the hot metal ladle, by wear amount at which the service life of hot metal ladle is generally regulated. The surface appearances and a cross section of new wear bricks relined in the lower part of the side wall in the hot metal ladle that operated for the 1978 heats of hot metal transportation, are shown in figure 10 and figure 11, respectively. As shown in figure 11, the localized wear depth at the brick joints was reduced to 11 mm from 29 mm in conventional wear bricks. Despite the significant permanent linear expansion of the new wear brick, no corner cracks caused by the

Fig. 10: Surface appearance of new ASC wear bricks at 1978 heats of service life.

Fig. 11: Cross section of the used wear brick made of sample material 2.

wedge effect were observed. Owing to the suppression of localized wear at the brick joints, as shown in figure 12, the wear rate of the new wear brick improved by 31 %. Consequently, as shown in figure 13, the average service life of the hot metal ladle relined with the new wear bricks was extended by approximately 20 %, and the unit refractory cost consumption was reduced by 17 %.

*Fig. 12: Comparison of the wear rates of conventional and sample2.*

## INTRODUCTION OF MONITORING SYSTEM ON HOT METAL LADLE

### Confronting issues of online hot metal ladle inspection

Despite the suppression of localized wear at brick joints, a new wear brick surface in a hot metal ladle is still accompanied by irregularities; hence, the exposure of permanent bricks can be overlooked during visual inspection. Therefore, a hot metal ladle monitoring system was introduced to improve the accuracy of the hot metal ladle management system. Online maintenance on a hot metal ladle has been conventionally performed by combining visual inspection of the brick surface appearance by an operator and careful weight management, but the maintenance accuracy is unsatisfactory, and relatively large scattering exists. By introducing a ladle steel shell temperature monitoring system, which is broadly applied for teeming ladles, an improvement in the daily hot metal ladle maintenance accuracy was achieved.

### Introduction of the Steel Shell Temperature Monitoring System

The layout of the hot metal ladle steel shell temperature monitoring system is shown in figure 14. A set of observed thermal images is shown in figure 15. The entire sidewall of the hot metal ladle steel shell was monitored using three (3) cameras, and the ladle bottom was monitored using one (1) camera. A monitoring display was placed in the operating room to monitor the photographed thermal images at any time. When the photographed steel shell temperature exceeded a threshold value, a warning light was automatically activated along with an alarm sounding. As supposed steel shell temperature at 50 mm of remaining thickness of relined wear brick in hot metal ladle, 400 °C and 350 °C were set as threshold values for the sidewall and bottom, respectively. In accordance with the information provided by the steel shell temperature monitoring system, hot metal ladle refractory maintenance could be scheduled before exposure of the permanent brick without the risk of hot metal leakage incidents.

## CONCLUSIONS

With a series of activities for extending the service life of the hot metal ladle in Nagoya Steel Works, the following performances were achieved.

1. By utilizing a 3D PFM, precise measurement of the remaining thickness of wear bricks relined in a hot metal ladle was enabled.
2. The mechanism of localized wear at the brick joints was clarified by investigating the damage patterns of wear bricks relined in a hot metal ladle.
3. A New ASC brick with a sufficiently large permanent linear expansion and improved erosion resistance was developed and applied in practical operation. Owing to the suppression of localized wear at the brick joints materialized by the newly developed ASC brick, the service life of the hot metal ladle was extended by 20 %, with a 17 % reduction in unit refractory cost consumption.
4. By introducing a hot metal ladle steel shell temperature monitoring system, the concern of hot metal leakage incidents was almost eliminated.

# REDUCTION OF HEAT LOSS IN STEELMAKING PROCESS

Kai Taniguchi *, Yuta Hino, Hisahiro Matsunaga
JFE Steel Corporation

## Abstract

In JFE Steel Chiba Works, torpedo car has been used to transport hot metal from the blast furnace to the steelmaking workshop. In many cases, the hot metal pre-treatment has been used by the flux injection to the hot metal in torpedo car to remove impurities such as Si and P. During pre-pretreatment, the liquid slag was adhered on the wear bricks at the roof of torpedo car. As a result, the bricks were corroded.

In order to extend the service life of the torpedo car refractory, the upper part of the outer steel shell of the torpedo car was cooled with water mist to reduce the brick corrosion rate.

At first, a heat transfer analysis was conducted to verify the effect of the reduction of the brick surface temperature by cooling the steel shell.

Secondary, rotary slag test was performed to evaluate the influence of the brick surface temperature on the brick corrosion rate.

Based on the above investigations, an experiment, in which the upper part of the outer steel shell was cooled with mist, was conducted.

## 1. Introduction

Torpedo car is the vessel to carry out the pretreatment as well as to transport hot metal from the blast furnace to the converter. The wear of the roof brick has been severe. Since the liquid slag was adhered on the wear bricks at the roof of torpedo car during pretreatment. As a result, the bricks were corroded. **Fig.1** shows a schematic diagram of the damage morphology of roof bricks. The roof bricks are heated by post combustion flame.

In this study, a technology to reduce the wear rate of the roof bricks by cooling the steel shell with water mist was developed.

**Fig. 1 Schematic diagram of the damage morphology of roof bricks**

## 2. Heat transfer analysis
### 2.1 analysis condition

A two-dimensional unsteady heat transfer analysis was performed to evaluate the effect of cooling. The general structural analysis code MARC 2008 r1 was applied to the treatment of the cross section of the torpedo car as a 1/2 symmetrical model.

As an improvement to reduce the hot face temperature of wear brick, the following two methods were thought. The one was to make the safety lining bricks material higher conductivity by changing the refractory lining. The another was to cool the steel shell forcibly. Regarding the improvement of the thermal conductivity of safety lining bricks, there is a concern that the deformation of the safety lining bricks may occur due to the increase of the temperature. Therefore, two cases of simulation were conducted, namely the wear bricks had full thckness and 0 mm. It was thought that this might cover all the refractory linings of the torpedo car in operation. **Table 1** shows analysis cases.

In addition to the case of the combination of safety lining bricks and castable, the case of the combination that the safety lining brick material was the same as the wear bricks were evaluated. The thickness of the wear brick was assumed as the two cases; an initial thickness and 0 mm. **Fig. 2** shows the refractory lining of torpedo car. The material properties specified thermal conductivity, specific heat and density for each temperature. The thermal conductivity of the hot metal is given by taking the stirring of the hot metal into consideration in order not to decrease the temperature due to the radiation.

It was assumed that that the torpedo car was operated in a single cycle of empty, hot metal tapping, transportation, pretreatment, transportation, and discharge. Here, it was assumed that hot metal should be taken a radiant heat source, and the convection heat transfer by the contact with hot metal could not be negligible.

The boundary conditions were set by dividing into 3 conditions: empty, with hot metal (hot metal tapping, transportation, and discharging), and conducting pretreatment. Steel shell cooling was performed in the process of pretreatment. Heat transfer from the outside surface of the steel shell was estimated to be $1,000 \text{W} \cdot \text{m}^{-2} \cdot \text{K}^{-1}$ as the heat transfer coefficient of the steel shell when cooled with water [1]. The heat transfer coefficients and ambient temperature were determined in each case.

Heat transfer calculations were repeated up to five cycles until the temperature stabilized.

| | Safety brick material | Cooling of steel shell | Thickness of wear brick |
|---|---|---|---|
| CASE 1 | Conventional | None | Initial brick |
| CASE 2 | Conventional | Done | |
| CASE 3 | High thermal conductivity | None | |
| CASE 4 | High thermal conductivity | Done | |
| CASE 5 | Conventional | None | 0mm |
| CASE 6 | Conventional | Done | |
| CASE 7 | High thermal conductivity | None | |
| CASE 8 | High thermal conductivity | Done | |

**Table 1 Analysis case for heat transfer.**

**Fig. 2 Schematic diagram of lining.**

## 2.2 Result of heat transfer analysis

The steel shell temperature distribution was obtained by heat transfer analysis. **Fig. 3** shows the change of temperature with time in the CASE 1,2,3 and 4 at the new wear brick. When CASE 1 was compared with CASE 3, the maximum temperature of the barks increased from about 450 K to 550 K because the thermal conductivity of the safety lining bricks became higher. Comparing CASE 4 with CASE 3, the temperature of the iron skin increased during the period from the completion of the pre-treatment to the discharge in all cases and the maximum temperature was shown just before the discharge although the temperature of the iron shell in the pre-treatment decreased due to the cooling of the steel shell. Although the figure doesn't show in this manuscript, the calculation has been done in the case that the work block was worn. The maximum temperature of the CASE 7 without cooling in the linings with modified safety lining bricl materials was 928 K, and even the case of the CASE 8 in which the steel shell was cooled could only be lowered to 913 K. The steel shell of the torpedo boat is made of heat-resistant steel and has a maximum endurance temperature of 723 K. When the torpedo car was used with worn wear bricks, deformation of the steel shell might occur.

Therefore, it could be difficult to detect the exposure of safety lining bricks by visual inspection. Therefore, the use of the wear brick material as safety ling brick was given up.

Next, the change of the hot surface temperature of refractory is shown in **Fig. 4**. The hot surface temperature reduction effect by the steel shell cooling by 7.4 K (in the case of new brick) and 20.6 K (in the case of worn brick) were obtained in 1 cycle on average. If the average thickness of worn bricks in torpedo cars is assumed to be 2/3 of the thickness of new bricks, the effect of lowering the thermal surface temperature of worn bricks can be expected to be 11.8 K.

**Fig. 3    The steel shell temperature.**

**Fig.4 The estimated result of temperature drop.**

## 3. Rotary Slag Testing
### 3.1 experimental procedure

A rotary slag test was caried out to evaluate the temperature dependence of the corrosion rate. Two kinds of safety lining bricks were prepared, and the same wear bricks were evaluated. To raise the hot face temperature, the safety lining refractory and a high-performance insulating material were used behind wear brick as a role of insulation and, and to lower the hot face temperature, an MgO-C brick was used behind wear brick.

263

Temperature and time for the test were 2073K × 4 h, and the slag was changed every one hour. The surface temperature was measured with a radiation thermometer during the test. The corrosion rate was calculated by dividing the difference in refractory thickness before and after the experiment by the experimental time.

### 3.2 Result and discussion of rotary slag testing

Considering the corrosion rate obtained in the rotary slag test, when the thermal conductivity of the backside was higher, the surface temperature was lower, and the wear rate was also lower.

The corrosion rate was evaluated assuming the mass transfer of alumina in the slag should be the rate controlling step by using the following equations expressed with Eqs(1) to (6). [2]

$$J = \left(\frac{D}{\delta}\right) \cdot (N_s - N_b) \tag{1}$$

$J$: mass flux $(g \cdot cm^{-2} \cdot s^{-1})$
$D$: diffusion coefficient $(cm^2 \cdot s^{-1})$
$\delta$: the thickness of boundary layer (cm)
$N_s$: saturated alumina content $(g \cdot cm^{-3})$
$N_b$: alumina content in liquid slag $(g \cdot cm^{-3})$

$$\rho \cdot B_f \left(-\frac{dr}{dt}\right) = B_f \cdot J \tag{2}$$

$\rho$: density of refractory $(g \cdot cm^{-3})$
$B_f$: interfacial area $(cm^2)$

$$V = k \frac{\rho_b}{\rho} \cdot \frac{\Delta(Al_2O_3)}{100} \tag{3}$$

V: corrosion rate of refractory $(m \cdot s^{-1})$
$\rho$: density of refractory $(g \cdot cm^{-3})$
$\rho_b$: density of liquid slag $(g \cdot cm^{-3})$
$k$: mass transfer coefficient $(m \cdot s^{-1})$

$$k = \frac{D}{\delta} \tag{4}$$

$$k = exp\left(-\frac{E_k}{RT}\right) \tag{5}$$

A: constant $(m \cdot s^{-1})$
$E_k$ : apparent activation energy $(J \cdot mol^{-1})$
R: gas constant $(=8.31 \ J \cdot mol^{-1} \cdot K^{-1})$

$$ln \ k = ln \ A - \frac{E_k}{RT} \tag{6}$$

The density $\rho$ of the refractory was measured from a sample taken from the hot surface side of the brick after usage. The density of the molten slag $\rho_b$ was obtained from the literature. [3] The saturated $Al_2O_3$ concentration of the slag was calculated using

FACTSAGE 7.2®. The value of the corrosion rate obtained in the rotatory slag test was used for the evaluation of mass transfer coefficient.

The Arrhenius plot of the mass transfer coefficient k of the refractory is shown in **Fig.5**. Since a good linear relationship was confirmed, the apparent activation energy was calculated from the slope of the regression line. The apparent activation energy was determined as 367 kJ· mol$^{-1}$. This value was almost similar to the apparent activation energy of CaO-SiO$_2$-Al$_2$O$_3$ slag (338 kJ・mol$^{-1}$) obtained by the same method as the result of the rotary slag test[2]. Then, this relationship was extrapolated to the low temperature side, and the reduction effect of wear rate by the steel shell cooling was estimated. The hot surface temperature of wear brick in actual torpedo car was set as 1673 K, and when the steel shell was cooled, the operating surface temperature was set at 1661.2 K using the reduction of 11.8 K obtained from the heat transfer analysis in Chapter 2. As a result of calculating the effect of reducing the wear rate by cooling the steel shell, it was found that 20% of the wear reduction effect could be expected.

**Fig. 5 The Arrhenius plot of the mass transfer coefficient k of the refractory.**

### 4. Demonstration experiment
### 4.1 experimental procedure

A water-cooling system for the Torpedo car was installed in hot metal pre-treatment centre in JFE Steel Workshop. The steel shell has been cooled from the start to the end of the treatment to reduce the corrosion rate of the wear refractory. The mist was sprayed to the top area of steel shell of torpedo car and the steel shell was cooled by the heat of vaporization. The area of about 2 m$^2$ where the wear rate was especially high was cooled by 6 nozzles. Cooling was carried out using a nozzle which sprayed a mist of 60-80 μm by water droplets at a

cooling water density of 10L·m$^{2-1}$·min$^{-1}$. The mist discharge direction was adjusted so that the cooling water did not enter the hot metal from the furnace mouth. And the flow rate was set so that the water did not spill to the line through the steel shell side surface. Also, the cooling water pipe was not exposed to radiation heat from the torpedo car mouth passing under the equipment. **Fig. 6** shows the torpedo car under cooling.

To evaluate the validity of the heat transfer analysis, the temperature of the steel shell before and after cooling was measured by a thermo-viewer. The corrosion rate of the refractory was calculated as the corrosion of the refractory during the repair period, which was divided by the number of cycles.

**Fig. 6    Torpedo ladle furnace under cooling..**

### 4.2 Result and discussion

**Fig. 7** shows the results of heat transfer analysis and measurement result. The actual steel shell temperature drop was almost similar to the results of heat transfer analysis, which was reduced by 100K. **Fig. 8** shows the corrosion rate of wear bricks. The wear rate was reduced by 10% (from 0.56 mm・ch$^{-1}$ to 0.50mm・ch$^{-1}$). Steel shell cooling was performed for 50% of all operations.

**Fig. 7 The temperature before and after the treatment.**

**Fig. 8    The erosion rate of roof bricks.**

The corrosion rate reduction of 10% in the actual plant test could be corresponded to the corrosion reduction effect of 20%, which was assumed in the laboratory, considering the execution rate of cooling of 50%.

## 5 Conclusions

In order to reduce the wear rate of wear bricks of torpedo car refractory, the mist cooling of the steel shell was carried out. As a result of the heat transfer analysis, the reduction effect of hot surface temperature was −11.8K. The relationship between the surface temperature obtained in the rotary slag test and the wear rate was evaluated assuming the mass transfer rate of alumina in the slag should be the rate controlling step, and the apparent activation energy $E_k=367kJ・mol^{-1}$ was obtained. Assuming the reduction of the hot surface temperature by cooling the steel shell as -11.8 K, 20% of reduction in wear rate could be expected. Wear rate of wear refractory in the actual plant test was reduced by 10%. This can be explained as the effect of cooling, taking the 50% of the steel shell cooling experiments conduction into consideration.

## ABSTRACT

Refractories are often exposed to thermal variations during their operational cycle, such as in torpedo cars and iron ladles, where molten metal is loaded and unloaded at a high frequency basis. Dealing with that aggressive thermal shock is not straightforward and the most common approach for these materials is to optimize the carbon sources, increasing the thermal conductivity of the bricks and reducing the thermal gradient between the hot and cold faces. If, on one hand, the material becomes more resistant to thermal shock damages, on the other hand, its higher conductivity imposes a negative consequence: higher thermal loss during operation. In this work, inspired by intelligent microstructures with the ability to adapt to the most severe environmental conditions, an innovative approach was evaluated, aiming at obtaining an Al2O3-SiC-C brick formulation designed to present a self-healing behavior, without variation in the carbon sources or content. The new developed structure successfully regenerated the cracks initiated during thermal cycles, resulting in an even tougher material after thermal shock tests. Other properties such as mechanical, oxidation, and corrosion resistance also showed promising results, pointing out the birth of a smart self-healing technology, able to completely change the role of refractories in thermal cyclic operations.

## INTRODUCTION

The steel production chain has been going through a transition process towards a descarbonized future, where a large variety of actions are under consideration [1]. Although most of them are predicted to be fully implemented before no less than two decades, others are already in place in the ironmaking sector, involving both the use of different fuel mixes and the addition of new metallic charges. Additionally, steel producers have been looking for opportunities to reduce energy losses and $CO_2$ emissions in process beyond the Blast-Furnace operations [2].

The refractory lining is directly responsible to keep the heat inside the equipment and prevent any metal temperature drop. Nonetheless, in some cases, such role becomes challenging as the refractory material must also withstand very aggressive thermal cycles, as in the case of torpedo cars and hot metal ladles. A classical approach to reduce the thermal damage is by adding carbon sources, mainly graphite, in the refractories' structure so that the heat is easily transferred through the material and a lower thermal stress is generated. As a side-effect, however, more energy is lost by thermal conductivity by the refractory walls, which is undesirable for the sustainability commitments of steel producers [3].

In this scenario, where avoiding the cracks generated by thermal cycles are not straightforward, a different perspective is needed and the right question to be asked is: what if we could recover such cracks during operation?

Self-healing mechanisms are quite largely explored in the polymers field, where, for instance, small capsules containing a setting agent are included in the materials structure [4]. When a crack reaches them, the capsules are broken and a hardening reaction takes place between the base material and the additive which is now available, promoting the complete sealing of the crack area. Likewise, a new class of concretes for building construction was also developed with biomineralization ability. In these materials, bacteria are introduced so that they can metabolically produce minerals to help repair cracks and damage to the concrete [5].

Although those self-healing mechanisms are well-known and proved to work efficiently, they are still limited to room temperature conditions. At very high temperatures, such as the ones contemplated during the steel process operations, the usual components incorporated to induce self-healing mechanisms in those materials are no longer functional. The main purpose of this work was, then, to investigate and develop an entirely novel high temperature self-recovery mechanism, based on nature-like phenomena adapted to refractory structures, giving birth to the utmost toughness mechanism ever seen.

## MATERIALS AND METHODS

### Materials

The introduction of the new self-healing mechanism was evaluated in a Al2O3-SiC-C brick, frequently used as the torpedo car lining material. In order to mimic the healing behavior of living creatures, the regular ACS microstructure was reengineered in such a way that it could smartly interact with the just-generated crack and seal it, just like the human tissue heals a fresh wound with the formation of a new tissue layer. For this purpose, a combination of two non-organic recovery agent was added to the torpedo car formulation, as show in Tab. 1. The reference ACS recipe (SRB REF) was selected due to its benchmarking performance in the market.

Tab. 1: ACS brick formulations evaluated in this work, in wt%. SRB REF is the Shinagawa reference brick in the market. SRB SH stands for the newly developed SELF-HEALING technology.

| Raw-material | SRB REF | SRB SH |
|---|---|---|
| Coarse $Al_2O_3$ | 55,0% | 55,0% |
| Fine $Al_2O_3$ | 13,0% | 13,0% |
| SiC + C | 13,0% | 13,0% |
| Binder | 4,0% | 4,0% |
| Anti-oxidants | 2,0% | 2,0% |
| Self-healing additives | - | 5,0% |

### Self-healing evaluation

For a better observation of the presence of eventual self-healing mechanisms, cyclic thermal shock tests were conducted for both formulations, using three prismatic samples (160mm x 40mm x 40mm) of each composition, pre-fired at 1450°C for 5h at reducing conditions. Each cycle started with placing the samples originally at room temperature (30°C) into a pre-heated furnace (1200°C), leading to an aggressive heating shock. After leaving them there for 30 minutes, the cycle ended by returning the pieces to room temperature for more 30 minutes, inducing a cooling stress. This step was repeated for sixteen times and, every two cycles, the modulus of rupture (MoE) of the samples were measured to follow any variation in the material's structure along the test.

Once the recovering benefits could be proved, a scanning electron microstructural (SEM) analysis were performed to identify the presence of healed cracks in the damaged samples of the SRB SH composition. The cracks in the SRB REF material were also investigated for comparison's sake.

### Performance evaluation

One of the project assumptions is that the introduction of a self-healing mechanism in the refractory's microstructure would not

damage any of the other properties and, therefore, compromise the well-know performance of Shinagawa's bricks for torpedo car. The following properties were then evaluated for the two formulations (SRB REF and SRB SH):

- Open porosity and apparent density: evaluated by using the Archimedes technique in kerosene, following the ASTM Standard C380;
- Modulus of rupture: carried out under three-point bending tests (ASTMC 583) using prismatic samples (160 mm x 40 mm x 40 mm);
- Corrosion tests: conducted in a rotary furnace, in a two-cycle process, where a mix of blast-furnace slag and pig iron was used (80% slag + 20% pig iron);
- Oxidation resistance tests: carried out according to the following procedure → cubic samples of 50 x 50 x 50mm were placed inside a pre-fired furnace at 1000°C, under oxidizing atmosphere, so they could go through an aggressive oxidation process. They were withdrawn after 6h or 24h and, after cooling down, they were cut and the cross-sections were used for measuring the oxidized layer.

For all the above-mentioned tests, samples were previously fired at 1000°C or 1450°C, for 5h, at reducing atmosphere.

**RESULTS AND DISCUSSION**

The results obtained during the cyclical thermal shock tests are shown in Fig. 1. It is possible to observe that the reference material (SRB REF) confirmed its denomination as the benchmarking product, with a very good performance after 16 thermal cycles. A small decrease in the Modulus of Elasticity is perceived after the two first cycles (~15%), indicating the formation of minor damage in the structure, with no more further deterioration, which, in other words, means that the SRB REF composition was well designed to sustain the initial thermal shock damage and gurantee a stable performance. The new developed formulation (SRB SH) also presented the same initial behavior, with the generation of thermal cracks in its microstructure. Nonetheless, better than just supressing the damage propagation along the the test, its smart microstructure was able to interact with the new cracks and progressively seal them as further thermal cycles were applied to the samples. As the test was concluded, the last MoE measurement presented an amazing result: its value was entirely recovered to the level of the original, non-damaged structure.

*Fig. 1. Residual Moduli of Elasticity (MoE) as a function of thermal shock cycles for SRB REF and SRB SH formulations.*

After the test, the samples of SRB REF and SRB SH were collected and used for a microstructural evaluation in order to identifiy and compare the cracks situation at both materials. Fig. 2 (a) shows the SEM image obtained for the SRB REF material using topographic

effects, where it is easy to point out the generated crack between a coarse grain and the matrix. Due to a well designed grain size distribution and proper thermal properties, the crack was succesfully deflected and stopped, enabling a stable behavior along the thermal cycles, as seen in the previous graph. In the microstructure of the SRB SH material (Fig. 2 (b)), one may also observe the same crack pattern between the matrix and coarse grains. The main and most important difference is that such crack is visually sealed with a new phase that was formed during the following thermal cycles by the activation of the self-healing agents in the microstructure when they interacted with the propagating crack.

*Fig. 2. Micrograph of (a) SRB REF and (b) SRB SH samples, obtained by SEM after sixteen thermal shock cycles.*

This innovative smart mechanism was responsible to restore the microstructure original condition and, therefore, could be used to implement a new series of $Al_2O_3$-SiC-C bricks virtually inmunne to thermal cyclic damages. For that, it is also important to verify other important physical and chemical properties in order to check whether the introduction of such new structure could lead to a non-expected side-effect. Fig. 3, 4 and 5 presents, respectivelly, the apparent density, apparent porosity and hot modulus of rupture for both materials after firing at 1000°C and 1450°C for 5h at reducing atmosphere.

267
Fig. 3. Apparent density of SRB REF and SRB SH samples after firing at 1000°C and 1450°C.

Fig. 4. Apparent porosity of SRB REF and SRB SH samples after firing at 1000°C and 1450°C.

Fig. 5. Modulus of rupture of SRB REF and SRB SH samples after firing at 1000°C and 1450°C.

Due to the difference composition of the brick's matrix and, consequently, to the new phase structures which are formed at high temperatures, the new SRB SH samples presented slight differences in the density and porosity values after firing at 1450°C. However, it is relevant to note that, despite of those differences, the new self-healing material presented a cohesive and well bonded structure, as the MoR values were entirely compatible with the benchmarking reference ones.

Besides keeping almost the same values for the basic physical properties, the introduction of the smart self-healing mechanism in the SRB SH material also led to an improvement of the corrosion resistance, as observed in Fig. 6 and 7. As the refractory corrosion takes place via the infiltration of metal and slag through voids and deffects in the material, a high-temperature sealing system may clearly help to block possible infiltration paths and to prevent chemical dissolution inside the brick.

Fig. 6. Corrosion wear index of SRB REF and SRB SH samples.

Fig. 7. Cross-sextion of SRB REF and SRB SH samples after the corrosion test.

Finally, Fig.8 presents the measurements of the oxidized area of SRB REF and SRB SH samples after exposition of 6h and 24h in air. Once again, the presence of the self-recovery additives did not affect the material's oxidation resistance and, actually, the smart sealing process could again have helped to slightly decreased the oxidation process for the SRB SH material.
*Fig.8. Oxidation resistance results after 6h and 24h for SRB REF and SRB SH samples.*

## CONCLUSIONS

Aiming at reducing the energy losses in the steel manufacturing process while also increasing the lifetime of refractories applied at high thermal cyclical areas, an exclusive smart self-healing structure was developed and introduced in a $Al_2O_3$-SiC-C torpedo car brick composition. The new mechanism was able to interact promptly with the cracks generated during thermal shock processes, activating the self-healing agents, and completely sealing the crack area. This innovative process induced a total recover of the original structure of the material and its modulus of elasticity returned to values as high as the pre-thermal shock condition. As neither the physical properties nor the corrosion and oxidation resistances were affected by this new smart structure, a very promising future is expected for refractories materials with the rise of such utmost and nature-inspired toughness mechanism.

Korea Refractories Company, Dangjin-Si, South Korea

**ABSTRACT**

Torpedo ladle car is the main apparatus for transporting the molten iron produced in the blast furnace. $Al_2O_3$-SiC-C refractory bricks were mainly used for the working lining of torpedo ladle cars and have excellent slag resistance, abrasion resistance and thermal shock resistance. When the torpedo ladle car was used up to a certain life, the used $Al_2O_3$-SiC-C refractory bricks are replaced for repairing. At this time, the amount of waste generated is about 2,000 tons per year in Hyundai Steel, and it is necessary to develop technology for recycling the used refractory brick. Therefore, in this study, recycled $Al_2O_3$-SiC-C refractory bricks were used for repairing torpedo ladle car to develop refractory recycling technology. The torpedo ladle car was repaired by shotcrete method with a certain life cycle. Recycled $Al_2O_3$-SiC-C refractory bricks were mixed with shotcrete refractories and compared with torpedo ladle cars that were repaired without recycled materials. When compared after about 100 heat of use, a slight peeling off was observed in the torpedo ladle car with the recycled Al2O3-SiC-C refractory bricks. However, the residual of refractory were similar when comparing the residual using 3D scanning equipment. In addition, the erosion rate difference of refractory was less than 3% when directly measured using a tool after using about 250 heat. In conclusion, it was confirmed that the shotcrete with recycled $Al_2O_3$-SiC-C refractory bricks was used without any problems until the next shotcrete repair period.

**INTRODUCTION**

$Al_2O_3$-SiC-C refractories were characterized by excellent thermal shock resistance, good abrasion resistance and non-sticking slag. So, $Al_2O_3$-SiC-C refractory brick are mainly used for torpedo ladle car lining. Torpedo ladle car play a vital role in transporting the molten iron from blast furnace.

*Fig. 1. Shotcrete repair in torpedo ladle car*

Torpedo ladle car are repaired by the shotcrete method when a low lifespan are used and by completely replacing the $Al_2O_3$-SiC-C brick when used over a high lifespan. Fig. 1 shows shotcrete repair in torpedo ladle car. At this time, about 2,000 tons of spent $Al_2O_3$-SiC-C refractory brick are generated and wasted each year in Hyundai Steel.

Thus, it is necessary for steel and refractories industries to develop research of recycle refractory waste materials. In this study, wasted $Al_2O_3$-SiC-C brick that was used in torpedo ladle car was recycled and investigated whether it could be applied to shotcrete refractory for torpedo ladle car.

**EXPERIMENTAL PROCEDURE**

*Fig. 2. Recycling method of spent Al2O3-SiC-C brick*

Recycled raw material was obtained as shown Fig. 2. Firstly, incrustations such as slag, metal deposit and dust on the $Al_2O_3$-SiC-C brick in torpedo ladle car were removed. And then, the materials were crushed using jaw crusher. Crushed materials were screening to obtain desired particle size. Finally, moisture of the recycled raw materials were inspected. If the materials had 0.3% over, that were dried for 24hour. Table 1 shows the chemical composition of recycled raw material. In order to investigate whether the recyclied $Al_2O_3$-SiC-C brick can be added as a shotcrete refractory material, tests were performed by adjusting the content of recycled raw materials. And then the field test was conducted by the optimal ratio of recycled raw materials.

Tab. 1: Chemical composition of recycled $Al_2O_3$-SiC-C raw materials

| Classification | | Value |
|---|---|---|
| Chemical composition (%) | $Al_2O_3$ | 64.5 |
| | $SiO_2$ | 8.7 |
| | $Fe_2O_3$ | 0.9 |
| | $CaO$ | 0.3 |
| | $Na_2O+K_2O$ | <0.8 |

To investigate the optimal ratio, physical properties and thermal properties were compared according to the ratio of recycled $Al_2O_3$-SiC-C raw materials addition as shown in Table 2. The samples of pysical properties test (40 mm × 40 mm × 160 mm) were cured at 25 °C for 24 h, and then dried at 110 °C for 24 h. Physical properties(cold modulus of rupture (CMOR), The cold crushing strength (CCS) and bulk density) were measured with dried sample and heat-treated sample at 1,500°C for 3h. Erosion test was performed using a blast furnace slag with $CaO/SiO_2$ = 1.21 on a rotary corrosion tester.

Tab. 2: Composition accroding to recycled Al₂O₃-SiC-C raw materials addition

| Raw material | R0 | R1 | R2 |
|---|---|---|---|
| Recycled ASC brick(%) | 0 | α | 2 α |

Table 3 shows the field test conditions by applying optimal ratio to shotcrete refractories for torpedo ladle car. Each test was conducted twice. The torperdo ladle car was divided into two sides (Side M and D), and shotcrete with recycled Al₂O₃-SiC-C raw materials was applied to one side, and shotcrete of not including recycled Al₂O₃-SiC-C raw materials was applied to the other side. Then, after using about 100 heat, the remaining refractory was measured through laser sccaning system.

Tab. 3: Field test conditions

| Classification | Side M | Side D |
|---|---|---|
| 1st test (2EA) | R1 (α%) | R0 (0%) |
| 2nd test (2EA) | R0 (0%) | R1 (α%) |

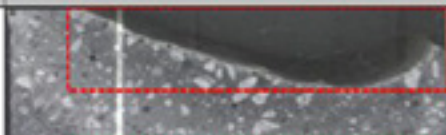
**RESULT AND DISSCUSSION**

Table 4 shows the physical properties of shotcrete refractory mixed with recycled raw material. Bulk density increases as the content of recycled raw material increases. This result was because impurities with high specific gravity such as FeO remained in the recycleid raw material. In the case of CCS and CMOR, as the content of recycled raw materials increases, it tends to decrease gradually. The reason was due to the low purity of the material due to impurities in the recycled raw materials. In the case of permanent linear change, there was no change at 110°C, but it showed a tendency to increase after heat-treatment at 1500°C. This was presumed to be because impurities such as CaO in the recycled raw material reacted at high temperatures.

Tab. 4: Physical properties according to recycled raw material content

| Physical properties | | R0 | R1 | R2 |
|---|---|---|---|---|
| 110°C × 24h | Bulk density | 2.49 | 2.53 | 2.57 |
| | CCS(kgf/cm²) | 450 | 425 | 412 |
| | CMOR(kgf/cm²) | 94 | 88 | 86 |
| | PLC(%) | 0.01 | -0.01 | -0.01 |
| 1,500°C × 3h | Bulk density | 2.47 | 2.49 | 2.52 |
| | CCS(kgf/cm²) | 1630 | 1390 | 1265 |
| | CMOR(kgf/cm²) | 193 | 188 | 160 |
| | PLC(%) | 0.12 | 0.20 | 0.22 |

Fig. 3 shows the erosion test results. Erosion test results show a tendency for corrosion resistance to decrease (corrosion index increase) as the recycled raw material increases. Similar to the pysical test result, it seems that the corrosion resistance decreased like this because the impurities affected the shotcrete refractory. therefore, The field test was conducted with the composition of R1 because the properties of R1 and R0 were not significantly different.



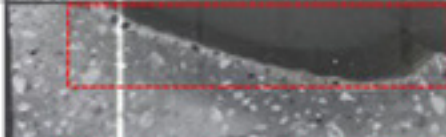


*Fig. 3. Rotational erosion test piece cross section with recycled raw materials*

*(a)*

*(B)*
*Fig. 4. Laser scanning result of first field test: (a) test 1 and (b) test 2*

Fig. 4 shows the results of the first field measured by laser scanning equipment after using about 100 heat. In the first test, shotcrete with recycled raw materials was repaired to the M side. As a result of the test, it was confirmed that there was some peeling on the M side, but it seems similar with D side. After using 250 heat, The inside of the Torpedo ladle car was observed and it was confirmed

that there was peeling on the M side compared to the D side like laser scanning result. It was shown Fig. 5. However, when directly measured after 250 heat, the erosion rate of M side was 3% higer than D side.

*(a)*

*(b)*
*Fig. 5. First field test result after using 250heat: (a) test 1 and (b) test 2*

Laser scanning result of the second field test was shown in Fig. 6. In the second test, shotcrete with recycled raw materials was repaired to the D side. As a result of the test, in the second test, some peeling occurred on the M side after using 100 heat, and the remaining refractory brick on the D side was better.

*(a)*

*(b)*
*Fig. 6. Laser scanning result of Second field test: (a) test 1 and (b) test 2*

*(a)*

*(b)*
*Fig. 7. Second field test result after using 250heat: (a) test 1 and (b) test 2*

The second field test result was shown in Fig. 7. Second test also can be confirmed that peeling-off of shotcrete refractory on the M side after using 250heat. Therefore, it was assumed that this result came out because the damage on the M side during use was more severe than the effect of recycled raw material. When direcytly mesured after 250 heat, the erosion rate of M side was 2% higer than D side. In conclusion, although shotcrete refractory with recycled $Al_2O_3$-SiC-C raw material affects physical and thermal properties, it can be used in the field by adjusting the content. And also, it was confirmed that the shotcrete with recycled raw material

was used without any problems until the next shotcrete repair period.

## CONCLUSIONS

The problem of handling waste refractories in the steel and refractory industry was a major issue, and research on refractory recycling was needed worldwide. In this study, shotcrete refractory was mixed with recycled $Al_2O_3$-SiC-C brick to confirm the possibility of using of spent $Al_2O_3$-SiC-C bricks used in torpedo ladle cars. In order to repair the shotcrete refractory with recycled raw material in torpedo ladle car, the physical and thermal properties were confirmed by adjusting the content. As a result, the physical strength and erosion resistance decreased due to the impurities present in the recycled raw material, and the field test was conducted by the shotcrete refractory with $\alpha\%$ recycled raw material as the optimal content. In the field test, the torpedo ladle car was divided into two sides and repaired with shotcrete with recycled raw material mixed to only one side. As a result of the field test, after using 100 heat, the M side was slightly inferior in both the 1st and 2nd tests in laser scanning, but after using 250 heat, the erosion rate showed a difference of about 2-3%. In conclusion, it was confirmed that recycled $Al_2O_3$-SiC-C raw material can be used in the shotcrete refractory for Torpedo ladle car, and additional research is needed by increasing the content in the future.

## ABSTRACT

Blast Furnace ironmaking process is currently the dominant process for providing steelmaking raw materials worldwide. However, the blast furnace process relies heavily on metallurgical coke and involves coke-making and sintering operations, which often attract serious environmental concerns. Therefore, Direct Reduction and Smelting Reduction technologies using non-coking coal or other gases as reducing agents to replace metallurgical coke have emerged as alternative routes for iron production. Due to the vast difference in operating conditions between these processes, requirement of suitable refractory lining and critical parameters also vary to a large extent.

Silicon Carbide based refractories with different bond system e.g. Silicon Nitride, SiAlON have been established as most suitable lining refractory in the critical area of blast furnace over the years. The major advantage of Silicon Carbide Refractory with Silicon Nitride and SiAlON bonding are Alkali Resistance, Oxidation Resistance, Thermal Conductivity, Thermal Shock Resistance, Abrasion Resistance etc.

For direct reduction of iron in shaft furnace process using natural gas, high alumina refractory specifically for bustle port and the wall requires superior Refractoriness Under Load and Creep resistance properties.

Characterisation of developed refractories for lining of blast furnace, Smelting Reduction and gas based DRI shaft kiln has been discussed here.

## EVOLUTION OF IRON MAKING PROCESS

Historically ironmaking was more an art than a science as it began in Egypt, India, China and in Europe. Early iron producers learned this art over many generations through training and practices. By mid-nineteenth century, scientific innovations and improvements became primary approach in iron smelting.

This practice and innovation has come a long way in 4000 years. The transition from sponge iron produced in Catalon forges to liquid iron produced in Stuckofen, Flussofen and then through charcoal blast furnaces were significant milestones in advancement of iron smelting process.

Then came the change from cold blast, charcoal furnaces to hot blast, coke furnaces in the mid-1800s which brought iron making into the modern era. Better understanding of iron-making reactions and improved equipment evolved into the hard-driving furnace operation centered in the 1880s to 1900s. Finally, the revolution in scientific applications to iron smelting, installation of sophisticated equipment and advent of electronically controlled systems augmented blast furnace iron making into current state. Catalon Forge, Charcoal based BF  and current BF are shown in Fig.1.

Blast furnaces are estimated to have been responsible for over 4% of global greenhouse gas emissions between 1900 and 2015, but are difficult to decarbonize.

Smelting Reduction (SR) processes were developed as an viable alternative for blast furnace in producing hot metal. These processes combine the gasification of non-coking coal with the melt reduction of iron ore. As alternative to blast furnace process, smelting reduction is economical and environment friendly.

In smelting reduction, Hot metal is produced in two stages. Ores are partly reduced in the first step, final reduction and meting takes place in secold stage. Some of the common processes are COREX

*Fig. 1. (A) Catalon Forge, (B) Charcoal based BF, (C) Current BF*

[Coal Reduction Process], FINEX [Direct use of fine ore], DIOS [Direct Iron Smelting], AUSMELT [Australia Smelting], HISMELT, ROMELT, PLASMASMELT etc.

Steelmakers have also found that a combination of the different processes could be fundamentally utilized to develop new processes that could compete with the productivity and quality of the BF hot metal, more economically competitive and finally environmentally friendly.

The COREX and FINEX technology (shown in Fig. 2) are major economic and ecologic industrially realized alternative to the blast furnace route for the production of hot metal.

*Fig.2. Corex® and Finex® process flow sheets; 1) melter-gasifier, 2) reduction shaft,3) hot gas cyclone,4) process gas scrubber,5) hot compacted iron bin, 6) fluidized bed reactor (Wieder, et al., 2009)*

Advantages of this process are following:
- Substantial reduction in investment costs compared with conventional blast furnace steelmaking process
- Production cost less up to 25% compared with a blast furnace
- Outstanding overall environmental compatibility, due to reduction in CO2 generated per ton of iron production
- Use of COREX export gas for a wide range of applications
- Use of a wide variety of iron ores, coals and elimination of coking
- Hot-metal quality suitable for all steel applications
- Combined production of DRI possible.

Development of suitable Refractory and improvement played major role for long campaign life of BF, DRI and Smelting-reduction.

## BLAST FURNACE LINING APPLICATION AND DEVELOPMENT OF SUITABILE REFRACTORIES

In the Upper Stack, resistance to abrasion from downward moving ore, pellet, sinter is the major function for the lining refractory. NBSiC is good option over High Alumina

In the lower stack, refractory lining need to withstand reducing effect of carbon monoxide, alkali vapours, zinc and aluminium penetration and oxidation from carbon dioxide at temperatures as high as 820 Deg. C over and above abrasion. Also as the burden moves, thermal shock can be extreme in the lower stack. NBSiC and SiAlON-SiC is found to be very suitable.

In the Bosh, Slag and molten iron dribbled down as the blast furnace mass descends. Erosion and abrasion of Refractories are very severe. Here Modulus of Rupture (MOR), generally equated by refractory engineers as a good indication of high temperature abrasion resistance. Here the SiAlON-SiC brick meets overall requirement of high MOR and alkali attack resistance.

In the Mantle or Belly region, conditions are extremely severe. There is a change of direction in the descending charge causes tremendous abrasion. Carbon monoxide and alkali attack is more severe as there is less slag coating for protection. Occasional violent thermal shock occurs with burden shifts. Hot strength (modulus of rupture and refractoriness under load) of SiAlON-SiC is a key for longer life of the lining.

In the Tuyere Bowls, in addition to hot air and steam oxidation, attack from alkali & zinc vapour, tremendous erosion and corrosion by molten iron and slag directs to selection of SiAlON-SiC. Thermal conductivity of the SiAlON-SiC brick is sufficiently high to freeze and hold a slag coating in this area.

In the hearth, many blast furnaces have Carbon based lining, however to extend the hearth life and to save energy addressing good resistance to iron and slag, reducing chance of infiltration of hot metal; keeping isotherm of 1150 °C close to the working hot surface, SiAlON-Corundum lining in the hot face together with high creep resistance Mullite are considered for Ceramic Pad.

## REFRACTORY LINING IN THE CRITICAL ZONE OF SMELTING-REDUCTION (SR) PLANT

**Typically in Melter-Gasifier of SR Plant, following zonal refractory configurations are considered**

Above Tuyere Band and Charbed Zone : SiAlON-SiC
Calming Zone : SiAlON-Corundum
Dome Nozzles : NBSiC
Hearth Ceramic Pad : Mullite, Corundum
Stave Inserts/ Dust Burner : NBSiC, SiAlON-SiC

Study conducted by Xiaoge Wang[3] et. al showed that the maximum average erosion of refractory lining bricks happened in the drip zone. Its surface was mainly affected by slag erosion and mechanical scour of slag.

## CHARACTERISATION OF CRITICAL PROPERTIES

Present work carried out to make improvement in desired properties and samples drawn from bulk manufactured lots of NBSiC, SiAlON-SiC, SiAlON-Corundum. Following properties are evaluated :
-   Resistance to Alkali
-   Thermal Conductivity
-   Resistance to Carbon Monoxide
-   Abrasion Resistance
-   Refractoriness under Load
-   Microstructure Analysis

Addressing critical application at Hearth with Ceramic Pad, Creep under Compression evaluated for Mullite based products.

**Effect of Alkali Attack:**

Resistance to Alkali is evaluated in line with Bethlehem test. Samples of 150x25x25 mm. kept inside a steel tray, filled with technical grade $K_2CO_3$ powder all around. This steel tray closed with a lid kept inside a refractory sagger, filled with coke breeze all around and closed with a refractory lid. This sagger heated in a laboratory furnace at 950°C for 3 hours. After every cycle, samples were cleaned and same process with new $K_2CO_3$ and calcined pet coke repeated for three cycles. Modulus of Rupture (MOR) test is carried out before and after test as per ASTM C 133. Samples and chamges in MOR are shown in Fig.3 & Tab.1 respectively.

*Fig. 3 : Samples after three cycles of Alkali Test*

Tab.1: Chamges in MOR after Alkali test (Also refer graphs below)

| Samples | Average Variation in MOR (%) after Alkali attack |
|---|---|
| NBSiC | -13.2% |
| SiAlON - SiC | -9.3% |
| SiAlON - Corundum | -30.2% |
**Thermal Conductivity**
Test data by hotwire (parallel wire) method, EN ISO 8894-2 is shown in Tab. 2

Tab. 2. Thermal Conductivity (values in W/m.$^o$K)

| Temp. ($^o$C) | NBSiC | SiAlON-SiC |
|---|---|---|
| 350 | 22.0 - 24.0 | 16.0 - 20.0 |
| 700 | 19.0 - 21.0 | 13.0 - 16.0 |
| 1000 | 15.0 - 18.0 | 11.0 - 13.0 |

**Resistance to Carbon Monoxide (CO):**
Disintegration of refractories under CO evaluated as per ASTM C 288 for NBSiC and SiAlON-SiC. All were found unaffected / classified as A category. Images of test samples are shown in Fig. 4 and Fig. 5 respectively.

*Fig. 4 : NBSiC  Unaffected / Class A*

*Fig. 5 : SiAlON-SiC Unaffected / Class A*

**Abrasion Resistance :**
Evaluation carried out following ASTM C 704. Samples after test and result is shown in Fig. 6 & 7  respectively.

*Fig. 6.  NBSiC & SiAlON-SiC samples after abrasion test*

*Fig.7.  Abrasion resistance of NBSiC & SiAlON-SiC*

**Refractoriness under load (RUL)**
Test carried out as per ISO 1893 (DIN EN 993-8) under protecting gas (N$_2$), T05/T1/T2/T5 for NBSiC and SiAlON-SiC is found > 1674$^o$C (Dmax at 1674$^o$C = 0.62%) and >1660$^o$C (Dmax at 1505$^o$C = 0.52%) respectively. RUL curves is shown in Fig. 8.

*Fig. 8. RUL curves for NBSiC & SiAlON-SiC*

**Microstructure analysis**
Scanning Electron Microscopy (SEM) shown below in Fig. 9 & 10.

*Fig. 9. SEM image of NBSiC showing SiC grain with both granular and fibrous nature of Si$_3$N$_4$ bond matrix*

*Fig. 10. SEM image of SiAlON-SiC showing Fused Alumina grain with  SiAlON+Nitride bond matrix (primarily fibrous in nature)*

**Resistance to Creep under compression**
W.r.t severe load bearing application in Ceramic Pad, Creep under compression test carried out as per EN 993-9, shown in Tab, 3.

Tab. 3 : Creep under Compression for Mullite grades

| | Mullite (based on Andalusite + Fused Mullite) | High Purity Mullite (based on Fused Mullite) |
|---|---|---|
| At 1450 deg. C / 5 – 25 Hrs. | - 0.268 % | - 0.019 % |
| At 1550 deg. C / 5 – 25 Hrs. | - 0.532 % | + 0.001 % |
| At 1600 deg. C / 5 – 25 Hrs. | - | + 0.008 % |

## DRI PROCESSES

Direct reduction of iron (DRI) ore has been an alternative solution to the BF process to provide the steelmaker the opportunity to utilize raw materials without the need for sintering and cokemaking. Several alternative ironmaking processes have been developed and commercialized. Among various DRI processes (shown in Fig. 10 ), Shaft furnace route with natural gas (or other reducing gases) has become a major DRI manufacturing method[2].

*Fig. 10. DRI Processes with Coal & Gas as reducing agent*

For direct reduction of iron in shaft furnace process using natural gas, high alumina refractory specifically for bustle port and the wall requires superior Hot strength properties i.e. Hot Load Deformation Creep resistance, Refractoriness Under Load, Resistance to CO etc.

### Hot Load Deformation

W.r.t severe load bearing application in the bustle port blocks, test carried out as per ASTM C 16.
Deformation at 3000 $^{o}$F (i.e. at 1650$^{o}$C) / 100 Hrs. is 0.68 %
Deformation at 2400 $^{o}$F (i.e. at 1316$^{o}$C) / 50 Hrs. is < 0.10 %

### Resistance to Creep under compression

Addionally this test carried out at 1550$^{o}$C/ 50 Hrs. as per DIN EN 993-9.  Deformation observed during 5 – 50 Hrs. is 0.044 %

### Resistance to Carbon Monoxide:

Disintegration of refractories under carbon monoxide evaluated as per ASTM C 288 for (a) burnt phosphate bonded high alumina brick and low iron Insulation Firebricks (b) grade 23 and (c) grade 28. All were found unaffected / classified as A category.
Images of test samples are shown in Fig. 11.

*Fig.11. Images of refractories after exposure to CO [All Unaffected / Class A]*

## Corrosion test under H$_2$-atmosphere

To ascertain condition of  high alumina refractory in highly reducing condition, carried out this test at 1350°C/ 100 Hrs. Changes in physical dimension, cold crushing strength (EN 993-5) and modulus of rupture (EN 993-6) data obtained before and after exposure to H$_2$. Images of samples and test data shown in Fig. 12 and Tab. 4 respectively.

*Fig. 12. High Alumina refractory samples after H$_2$ exposure*

Tab. 4. Changes in strength properties after H$_2$ exposure

| Under H2 Atm., 1350 Deg. C/100 Hrs. | Changes in Strength | |
| --- | --- | --- |
| | Cold Crushing Strength | Modulus of Rupture |
| +90% Alumina Refractory. | Approx. - 28 % | Approx. - 30 % |
| +99.5% Alumina .Refractory (Various compositions / fired at different Temp.) | -26% to +2 % | -12 % to +40 % |

## CONCLUSIONS

NBSiC, SiAlON- SiC and SiAlON-Corundum are well established in zonal lining of Blast Furnace, Smelting-Reduction Furnace owing to their superior properties like alkali resistance, resistance to CO, Hot Strength properties, Abrasion resistance, Thermal conductivity etc. while high creep resistant Mullite and Corundum serves the critical areas of Ceramic Pad, Bustle port etc.

With new generation Green DRI process becomes a reality, iron ore pellets will be reduced by green hydrogen in direct reduction process. Reduction occurs in a solid state at a lower temperature. Development of suitable refractories and Effect of Ccorrosion Analysis in H2 atmosphere at appropriate temperature will be a major step forward in the selection of superior refractory in the journey  and making positive contribution to our environment.

# TRADITIONAL REFRACTORY DESIGNS REPLACED BY INNOVATIVE REFRACTORY SOLUTIONS IN HOT BLAST STOVES

F. van Laar, B. Hansen, J. Carreau
Allied Mineral Technical Services, Columbus, OH, USA

B. Byerman, B. Eschbach
Burns Harbor, Burns Harbor, IN, USA

**ABSTRACT**
This paper will discuss novel repair methods for refractory systems in Hot Blast Stoves. The failure of refractory systems in a fast-paced industry creates demand for reliable repairs that offer the shortest timeline. Therefore, innovative solutions must improve the refractory design and installation methods to repair older, traditional refractory systems promptly. An alternative design with monolithic materials was successfully implemented in 2020 and 2021 at stove D1 and D3, and currently stove C4 at Burns Harbor. Failure of the traditional (brick) hot stove refractory system led to the casting of a complete monolithic dome and large sections of the walls. A post-construction analysis will demonstrate the validity and feasibility of the design.

**INTRODUCTION**
In July of 2020 Stove D1 suffered a catastrophic failure where the dome shell separated from the cylindrical portion of the stove. The dome refractories as well as approximately twenty feet of the checkers, ring wall and combustion chamber walls were significantly damaged. Stove inspections were ordered for the remaining three hot blast stoves to ensure that the furnace could operate on a three-stove operation. Hot endoscopic inspections for Stoves D2, D3 and D4 were performed in August of 2020. Repairing these stoves with traditional refractory systems using alumina and/or silica brick shapes would mean long lead times for engineering, procuring and manufacturing the standard and special shape bricks. Refractory suppliers were uncertain on actual delivery dates with estimates at over one year. Suppliers struggled with overseas raw materials and unpredictable shipping port delays. Clearly, Stove D1 must be repaired and online immediately with other material options before another stove could be taken offline for repairs. Therefore, Allied Minerals Technical Services LLC offered an innovative and proven solution to repair the stove refractories with the use of in-place castable pours. The in-place castable pours was selected for the following reasons:

i.    Material availability (in stock).
ii.   Short lead times compared to brick for unplanned repairs (Brick 1yr+).
iii.  Shorter construction period (ability to cast large panels at once.)
iv.   The castable design alleviates stress build-up in dome (Patent # US9194013B2).
v.    Tighter gas restriction in the partition wall by means of a significant reduction in mortar joints.
vi.   The ability to adjust the castable according to site conditions.

As the construction was finishing up on D1 (6 months after the failure) the total cost for in place castable was comparable to that of conventional refractory shapes. The castable design would again be implemented on Stove D3 once Stove D1 was completed and back on-line. The success of the castable repair on Stoves D1 and D3 lead to the decision to repair Stove C4 with in place castable as well. This paper will discuss the difference between castable and brick, castable design features, and construction techniques that make a castable repair option not only feasible, but a preferred option.

**HIGH SIGMA EVENT DESCRIPTION**
On the morning of July 16th, 2020, Blast Furnace D Stove No. 1 (D1) suffered a catastrophic failure at the connection of the cylinder and dome of the hot blast stove. Stove refractory was blown out of the top of the stove as the dome failed at the base circumferential rim. This violently distributed ~2000°F refractory brick across a vast area destroying equipment, burning wire trays, and taking away hydraulic controls from top charging, gas cleaning and stove functionality. No injuries were sustained but the potential for a life-threatening injury was substantial. Blast Furnace D was taken offline safely as it was isolated from the utilities and the uncontrolled fire at the top of the open hot blast stove D1 was dramatically minimized.

**CASTABLE VS. BRICK**
**Engineering and Logistics**
There is a clear advantage to using castable material over alumina or silica bricks when time is a factor. Designing a repair using castable requires less engineering and a shorter lead time to secure and manufacture the material. Using alumina and/or silica bricks requires engineering to ensure the bricks fit the designed radius. With castable, this engineering is eliminated and the castable follows the existing walls and formwork without cutting brick. Figure 1 below shows an example of a combustion chamber repaired using an alumina castable.

*Fig. 1: Complete castable combustion chamber*

**Expansion**
Traditional brick refractory systems can either use a panel construction or plastic packs for expansion. Both designs use mortar between the alumina bricks along with radial expansion provisions. This is a viable solution if designed and installed properly. However, upon cooling of hot blast stoves in which the refractory systems have failed, inspections have shown that using plastic as expansion provisions with mortar does not always work as intended. The expansion designed in panel construction has proven to show more longevity and less issues than the plastic pack design. If the expansion allowances are not followed correctly during construction, the panels can become unlocked allowing large sections of the combustion chamber walls to collapse. The telescopic brick used for expansion can crack at the tongue causing the panels to unlock (Figure 2).
*Fig. 2: Panels unlocked due to cracked telescopic bricks at the tongue*

For castable stove designs, the combustion chamber walls are cast in large sections using a tongue and groove system to lock-in the panels. Expansion joints are placed between panels to absorb the growth of the castable in the radial direction to minimize the stress in the lining (refer to Figure 1). Furthermore, using castable eliminates the need for mortar joints, which are common deficiencies in traditional refractory systems when they are not applied correctly. Mortar joints that are not evenly applied to the brick's surfaces can create localized stress points on the refractory bricks as the refractory system expands and the pressure between each brick increases. Finally, the use of castable eliminates gaps between bricks that result from poor installation and/or design which cause localized hot spots on the shell.

### Installation

Installing bricks in traditional refractory systems is also labor intensive. The number of different brick shapes and different types of materials required for the installation requires a large lay down area and a competent expeditor to stage the bricks properly for installation. Monolithic materials come in powder form and are mixed with water on-site before being pumped into place between forms. The castable must be kept dry and above freezing to install correctly. Generally, once the pouring starts on one level, the formwork can begin on the next level. Installation of castable materials is straight forward once the formwork is in place. Figure 3 shows an example of how an original brick lining can be tied into a new castable lining.

*Fig. 3: Castable pours integrated with existing brickwork*

### Material Properties

It is important to first note that the chemical, physical and mechanical properties of a material will vary depending on the supplier (higher % of andalusite versus lower % of andalusite and mullite/bauxite). Table 1 shows a chemical composition comparison between a typical high alumina brick and castable.

Tab. 1: Typical chemical composition of a high alumina brick and castsable

| Constituent | High Alumina Brick (%) | Alumina Castable (%) |
|---|---|---|
| $Al_2O_3$ | 65 | 62 |
| $SiO_2$ | 33 | 35 |
| CaO | N/A | 2 |
| $Fe_2O_3$ | 1 | 0.7 |
| $TiO_2$ | 0.3 | N/A |

The alumina and silica content are similar in both brick and castable. The differences arise in manufacturing and result in differing physical and mechanical properties, as shown in Table 2. Typical values are shown.

Tab. 2: Typical physical and mechanical properties of a high alumina brick and castable.

| Property | High Alumina Brick | Alumina Castable |
|---|---|---|
| Density (kg/m$^3$) | 2500 | 2680 |
| Porosity (%) | 18 | 16 |
| Cold Crushing Strength (MPa) | 40 | 64 |
| Modulus of Rupture (MPa) | 14 | 14 |

The andalusite-based alumina castable shows superior physical and mechanical properties. The castable has a higher density and lower porosity compared to the high alumina brick. Furthermore, the cold crushing strength is 60% higher than the alumina brick. The decreased porosity in the alumina castable improves its strength, load bearing capacity and corrosion resistance, however, reduces the thermal conductivity and thermal shock resistance. Therefore, while there are advantages to be gained by using castable instead of brick, there is also a compromise to be made. Materials are selected based on the conditions in the different zones of hot blast stoves to account for this in castable stove designs.

Some important properties for stove wall materials are creep and thermal shock resistance. The specific Allied andalusite castable was designed for stove internals. Table 3 below shows the results from an application-specific thermal shock test which indicates the relative difference between samples. A higher number indicates large loss in material strength, while a lower number indicates the material retained strength. The Allied andalusite-based castable proved superior to the other traditional andalusite-based stove bricks tested by a factor of 3 to 5. This material performs well in the lower combustion chamber due to the temperature fluctuations imposed by the flame.

Tab. 3: Thermal shock test results.

| Sample | Thermal Cycling Test Strength Loss (% of original) |
|---|---|
| Supplier A | 94.9% |
| Supplier B | 69.0% |
| Supplier C | 58.5% |
| Allied Andalusite-Based Castable | 19.9% |

The creep testing at the dome temperature for andalusite castable is an important part of the design. Samples were selected for creep testing during the repair of Stove D1 and D3. Table 4 shows the results.

Tab. 4: Creep test results per ASTM standards C-832.

| | Sample 10 Stove D1 | Sample 7 Stove D3 | Sample 11 Stove D3 |
|---|---|---|---|
| % Reduction of height of the sample under load at 1400°C after 20-50 hours | 0.27 | 0.34 | 0.34 |

The results show that the material is in a very good range with typical brick specifications and working conditions for these stoves.

## INSTALLATION / CONSTRUCTION

The stove refractory demolition began immediately with internal steel workers to provide an assessment of the remaining stove refractory. A field assessment was completed on Stove D1 to ensure the overall condition was satisfactory for rebuild. The objective was to salvage the 10-year-old checker column. A high-level scope of work was defined with the understanding that it was probable that additional issues would be discovered in the remaining refractories. Refractory in the combustion chamber required repairs in various areas and degrees in the hot face linings, crushed combustion wall intersections (Figure 4), burner inlet and hot blast outlet arches required repairs and design upgrades. Allied provided basic design changes including poured monolithic lintels arches and nozzles along with wall panel sections that tie-into to the existing refractory.

A contractor was selected in September 2020 and a construction plan was developed with much discussion regarding forms. All parties agreed to use a combination of wood forms and engineered scaffold which allowed for field adjustments to the existing conditions by the carpenters and bricklayers. The contractor began a slow methodical demolition with jack bracing down the combustion well with input from the operations and engineering departments (Figure 5). While demolition continued, the dome forms were under fabrication off-site (Figure 5). The first major cast was the burner inlet at the bottom of the combustion chamber. The nozzle back-up wall and hot face were made in two pours: one for the bottom section and one for the top section (Figure 6). The hot face walls were cast in sections with each pour approximately eight feet in height. The hot face pours continued up the combustion chamber until the bottom of the dome skewback pour. The various dome ring pours required a maze of form supports with the monolithic skewback pour being the largest at 96,000 pounds. The dome ring pours gradually reduced in size until the dome plug was the final pour (Figure 6). While installing the dome materials, the formwork in the combustion chamber was removed and a final inspection was completed for the poured walls.

Fig. 4: "Football tips" of the combustion chamber.

Fig. 5: Bracing the existing walls during demolition (left) and fabrication of the dome forms (right).

Fig. 6: Burner inlet pour (left) and complete castable dome (right).

## POST-REPAIR ANALYSIS

D1 stove was returned to service after a sufficient heat up / dry out in January of 2021. At the end of July 2021, an inner dome inspection was completed by Fosbel and Allied. Four videos were captured during this inspection and overall, the cast design of the inner dome proves to be holding up very well. Thermal scans were also performed on domes of stoves D1 and D3 during operation post-repair. The shell temperatures are in range with design calculations and are in an acceptable range for operation and validate the integrity of the repair. See Figure 7.

Fig. 7: Post-repair thermal scans of dome shell, stove D1 (left) and stove D3 (right).

The dome and stack temperature were compared before and after the repairs of stove D1 and D3.

Tab. 5: Dome and waste gas process temperature before and after the repairs of stove D1 and D3.

| | Stove D1 | | Stove D3 | |
|---|---|---|---|---|
| | Before Repair February 2021 | After Repair February 2022 | Before Repair February 2021 | After Repair February 2022 |
| Dome Temperature °F / °C | 2220 / 1216 | 2450 / 1343 | 2180 / 1193 | 2550 / 1400 |
| Waste Gas Temperature °F / °C | 525 / 274 | 535 / 279 | 540 / 282 | 530 / 277 |

**CONCLUSIONS**

In summary, a castable stove repair is superior to traditional brick designs for the following reasons:

  i.    Less engineering required.
  ii.   Shorter lead time to secure and manufacture the material.
  iii.  Ability to cast large panels at once.
  iv.   More functional expansion design due to panel construction.
  v.    Superior thermal shock properties compared to traditional andalusite bricks.
  vi.   Ability to retain strength under load at elevated temperatures (creep resistance).
  vii.  Eliminates the need for mortar joints, which are common deficiencies in stove construction if not applied correctly.
  viii. Helps to prevent short circuiting through the division wall (no bed or head joints).
  ix.   Can easily be tied into existing brick designs.

Burns Harbor management is confident in the new castable design. Enough so that three full stove repairs have been completed with this design and the current plan is to have four total castable designed stove repairs (two on each furnace).

# CORROSION MECHANISMS OF AL$_2$O$_3$–SIC–SIO$_2$–C REFRACTORY CASTABLES BY IRON AND SLAG BASED ON POST–MORTEM ANALYSIS OF INDUSTRIAL SAMPLES

Sina Darban[1], Laurent Cassayre[2], Simon Chiartano[3], , Laurie Lacarrière[1], Martin Cyr[1], Cédric Patapy[1], Pascal Prigent[3]

**ABSTRACT**
The Al$_2$O$_3$-SiC-C or (ASC) castables are used in the main runners of blast furnaces. Most of the published papers are focused on the laboratory corrosion tests due to the difficult access to the post-mortem samples of ASC castables. However, investigating the post-mortem samples is a key factor for reducing the wear of ASC castables. In this study, the microstructure of post-mortem samples located in working linings were investigated by SEM /EDS. The thermodynamic simulations were carried out in different systems such as slag/refractory and iron/refractory using the FactSage software. The SEM/EDS results showed formation of low melting phases such as gehlenite, anorthite, as well as spinel solid solutions in the matrix and calcium dialuminate near the alumina aggregates. The thermodynamic simulations showed that the slag and iron are prone to react with alumina and silicon carbide, respectively.

## 1. Introduction
To understand the corrosion mechanisms of ASC castables, it is informative to perform the corrosion tests in laboratory conditions. Nevertheless, the conditions (atmosphere, temperature, heating rate) of the laboratory tests can be far from industrial conditions. Therefore, investigating the post-mortem samples that were exposed to the real industrial conditions could be interesting to achieve better understanding of the real needs for improving the next generation of refractory materials. The study on the post-mortem ASC castables, especially, in the various zones of the runner is determinant of their lifetime. Comparing the post-mortem samples of ASC castables located in the working linings of the runner could give important information regarding their chemical and mechanical degradations.

As such, this research is focused on the corrosion mechanism of ASC castables by implementing the post-mortem analysis as well as thermodynamic computations. For this means first the microstructure of the post-mortem samples of ASC castables from different (turbulence, middle, non-turbulence) zones of the main runner were investigated by SEM/EDS. Next, the thermodynamic simulations were performed with the FactSage commercial software. Based on the principle of the main runner of blast furnace, the thermodynamic computations investigated phase equilibria with presence of slag or iron in contact with ASC castables at high temperature as well as during the cooling steps.

## 2. Materials and method
### 2.1 Slag and refractory castable
Tab. 1 shows the chemical composition of blast furnace (BF) slag used in this study. The major components are (wt.%) SiO$_2$ 37.2, CaO 34.4, Al$_2$O$_3$ 14. The minor components are (wt.%) MgO 8.8, K$_2$O 1, SO$_2$ 0.9, TiO$_2$ 0.7, MnO 0.6, Na$_2$O 0.6, FeO 0.4. Based on CaO/SiO$_2$ the percentage of the basicity is around 0.9 % which indicate that the BF's slag is an acidic slag.

Tab. 1: Chemical composition of blast furnace slag.

| Components | wt.% |
|---|---|
| SiO$_2$ | 37.2 |
| CaO | 34.4 |
| Al$_2$O$_3$ | 14 |
| MgO | 8.8 |
| K$_2$O | 1 |
| SO$_2$ | 0.9 |
| TiO$_2$ | 0.7 |
| MnO | 0.6 |
| Na$_2$O | 0.6 |
| FeO | 0.4 |
| Others | 1.4 |
| Sum | 100 |
| %B (CaO/SiO$_2$) | 0.9 |

The mineralogical composition of ASC castables is shown in Tab. 2 The major components of the castable are (wt.%) 60-65 alumina aggregates (0-1 mm,1-3 mm, 3-5 mm, 5-10 mm), 15-25 silicon carbide (0-200 μm, 0-1mm), 8-15 fine alumina (3-6 μm). The minor components are (wt.%) 2-3.5 carbon, 1-2.5 cement, 0-2.5 silica fume, 0.5-3 antioxidants, and 0.1-0.2 additives for flowability and setting time.

Tab. 2: The chemical composition of Al$_2$O$_3$-SiC-C castables.

| Components | wt.% |
|---|---|
| alumina aggregates | 60-65 |
| Silicon carbide | 15-25 |
| Fine alumina | 8-15 |
| Carbon | 2-3.5 |
| Cement | 1-2.5 |
| Silica fume | 0-2.5 |
| Antioxidants | 0.5-3 |
| Additives | 0.1-0.2 |

### 2.2 Selection of the post-mortem bricks of the main runner
The post-mortem Al$_2$O$_3$-SiC-C (ASC) castables are received from the industrial partner of this project. According to Fig.1 (b) the (post-mortem) samples are (from top to bottom) called slag line (sample 1), slag/metal line (sample 2), and metal line (sample 3). Samples A-1 and A-2 were investigated from turbulence (A) zone.

Fig. 1: *Schema of main runner of blast furnace before (a) and after (b) corrosion. The runner is divided into air/slag/refractory (zone 1) and slag/iron/refractory (zone 2). The post-mortem samples selected from slag line (1), slag/metal line (2), metal line (3).*

### 2.3 Thermodynamic simulations with FactSage software
The commercial software FactSage® v8.2 [1] was implemented for the high temperature thermodynamic calculations. The calculation consisted in adding an increasing amount of slag in a system composed initially of pure ACS castable, in order to calculate the nature and amount of the phases resulting from the equilibrium, and thus simulate the corrosion reactions. The temperature was 1550 °C, and the pressure was 1 atm.

## 3. Results and discussion

Fig. 2(a, b) shows the SEM images with lower and higher magnification of the hot face of the sample A-2, respectively. The sample A-2 was positioned in the slag/metal transition area during the lifetime of the main runner. Fig. 2(a) shows that the crystallized slag is mainly made of gehlenite ($Ca_2AlSiO_7$). The in-situ spinel particles with rectangular shapes are present in the interaction within the infiltrated zone. On the right upper side, the titanium particles accumulated near the spinel ($MgAl_2O_4$) particles. The thin interaction zone between slag and alumina aggregate is shown in Fig. 2(b). A layer of calcium dialuminate ($CA_2$) is formed along the alumina aggregate [2].

Fig. 2: *SEM-BSE mode images of hot face of sample A-2, low magnification (a) and high magnification (b).*

Fig. 3 shows the main stable phases during the addition of slag to 100 g of ASC castables at 1550 °C, where the amount of slag was increased from 0 g to 50 g by step of 5. These calculations aim to represent the reaction of slag infiltrating into the refractory. It could be observed that without slag in the system (i.e. for the x-axis value of 0 in Fig. 3), the calculation predicts the presence of two major phases, $Al_2O_3$ and SiC, as well as small amounts (about 3 g) of anorthite ($CaAl_2Si_2O_8$) and mullite ($Al_6Si_2O_{13}$). These two later phases are probably not representative of the ASC castable's initial phase distribution, but, due to their low concentration, we considered they could be disregarded. Furthermore, these minor phases tend to disappear in contact with small amount of slag.

Increasing the amount of slag causes the amount of alumina ($Al_2O_3$) to decrease from about 70 g to 30 g. This means that the infiltration of slag can induce the dissolution of large amounts of alumina aggregates. Conversely, the content of silicon carbide (SiC) is constant, which means that silicon carbide cannot dissolve into the slag. For high amounts of slag (above 30 g for 100 g of refractory), the formation of minor secondary phases (calcium hexaluminate ($CaAl_{12}O_{19}$), and spinel ($MgAl_2O_4$)) is predicted. The detection of such phases in corroded materials could then be an indicator of a strongly corroded zone.

Fig. 3: *Predicted stable phases in the refractory+slag system at 1550 °C.*

Here, microstructural analysis of hot face region (Fig. 2) and the thermodynamic results of slag/refractory system (Fig. 3) are in line with each other. Regarding sample A-2, the thermodynamic results are in accordance with experimental SEM/EDS results.

The SEM images showed that the calcium dialuminate ($CA_2$) as well as spinel grains are present in the hot face. Based on the FactSage results, by increasing the content of slag in the ASC castables, both calcium hexaluminate and spinel were formed at 1550 °C in the final steps. Also, they were formed during the cooling procedure of slag-ASC castable. The mechanism of formation of calcium aluminates e.g., CA, $CA_2$, $CA_6$ is extensively explained in [3], [4] and it is not in the domain interest of this study.

According to the thermodynamic results, the calcium hexaluminate should form at 1550 °C, when large amount of slag reacts with alumina. Furthermore, it is also a stable phase during the cooling steps, due to the infiltration of $Ca^{+2}$ ions from the slag side into the calcium dialuminate layer. Nevertheless, our examinations (Fig. 2) showed that calcium dialuminate layer was formed around the alumina aggregates of sample A-2 rather than the hexaluminate phase, indicating that the system did not reach equilibrium because of the protective role of $CA_2$.

The SEM image in Fig. 2(b) showed that the anorthite and gehlenite were formed in the infiltrated matrix of sample A-2 that are in accordance with the thermodynamic simulations showed in Fig. 3. According to the thermodynamic results, during the cooling of slag, first the anorthite started to form at 1500 °C and the gehlenite appeared at 1100 °C. Hence, it is concluded that the formation of ternary phases such as gehlenite and anorthite is in the infiltrated matrix is progressed during the cooling of slag and not at the working temperature.

## CONCLUSIONS

Obtained experimental results were compared with those simulated by the thermodynamic software of FactSage. It was found that the simulated results correlated with the obtained results from the microstructural characterizations of the post-mortem samples of ASC castables.

The presence of gehlenite, anorthite, solid solutions of spinel were confirmed in the infiltrated regions of the matrix of post-mortem sample A-2 that were located in the slag/iron transition area of the working lining in the main runner.

According to the thermodynamic results the slag was mainly reacted with alumina from the refractory side and not silicon carbide or carbon.

# DEVELOPMENT OF HIGH-PERFORMANCE SILICA REFRACTORY WITH LOW RESIDUAL QUARTZ FOR COKE OVEN BATTERIES

D. Banerjee, J. P. Nayak, B. Ghosh, P. Das, H. Nagata, S. Sengupta, H. Sehgal, P. B. Panda

TRL Krosaki Refractories Ltd., Jharsuguda, Odisha, India

## ABSTRACT

Silica bricks have always been the standard refractory used in the construction of coke oven batteries for over a few decades now. With technological advancements, production challenges and requirements of longer campaign life of batteries, new and improved qualities of silica refractories have now been in great demand over the last few years. To meet these requirements, high-performance silica bricks have been developed with optimum amount of residual-quartz content.

Residual-quartz (RQ) in silica bricks plays a very crucial role in determining the life of the refractories, as well as the campaign period of coke oven batteries. RQ is basically the low-quartz phase in fired silica bricks which has not converted into high temperature sTable phases during firing. This undergoes transformations during heating up of the batteries, causing volume expansions, thus resulting in cracks and subsequent destabilization of the refractory structure. Lower the residual-quartz content, lesser will be the expansion in the refractory lining work of the batteries while heating, ensuring maintenance of a proper and an optimum battery heating curve with no fluctuations.

In the present article, the authors have elaborated the development of high-performance silica refractory with low RQ content 1-1.5%. The product has been designed using high-purity quartzite, selecting high-grade mineralizers and additives. The production process followed highly modernized equipment like high-capacity inclined mixer machine, automatic hydraulic presses and tunnel kiln designed to fire silica bricks. The developed product has been supplied to some of the leading steel plant's coke oven rebuilding job and is running successfully.

## MATERIALS AND PROCEDURE

### Selection of Raw Materials

Silica refractories are produced from chemically pure quartzite with $SiO_2$ content >97%. Naturally, quartzite comes in two variants namely coarse crystalline (hardened chemically) and crypto crystalline (hardened tectonically)[1]. With various internal trials, suitable source of medium to coarse crystalline quartzite was identified from Chuinpally, India having desired properties like silica greater than 99%, very low amount of fluxing agents, good thermal behavior, and ease of conversion to higher temperature form.

Materials which accelerate the conversion from low temperature form to high temperature polymorphic form are called mineralizers. Transformation process of quartz to tridymite and cristobalite is sluggish in nature because it involves bond breaking and bond formation (reconstructive transformation). To optimize the conversion of quartz into tridymite & cristobalite, without affecting the high temperature properties, combination of various mineralizers (lime, iron oxide and other calcium containing binder) were used. Types of mineralizers, their composition and method of addition to the mix were chosen based on the result of internal trials. According to Dale's theory, lime slurry (hydrated lime) loses

its physical moisture within 200°C and at around 400°C, it starts decomposing to form anhydrous lime and with increase in temperature to 800°C, reaction between nascent lime and fine silica starts and forms $CaO-SiO_2$ bonding phase in the refractory aggregates and further increase in the temperature to 1250°C-1300°C, liquid starts forming in the $CaO-SiO_2$ system in the presence of impurities like $Fe_2O_3$, $Al_2O_3$, $TiO_2$ etc. The basic mechanism of transformation involves dissolution of quartz in the $CaO-SiO_2$ liquid system and precipitation of cristobalite crystals from the liquid[2].

Tab. 1: Typical data of quartzite chosen for this development.

| Components | % | Quartzite Firing Analysis (fired at 1440°C, 36 hours soaking) | |
|---|---|---|---|
| $SiO_2$ | 99.01 | AP % (before firing) | 0.6 |
| $Al_2O_3$ | 0.42 | AP % (after firing) | 12.3 |
| $Fe_2O_3$ | 0.37 | BD (g/cc) (before firing) | 2.63 |
| CaO | 0.06 | BD (g/cc) (after firing) | 2.01 |
| $Na_2O+K_2O$ | 0.06 | ASG (before firing) | 2.64 |
| $TiO_2$ | Trace | ASG (after firing) | 2.30 |
| LOI | 0.10 | % of phase conversion (based on ASG) | 13.02 |

Fig. 1: Microstructure of a typical quartzite grain showing medium to coarse crystalline structure; average crystal size: 390μm - 400μm.

Fig. 2: Tridymite and Cristobalite phases well observed in burnt quartzite, suggesting good amount of phase conversion in raw material.
**Manufacturing Process**

*Washing, Grinding & Screening of Quartzite*

Quartzite lumps received from the mines are washed, dried, hand-picked and fed into jaw crusher for grinding and then into secondary crusher to get desired size fractions of coarse, fines and by magnetic separator system (using strong electromagnets) and then these materials are transferred to the silos.

*Batching & Mixing*

Balance car collects the raw material from silos according to the specified batch composition and charged into high intensity inclined EIRICH mixer machine which ensures mixing with high productivity and homogeneity. Mineralizers, organic green binders, and special additives (for high grade KS quality bricks) are added to prepare the workable mix.

*Pressing*

The mix is pressed in PLC-controlled high capacity 1600 Ton SACMI automatic hydraulic presses in metal molds. Complicated shapes are pressed in electric screw presses. Consistent green properties are ensured with careful monitoring of mix granulometry, moisture and binder content.

*Drying & Firing*

Natural drying of molded bricks is followed by tunnel drying and duration of drying depends on the weight of the brick.

Dried bricks are set on the cars, small bricks are placed on the top and bigger bricks are set on the bottom and are arranged in such a way that maximum area is exposed for the conduction and convection to take place for uniform firing thereby ensuring maximum transformations into the required phase and consistent properties of finished bricks.

Firing silica bricks is the most critical step in its manufacturing because of the polymorphic transformation of silica associated with moderate to high volume changes at different temperatures. As high as 4-5% linear expansion takes place due to these high temperature phase transformations. Firing curve is selected based on the thermal properties of raw material in a way to maximize conversion of quartz into tridymite and minimize residual quartz to the range of 1-1.5 % or lesser. At around 600°C slow cooling is required to accommodate any volume changes because of presence of residual quartz ($\beta$-quartz to $\alpha$-quartz).

Ried Hammer designed, gas fired, long tunnel kiln equipped with PLC controlled preheating, firing and cooling zone is used for the firing of the green dried silica bricks. Firing curve is maintained as designed by Ried Hammer. Firing temperature of silica bricks depends on the desired final phase (cristobalite/tridymite) in the brick. For tridymite, soaking temperature is maintained in the range of 1430°C-1450°C. Temperatures of different zones are digitally monitored for better RQ control and consistency in finished products.

*Inspection & Dispatch*

Each lot of the bricks passes through stringent quality check. ISO-5022, ISO-9001, DIN-1089-1 [3] are followed to carry internal quality checks.

Fig. 3: Flow chart depicting the manufacturing process of silica refractories.

**Characterization**

Following apparatus and methods were used for testing raw materials and finished products.

1. Chemical Analysis by XRF as per DIN 51001
2. Physical properties (AP, BD, ASG) as per DIN 51056
3. Microstructure by ZEISS EVO 18 Scanning Electron Microscope
4. Creep-in-compression by Netzsch Hot load Furnace as per DIN 51053 (part-2)
5. RUL test as per DIN 51064
6. PCE test as per DIN 51053 (part-1)
7. Abrasion resistance test as per DIN 50148
8. CCS test as per DIN 51067 (part-1)
9. RTE as per IS 1528-1991 (part-11)

## RESULTS AND DISCUSSIONS

The properties of different grades of silica refractories as per internationally recognized DIN 1089-1 standard and test results of developed high performance silica bricks at author's plant have been shown in Table-2. Apart from DIN 1089-1, additional characterization like RTE has also been carried out.

### Chemical Analysis

As observed from Table-2, the alumina and alkali content which deteriorate the high temperature properties of silica brick, are well below the permissible limit and this result shows that selected quartzite is suitable for high performance silica refractory.

### Mineralogy

During heating up of silica refractory, high amount of residual quartz (RQ) gives higher thermal expansion and so to keep the expansion value low, the brick should have low residual quartz [4]. Mineralizers, ease of conversion of raw materials, firing temperature and soaking period control the amount of RQ in silica brick. In the long run of application of silica brick in coke oven where application temperature is in the range of 1200°C-1380°C, following phenomenon occurs: 1) conversion of cristobalite into tridymite which results in positive expansion and 2) lattice contraction of tridymite particles which may result into maximum 0.3% negative expansion in the silica brick [5]. To counterbalance the effect of negative expansion, some amount of RQ should be present in the silica refractory.

### Physical Properties

Granulometry was adjusted to achieve high green bulk density and use of optimized combination of mineralizers helped in sintering which subsequently resulted in high bulk density and sufficiently low apparent porosity (as per DIN standard) and accordingly improvement in compressive strength was observed. High dense silica bricks improve the thermal conductivity, thus improving the efficiency of coke oven batteries by reducing the coking time.

### High Temperature Properties

PCE & RUL values were found to be well above standard value. High value was achieved by using purer raw materials having extremely low content of fluxing agents, thus ensuring minimal formation of viscous liquid at relatively low temperature and good high-temperature properties.

Creep-in-compression determines the long-term life of silica refractory in the coke oven. It gives an idea about the deformation of brick under load at high temperature. Excellent creep resistance quite below the specified value was found for silica bricks manufactured at author's plant. Creep test curve for KD quality has been shown with the testing condition in Fig-4.

### XRD Analysis for RQ Content Determination

XRD analysis of the samples were done to determine the residual quartz content. From Table-2, it is seen that RQ content is well within norms. This was achieved due to careful selection of quartzite having medium to coarse crystalline crystal structure with average crystal size in the range of 390μm - 400μm, and by maintaining a stable firing curve during the entire firing process with enough soaking period to ensure maximum conversion of quartz to tridymite and cristobalite.

Low level of residual quartz ensures very low and minimal volume changes due to displacive transformations ($\alpha\leftrightarrow\beta$ phase transformations) during application, thus ensuring good structural integrity of the refractory structure over the long-life cycle of coke oven batteries.

### Microstructure

Microstructure images of TRLK developed KD, KN, KS quality silica refractory by SEM have been shown in figures Fig. 5-6, Fig. 7-8, and Fig. 9-10 respectively.

*Fig. 4: Creep test curve of TRL SCW KD.*

*Fig. 5: KD quality brick showing tridymite and glassy phase formation in the matrix region and conversion of fine silica grain into cristobalite.*

*Fig. 8: KN quality bricks showing coarse silica grain converted to cristobalite.*

*Fig. 9: KS quality bricks showing well-formed grain boundaries.*

*Fig. 10: Special additive grain in KS quality bricks; increases abrasion resistance of oven sole bricks.*

## CONCLUSION

High performance silica refractories with improved properties like lower residual quartz, high creep resistance, high density and optimum distribution of tridymite and cristobalite phases have been developed at author's plant meeting the internationally accepted specification like DIN 1089-1. The selection of appropriate grade of high purity quartzite, optimum combination of mineralizers and binders and state-of-the-art manufacturing technology has resulted in improved quality of silica bricks which have been supplied globally to steel plants for modern and high-efficiency coke oven battery construction, and have been running successfully.

# ONLINE REPAIRING OF BLAST FURNACE TROUGH TO ENHANCE HOT METAL THROUGHPUT

Arup Kumar Samanta*, Sougata Roy, Subhadeep Chatterjee, Amit Banik, Yoshihiro Mizuma, Sunanda Sengupta, P. B. Panda

TRL Krosaki Refractories Limited, Belpahar-768218, Odisha (India)

## ABSTRACT

In the field of Iron making, new technologies are being adopted for improving the quality of hot metal and to increase the productivity. Many integrated steel plants are gradually increasing their Blast furnace capacity to achieve higher productivity with lower rate of coke consumption, in turn, energy consumption. To make such advancement successful, running of trough without interruption is imperative to continue the supply chain of hot metal. Thus, it is becoming a big challenge for refractories technologists to further increase the hot metal throughput before taking a shut down for repair works. To address this, improvement in castable quality is not sufficient, rather, online repairing is the most beneficial technique to further extend refractory life with minimum down time. Moreover, cracking in trough is a common issue due to intermittent operation and frequent hot metal discharge which restrict to get expected hot metal throughput. Online repairing not only extends the throughput and controls the specific consumption of refractories but also protects the trough from metal leakage due to cracking.

In the present work, one new trough repairing material is developed by careful selection of base raw materials and special additives suitable for wide variation of temperature range. The removal of moisture was studied at temperatures ranging from $(200 – 500^{0}C)$ along with strength development. The blasting/explosion behaviour was examined at $1000^{0}C$ and $1300^{0}C$. The developed material is used in several integrated steel plants and the performance is satisfactory in terms of extended hot metal throughput.

## INTRODUCTION

The iron ores which were not very rich in Fe (Iron) and having high impurities of other metallic elements (like Mn) and oxides (like $Al_2O_3$) have not been used earlier days in BF operations. However, with increase of production facilities supplies of good quality iron ore are becoming expensive for iron making.

While using good quality iron ores the MnO content varies from 0.2 to 0.5% in slag. But it may go upto 3% while using low grades iron ore. The MnO present in slag affects the refractory through different mechanisms. It forms several low eutectic compounds[1] with other oxides like $Mn_2Al_4Si_3O_{18}$ ($1180^{0}C$), $Mn_3Al_2Si_3O_{12}$ ($1200^{0}C$), $MnSiO_3$ ($1293^{0}C$), $Mn_2SiO_4$ ($1347^{0}C$) and lowering the viscosity of the slag. It also increases the wettability of refractory surface while changing the wetting angle below $90^{0}$ between solid and liquid.

Under the present circumstances, usages of iron ores with high manganese oxides, the frequency of repairs of normal $Al_2O_3$- SiC-C bearing trough castables has increased many folds with decreased reliability of performance. But frequent shutdown of trough is not permitted from the view point of Blast furnace operation. Therefore, *Online* repairing of blast furnace trough is only the solution to enhance the trough throughput. So, the need is to design a good repairing material which can be used *Online* by gunning. There are several advantages while repairing trough without taking shut down like cracks are filled up with gunning after trough discharge, no metal penetration through the affected areas and no formation of any rat/dent hole after discharge. Additionally, it is safe, user friendly and easy to install. No need to arrange manpower for repairing cracks or localize affected areas and finally life of trough can be stretched to a certain limit while keeping minimum corrosion/erosion of original working lining castable.

## EXPERIMENTAL

The present trough repairing material is having some shortcomings specifically it is not suitable when there is wide variation of trough surface temperature at the time of application by gunning as it is based on high alumina cement. The major issue is blasting/explosion followed by chipping out. To avoid this issue two more recipes are designed without high alumina cement and introducing several additives. It has been observed that the trough temperature varies between $200^{0}C$ to $500^{0}C$ before applying the repairing material through gunning. Blasting or explosion is basically due to presence of moisture inside the repairing material and hence blasting can be avoided if moisture is removed before tapping the hot metal in trough. To understand the presence of residual moisture, the rate of removal of moisture in the temperature range of $200^{0}C$ to $500^{0}C$ was studied upto 90 minutes along with development of strength. The blasting cum explosion tendency was studied while putting the samples inside the furnace at $1000^{0}C$ and $1300^{0}C$ for 30 minutes.

## RESULTS & DISCUSSION

The recipe of existing repairing material along with two trial recipes are shown in Table.1. In case of two trial recipes there is no high alumina cement binder rather several non-hydraulic binders are introduced.

Table:1 Recipes of existing and trial through repairing material

| Raw Materials | Trough Gun | Trial - 1 | Trial - 2 |
|---|---|---|---|
| HAC binder | 3.5 | 0 | 0 |
| Additive - 1 | 1.8 | 4.8 | 2.4 |
| Additive - 2 | 0 | 0.5 | 0.25 |
| Additive - 3 | 2 | 0 | 0 |
| Additive - 4 | 0.05 | 0 | 0 |
| Additive - 5 | 0.5 | 0 | 0 |
| Additive - 6 | 0.7 | 1.2 | 0.6 |
| Organic fibre | 0.25 | 0.2 | 0.2 |
| Others | 93 | 97 | 94 |

In Fig.1, removal of moisture at $200^{0}C$ is shown with the time duration of 30, 60 and 90 minutes. The strength development was studied while measuring the CCS. The same is shown in Fig.2 at $500^{0}C$. The observations both at $200^{0}C$ and $500^{0}C$ are same.

*Fig.1: Moisture removal and sgtrength development at $200^{0}C$*

For existing trough gun, there is maximum moisture removal at both the temperatures as it is having high alumina cement binder. On the other hand, strength development is highest for Trial -1 material.

*Fig.2: Moisture removal and strength development at 500$^0$C*

The blasting tendency was studied at 1000$^0$C and 1300$^0$C and the appearance of samples is shown in Fig.3 after conducting the test at 1300$^0$C. Both at 1000$^0$C and 1300$^0$C there is damage in existing sample whereas Trial-1 and Trial-2 samples are almost in good condition. However, slight damage is observed in Trial-1 sample at 1300$^0$C. But Trial-2 sample is in good condition. Therefore, considering the blasting tendency, Trial-2 sample is showing the best results.

*Fig.3: Samples appeatance after blasting test at 1300$^0$C*

Considering the strength development and blasting/explosion tendecy, Trial -1 material was applied in an integrated steel plant in two troughs (T-1 & T-2). The appearance of trough before application and after application is shown in Fig.4. The appearance of trough after repairing is very smooth and all the cracks are filled up with the repairing material.

*Fig.4: Appearance of trough before (Left) and after application (Right) of repairing material*

The application details like thickness build up approximate rebound loss, material used and throughput after each gunning is shown in Table.2. The hot metal throughput acheived after gunning with repairing material is shown in Table.3
From our previous experience and data we have calculated the total erosion of working lining to achieve the certain hot metal through put. The same is compared when repairing material was applied. While applying the repairing material there is significant reduction in erosion is observed and it is shown in Table.4.

Table 2: Details parameters while using trough repairing material

| Parameter | T1 Trough | | | T2 Trough | | |
|---|---|---|---|---|---|---|
| Campaign | 1st | 2nd | 3rd | 1st | 2nd | 3rd |

| | 12.5 | 26/46 | 51/36 |

**CONCLUSIONS**
Due to high productivity of blast furnace, it is not permitted to allow frequent shutdown of trough for intermediate repairing. Online repairing by suitable material is the solution to stretch the life of trough. There is wide variation in temperature observed in trough before applying the repairing material and therefore the material should be designed which can be applied without any blasting or explosion. In general, several repairing materials are available with high alumina cement as binder. However, these materials are having some issues when there is variation in temperatures at the time of application. The newly designed material is designed with several additives and has already been applied at several integrated steel plants and gives satisfactory performance.

# INFLUENCE OF PITCH TYPE ON PROPERTIES OF BLAST FURNACE TROUGH CASTABLE

Takuma Kangawa*, Kenji Suzuki and Takashi Iida
Shinagawa Refractories Co., Ltd.

**ABSTRACT**

The influences of pitch type on the physical properties of blast furnace trough castable refractories were investigated by focusing on softening point and QI (quinoline-insoluble) content among the various characteristics of pitch powder.

When pitch powders of identical starting materials and preparation method with various softening points, were used, the hot modulus of rupture as well as corrosion resistance was lowered in accordance with an increase in softening point. When different types of similar softening point levels pitch powders with different starting materials and preparation methods, were used, the hot modulus of rupture and corrosion resistance were higher. In accordance with the increase in the QI content of the pitch powder, irrespective of pitch type, the hot modulus of rupture and corrosion resistance of the castable refractory sample was lowered.

QI signifies heavy pitch components with molecular weight exceeding 1200. QI components have been confirmed to inhibit infiltration or penetration of pitch into small pores in refractory bodies. It is inferred that, since pitch powder with low QI content tends to be diffused evenly and broadly into refractory bodies, associated with reinforcement of refractory structure by extensive carbon bond formation, both the hot modulus of rupture and corrosion resistance of castable refractory are improved.

## 1. INTORODUCTION

As a blast furnace trough castable refractory, Al2O3-SiC-C castable refractory is generally applied using carbon black and/or pitch powder as the carbon resource. Since pitch powder is used as a raw material for various kinds of refractory products, its influences on the characteristics of refractory products have been reported aboundingly [1,2]. In many of these reports, attention is put on the softening point of pitch powder, because a correlation can be found between the softening point of pitch powder and various properties of refractories in many cases. However, there are some experiment results which are not explainable by the softening point of pitch powder. In this study, focusing on other characteristics of pitch powder, the influences of pitch type on the properties of blast furnace trough castable refractories were investigated.

## 2. EXPERIMENT METHOD

### 2.1 Sample preparation

Table 1 shows the characteristics of pitch powders used in this study. Pitch powder A20，A25，A30 and A35 (which are collectively called A pitch) were prepared from a certain starting material and the softening point of each pitch powder was varied by applying different heat treatments. The starting materials as well as preparation methods used for pitch powders B and C were different from those for pitch powder A. Table 2 shows the blend compositions of the test samples. Al2O3-SiC-C castable refractory containing 19 mass% SiC and 1 mass% carbon black was used as a base, six different pitch powders were blended so that samples exhibit similar level of fixed carbon content.

Tab. 1: Properties of pitch powders

|  | A20 | A25 | A30 | A35 | B | C |
|---|---|---|---|---|---|---|
| Softening point / °C | 200 | 250 | 300 | 350 | 235 | 280 |
| Fixed carbon / mass% | 77 | 80 | 83 | 87 | 83 | 80 |
| QI / mass% | 24 | 42 | 51 | 62 | 11 | 23 |

Tab. 2: Blend composition of Al$_2$O$_3$-SiC-C castable refractory samples

| Additive pitch | | A 20 | A 25 | A 30 | A 35 | B | C |
|---|---|---|---|---|---|---|---|
| Chemical composition / mass% | Al$_2$O$_3$ | 72 | | | | | |
| | SiC | 19 | | | | | |
| | C | 3 | | | | | |
| Amount of carbonaceous materials / mass% | Carbon black | 1 | | | | | |
| | Pitch | 2.6 | 2.5 | 2.4 | 2.3 | 2.4 | 2.5 |

### 2.2 Hot modulus of rupture

The hot modulus of rupture of castable refractory samples was measured in order to study the influence of pitch type on mechanical strength. The Raw material mixture shown in Table 2 was mixed with a certain amount of water, followed by casting in a 40x40x160 mm mold. After curing at 30°C for 24 hours, the samples were demolded and dried at 110°C for 24 hours. Afterwards, the samples were fired at 1000°C for 3 hours in a coke breeze. The hot modulus of rupture of the fired samples was measured at 1000°C in a nitrogen atmosphere.

### 2.3 Corrosion resistance

In order to study the influence of pitch type on corrosion resistance, a rotary drum corrosion test was conducted on castable refractory samples at 1600°C for 5 hours with blast furnace slag (C/S = 1.2) as corrosive agent, which was exchanged every 1 hour.

## 3. RESULTS

### 3.1 Hot modulus of rupture

The relation between pitch powder softening point and hot modulus of rupture is shown in Fig. 1. The relation between the QI (quinoline-insoluble) content of pitch powder and hot modulus of rupture is shown in Fig. 2. The hot modulus of rupture is lowered in accordance with increase of softening point of A pitch powder. Both B and C pitch powders, with softening points similar to that of A pitch powder, exhibit higher values of hot modulus of rupture than A pitch powder. In accordance with the increase in the QI content of the pitch powder, the hot modulus of rupture is lowered.

### 3.2 Corrosion resistance

The relation between the softening point of pitch powder and the corrosion index is shown in Fig. 3. The relation between the QI content of the pitch powder and corrosion index is shown in Fig. 4. The corrosion index is steadily increased in accordance with the increase in softening point of A and B pitch powders. However, C pitch powder, with a softening point similar to that of A pitch powder, exhibits a bigger corrosion index. The corrosion index increased in accordance with the increase in the QI content of the pitch powder.
*Fig.1 Relation between softening point of pitch powder and hot modulus of rupture at 1000°C*

*Fig.2 Relation between QI of pitch powder and hot modulus of rupture at 1000°C*

*Fig.3 Relation between softening point of pitch powder and corrosion index.*

*Fig.4 Relation between QI content of pitch powder and corrosion index*

## 4. DISCUSSION

A correlation observed between the softening point and properties of castable refractory samples were affirmed in A pitch powders, of which the starting material and preparation method were identical. However, pitch powder B and C exhibited different experimental results which deviated from the relation observed in A pitch powders. Taking the QI content of the pitch powder into consideration, in accordance with the increase in the QI content of the pitch powder, irrespective of pitch type, the hot modulus of rupture and corrosion resistance of the castable refractory sample was lowered. The QI content signifies the content of heavy components in pitch with molecular weights exceeding 1200. It is well known that QI components inhibit infiltration or penetration of pitch into small pores in the refractory body [3]. It is inferred that, since pitch powder with low QI content can be easily diffuse into pores in the refractory body, a carbon bonded structure is evenly and broadly formed in the refractory body, associated with high hot modulus of rupture.

The dissolution of Al2O3-SiC-C castable refractory into blast furnace slag is composed of the following series of events; (1) infiltration of slag into refractory body, (2) oxidation of SiC by infiltrating slag associated with formation of SiO2, and (3) dissolution of refractory into formed low melting point SiO2 phase [4]. Taking into account such a corrosion mechanism, the influence of pitch powder QI content on castable refractory corrosion resistance can be summarized as follows. Since pitch powder with low QI content tends to be diffused into the refractory structure, carbon bond formation materializes in a broad area of the refractory body. As a result, such carbon bonded structure is hardly wetted by molten blast furnace slag and slag penetration into the refractory structure is effectively suppressed. It can be concluded that, since suppresion of slag penetration into the refractory body decelertes the dissolution rate of refractory into blast furnace slag, castable refractories blended with low QI content pitch powder exhibit improved corrosion resistance.

## 5. CONCLUSIONS

A correlation was observed between the QI content of pitch powder and properties of castable refractory through investigating the influences of pitch powder characteristics on properties of blast furnace trough castable refractory. It was indicated that, in accordance with lowering the QI content of pitch powder, pitch components can diffuse more evenly and broadly into the refractory body structure. This results in a reinforced refractory structure attained through carbon bond formation.

# UNDERSTANDING HOW THE BINDER SYSTEM INFLUENCES THE PROPERTIES AND PROCESS PERFORMANCE INDICATORS OF TAPHOLE CLAYS

I.J. Cameron[a], A.M. Garbers-Craig*[a], [a]University of Pretoria, Pretoria, South-Africa

## ABSTRACT

The use of conventional high-volatile coal tar pitch as a binder in taphole clays has notoriously been under scrutiny for replacement with non-toxic alternatives. The health and environmental impacts associated with the use of coal tar pitch (CTPht) have led to investigations into obtaining suitable non-toxic (free from polycyclic aromatic hydrocarbon, PAH) or less toxic alternatives (lower PAH-containing) to CTPht. In order to propose alternatives to CTPht, the binder-related features of the clay, as well as associated process performance indicators need to be considered. There are certain key properties of the taphole clay that are required during the process stages of ramming (closing of the taphole), drilling (opening of the taphole), and tapping. But while these processes are proceeding, the integrity of the taphole must be maintained throughout. This paper discusses the role of the binder system on the performance of the taphole clay during each of these process stages, and how these performance criteria can be measured and evaluated.

## LITERATURE

### Process and performance indicators

The main function of taphole clays is to form a semi-permanent seal that can withstand the conditions inside a smelting vessel (mechanical load and gas pressure) until the seal is opened to release the molten mixture inside the smelter or furnace. The three main taphole clay processes are ramming, which involves closing the furnace with a clay mass through the use of a mud gun; tapping, which involves emptying the furnace by opening it using either mechanical or oxidation methods; and protection, which involves preserving both the inside and surrounding area to the taphole [1] [2]. For each of these processes, there are performance indicators that are used to evaluate the process efficiency, and linked to these performance indicators are taphole clay features and properties. These relationships are shown in Figure 1.

*Fig. 1: Relationships between taphole clay processes, performance indicators and clay features (R – ramming, T – tapping, P-protection) [1] [2] [3] [4] [5] [6] [7] [8]*

### Performance indicators for ramming process

The main objective of ramming is to properly close the taphole and ensure that a seal is maintained throughout the operation of the furnace. The two performance indicators for ramming the clay are the mud gun extrusion pressure and the expansion of the clay upon heating [1]. The clay features related to the extrusion pressure are the rheology of the clay during ageing and heating. For the expansion of the clay, movement in both the ramming direction and the radial direction is critical, which depends on the constitution of the clay (type of aggregate used like pyrophyllite and kyanite). The expansion of the clay influences the plasticity of the clay, and this is one of the critical clay features [1]. With insufficient expansion of the clay, from aggregates, the plasticity of the clay in the injection direction and direction perpendicular is reduced. This can be evaluated through the compressive strength of the clay, clay extrusion simulation by means of Marshall Extrusion Pressure (MEP) [9] evaluations, visual inspection of clay spreadability, and clay compactability evaluated by means of workability measurements. The workability and MEP of a blast furnace taphole clay are shown in Figure 2 [9]. The importance of achieving a plateau in both workability and MEP after ageing, as observed for Clay B in Figure 2, determines process stability through reduced mud gun pressure variation during ramming. A low extrusion pressure ensures that taphole clay material is moved further along into the mud gun which increases the taphole clay length, while good compaction ensures the clay attains the required strength. Both factors are related, where the decrease in workability during ageing, results in an increase in MEP.

*Fig. 2: Taphole clay plasticity results of blast furnace clay workability and MEP ageing (Clay A – synthetic coal tar pitch & phenolic resin binder, Clay B – crude coal tar pitch binder) [9]*

### Performance indicators for tapping process

The main objectives of the tapping process are to allow easy discharge of molten material from the taphole, stable flow rate of material from the taphole, minimal slag splashing, reduced refractory consumption (including waste from the mud gun) and a reduced workforce (labour) due to the risk of injury close to the tap hole [1] [2] [3] [4]. The performance indicators for the tapping process include efficient drilling practices, measured through the drilling time, the casting duration (time from opening of the taphole to closure of the taphole) and slag/metal splashing.

#### Drilling practice

The requirements for efficient drilling practice are short drilling times without implementing additional measures such as vibration assist on the drill to open of the tap hole. The opening of the tap hole should result in a stable flow rate of molten material from the tap hole to minimize damage to the taphole area due to increased heat flux or erosion. The drilling ability is strongly influenced by the durability of the clay, i.e., sintering strength and the sintering strength is influenced by the taphole clay plasticity, adhesion (drying ability), and strength development [1]. With high plasticity, the taphole clay will have a resulting high spreadability [1],

allowing the clay to move further along the axial direction of the taphole and prevent accumulation of molten material. This accumulation of molten material on the inner part of the tap hole, where clay material should have occupied, can lead to drilling difficulties [5] and longer drilling times. The high adhesion of the clay ensures a high sinterability [1] of the clay through limiting low temperature volatilization that increases the viscosity of the binder (drying ability), to reduce voids or cracking in the clay when heated inside the tap hole. The high adhesion of the clay increases wear resistance and prevents material from entering the clay matrix or breaking it down through penetration and erosion. Controlling both the adhesion of the clay and strength development largely relies on the phenolic resin used in the clay [9] [13] [14]. For improved high temperature strength development of the clay, early strength development (<300°C) is important which is largely controlled by the phenolic resin in the case of phenolic resin containing clays. During cross-linking of the phenolic resin when heated, volailization occurs up to the decomposition temperature of the resin. This increased volatilization of the phenolic resin lowers the adhesion of the clay by premature drying of the binder [15].

*Casting duration*
The casting duration is the time between tapping and ramming, i.e., when the melt is transported away from the furnace into ladles or cast directly. The casting duration is largely determined by the molten flow rate, and this influences the wear rate of the taphole refractory. The sintered clay inside the tap hole needs to erode to an extent, during tapping, for two main reasons: to ensure the same amount of clay is rammed for the next heat (taphole length) and to maintain the casting duration by allowing small increases in flow rate during casting. The degradation of the refractory is due to extreme heat fluxes, thermal shock, and corrosion [5]. Depending on the smelting practice, one of these usually dominates the degradation of refractories [10]. These factors need to be limited to the tap hole and surrounding areas. The casting duration is also influenced by the plasticity of the clay, the binder quantity, and sintering strength (Figure 1). Regarding plasticity, it is crucial to maintain a low extrusion pressure, high compaction of the clay, and good spreadability to ensure limited corrosion and erosion of the taphole refractory including the taphole clay. If the plasticity of the clay is not sufficiently high, the casting duration will decrease (due to insufficient movement of the clay into the taphole), but the corrosion rates of the surrounding taphole area will be high [1] [6] [11]. To achieve the desired casting duration, sufficient sintering strength needs to be maintained with low porosity to limit penetration [1] of molten material and thereby reduce corrosion [12].

*Slag/metal splashing*
There are certain taphole clay features that are important for reduced slag splashing, which includes high plasticity, optimized binder content, fast curing speed of the binder, good adhesion, and strength development [9], [13]. Limiting the binder content reduces the volatile gas turbulence behind the tap hole and ensures less erosion of the tap hole. The strength development of a taphole clay needs to increase by 0,5% of the starting compressive strength, and the strength gain should not be too high, as this would complicate drilling operations [9].

**Protection of taphole clay materials**
The protection of the taphole clay is complex and influenced by several features, but the most important is the wear resistance of the clay, which is largely influence by its plasticity [14]. Having a high plasticity (compressive strength) [1] will ensure that long taphole clay lengths are maintained, and erosion of the taphole refractories are reduced [14].

**CONCLUSIONS**
There exists a relationship between the taphole processes, performance indicators, and clay characteristics. These factors need to be optimized for each individual operation. Both the processes- and performance indicators depend on the clay characteristics that should be controlled to ensure good taphole practices (ramming, drilling, tapping) and maintain the integrity and longevity of the tap hole. The taphole clay characteristics that need to be considered when altering binders include plasticity, wear resistance, binder quantity, open porosity of the clay, curing speed of the clay, adhesion, and strength development.

## ICR — International Colloquium on Refractories

**SCIENTIFIC CONFERENCE AND TRADE FAIR**

The International Colloquium on Refractories ICR® is a world-renowned event held annually in the city of Aachen. The event consists of a scientific conference, a trade fair for refractory companies and suppliers of raw materials, machinery, services and knowledge to the refractory industry, and of a varied supporting programm and social event.

Two days of scientific presentations and posters covering all aspects of the latest refractory research (raw materials, processing, refractory materials, applications and recycling)

Trade fair for refractory companies, customer and for suppliers of raw materials, machinery, services and knowledge to the refractory industry.

# AL$_2$O$_3$–SIC–C CASTABLE DEVELOPMENT WITH IMPROVED OXIDATION RESISTANCE

ByoungWook Jung[1*], TaeWan Kim[1], JaeNyung Heo[1], KwangHo Shin[2]

[1]Korea Refractories Company, Dangjin, South Korea
[2]Hyundai Steel Company, Dangjin, South Korea

## ABSTRACT

The castable primarily used in the slag zone of a blast furnace runner is composed of Al$_2$O$_3$-SiC-C materials. Major types of damage to the slag zone include wear owing to the efflux of molten iron, erosion from slag reactions, and the oxidation and spalling of the castable caused by cyclic exposure to molten iron and air. To enhance the operational stability of a blast furnace and increase throughput, it is necessary to improve oxidation resistance under an oxidizing atmosphere and enhance mechanical strength and erosion resistance against efflux. Given their low wettability with molten slag and high thermal conductivity, silicon carbide (SiC) and carbon—the primary raw materials of castables—are widely used as refractories in blast furnace runners. One drawback, however, is that carbon is prone to oxidation. This study, therefore, reviewed the optimal carbon addition rate depending on SiC content and experimentally compared physical and thermal characteristics using tests involving various types and amounts of oxidation inhibitors. We evaluated oxidation resistance by producing specimens of the same size and performing oxidation firing at temperatures similar to operating conditions. We evaluated erosion resistance using blast furnace slag (C/S=1.17~1.21) in a rotation corrosion test. The results showed that increasing the appropriate amounts of SiC and carbon improved oxidation resistance. This improvement was attributed to the suppression of carbon oxidation as more SiO$_2$ film formed at high temperatures owing to the increase in SiC. By adjusting the types and ratios of boron-based oxidation inhibitors, we achieved superior oxidation and erosion resistance compared with existing solutions. However, the overuse of oxidation inhibitors could lead to reduced fluidity of the product and property degradation; thus, tests were conducted with optimal amounts. When boron-based oxidation inhibitors were applied, excellent oxidation resistance was achieved owing to the densification of the structure caused by the formation of B$_2$O$_3$ and C and the formation of an oxidation inhibition layer through B$_2$O$_3$ melting. Based on the test results, we applied the product to Blast Furnace No. 3 at H Steel Mill in South Korea. This achieved an 8% improvement in erosion rate and a 30% reduction in repair volume compared with the existing product.

## 1. INTRODUCTION

Al$_2$O$_3$-SiC-C (hereafter, ASC) castables are refractories widely used in areas such as the main runner of a blast furnace and both the iron and slag runners. This is because of their superior resistance to thermal shock and excellent erosion resistance against slag [1]. Silicon carbide (SiC) and carbon, the primary raw materials of ASC castables, are chosen for their low wettability with molten slag and high thermal conductivity, which make them suitable for most blast furnace runners [2, 3]. However, because of harsh operating conditions created by efforts to increase both the refractory usage lifespan and blast furnace output, the features of ASC castables need improvement, especially in the slag zone where conditions are the most severe. The major types of damage to slag zone castables include wear owing to the efflux of molten iron, erosion, and the oxidation and spalling of the castable caused

by cyclic exposure to molten iron and air [4–6]. Fig. 1 shows the types of damage occurring in the slag zone during actual use. Compared with the metal zone, the erosion rate is substantially higher, and there is also damage attributable to spalling caused by oxidation. To extend the lifespan of the slag zone, it is necessary to improve oxidation resistance and enhance erosion resistance against slag [7, 8].

Fig. 1. Slag zone damage during main runner usage

In this study, we selected the optimal ratio of SiC to carbon in ASC materials and evaluated oxidation and erosion resistance according to the types and amount of oxidation inhibitors. A field test was conducted with a product whose hot properties had been improved. Analysis of the residual and repair volumes after the test showed an 8% improvement in the erosion rate and a 30% reduction in repair volume compared with the existing product.

## 2. EXPERIMENTAL PROCEDURE

The first test was conducted with four samples by increasing the SiC content and changing the SiC–carbon ratio based on the existing mixture C, as shown in Table I. In the second test, after selecting the SiC–carbon ratio with the best properties in the first test, we configured the mixture depending on the types and amount of oxidation inhibitors, as shown in Table II.

Table I.Composition of raw materials based on SiC–carbon ratio

| Raw materials | C | C1 | C2 | C3 |
|---|---|---|---|---|
| Al$_2$O$_3$ | 63 | 49 | 49 | 49 |
| SiC | 24.5 | 40 | | |
| Carbon | 3.5 | 2.5 | 4.5 | 6.5 |
| SiC–carbon ratio | 7.0 | 16.0 | 9.0 | 6.0 |

Table II. Composition based on the type and amount of oxidation inhibitors

| Raw materials | C | Oxidation inhibitor: A | | | Oxidation inhibitor: B | | |
|---|---|---|---|---|---|---|---|
| | | A1 | A2 | A3 | B1 | B2 | B3 |
| $Al_2O_3$ | 63 | 49 | | | | | |
| SiC | 24.5 | 40 | | | | | |
| Carbon | 3.5 | 6.5 | | | | | |
| Oxidation inhibitor | - | $\alpha$ −0.5 | $\alpha$ | A +0.5 | $\beta$ −0.5 | $\beta$ | $\beta$ +0.5 |

The main characteristics of oxidation inhibitors A and B are known to enhance erosion and oxidation resistance by forming a denser structure through the production of $B_2O_3$ and C and by forming an oxidation inhibition layer by $B_2O_3$ melting.

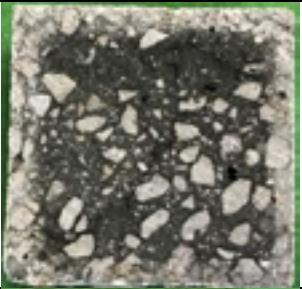
First, since the properties of castables can significantly change depending on the raw materials and oxidation inhibitors, leading to altered flowability, we evaluated flowability to determine the optimal amount to be added. To compare the hot properties of each test sample, we produced samples 60 mm X 60 mm X 60 mm in size for oxidation resistance evaluation, let them harden at room temperature for 24 hours, and dried them at 110°C for another 24 hours. We then fired them in an oxidizing atmosphere at 1,450°C for three hours and evaluated their oxidation resistance by calculating the total and non-oxidized areas. Based on the evaluation, we selected mixtures with excellent oxidation resistance and performed an erosion test using blast furnace slag with CaO/SiO2=1.17~1.21 in a rotary corrosion tester.

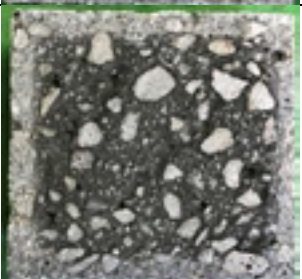
## 3. RESULTS

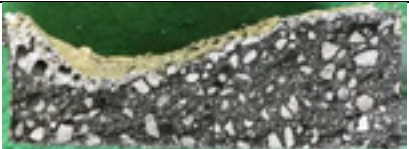
### 3-1. Impact According to SiC–Carbon Ratio

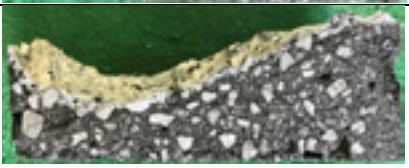
We maintained the particle size composition and designed it to be equivalent to the existing mixture C. Hence, the amount of water added and the fluidity index were at the same level as shown in Fig. 2.

Fig. 2. Flowability evaluation according to SiC–carbon ratio

Fig. 3 shows the results of the oxidation resistance evaluation. We found that oxidation resistance improved as the SiC and carbon content increased. This can be attributed to an increase in the amount of $SiO_2$ film formed at high temperatures as the SiC content increased, suppressing oxidation and the impact of the densification of the matrix area.








| | Cross-sections | Oxidation rate (%) |
|---|---|---|
| C |  | 32.6 |
| C1 |  | 31.7 |
| C2 |  | 28.8 |
| C3 |  | 26.7 |

Fig. 3. Evaluation of oxidation resistance according to the SiC–carbon ratio

As shown in Fig. 4, the erosion resistance evaluation results revealed the following order: C3 > existing >= C2 > C1. Therefore, from the evaluation according to the SiC–carbon ratio, we selected the C3 mixture—which yielded 18.1% and 4% improvements in oxidation resistance and erosion resistance, respectively—to further investigate the application of oxidation inhibitors.

| Cross-sections | Sample and corrosion index |
|---|---|
|  | C 1.00 |
|  | C1 1.07 |

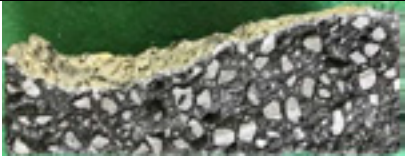
| | | C2<br>1.02 |
| | | C3<br>0.96 |


Fig. 4. Evaluation of erosion resistance according to SiC–carbon ratio

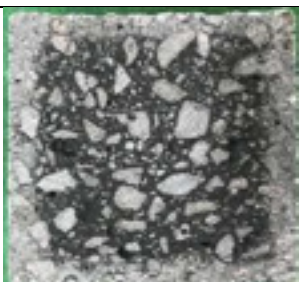
### 3-2. Impact based on the type and amount of oxidation nhibitors

When a large amount of oxidation inhibitors were added, we observed reduced workability and decreased pot life owing to rapid product settling in all cases. As shown in Fig. 5, we determined that A3 and B3 were unsuitable for field application owing to property degradation and construction issues caused by excess moisture. Thus, they were excluded from the oxidation and erosion resistance evaluations.


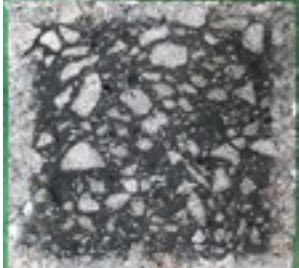


Fig. 5. Flowability evaluation

Fig. 6. shows the results of the oxidation resistance evaluation after applying oxidation inhibitor A. For A2, we observed a 35% enhancement in oxidation resistance compared with the existing level.

| | Cross-sections | Oxidation rate (%) |
|---|---|---|
| C | | 34.3 |
| A1 | | 25.7 |

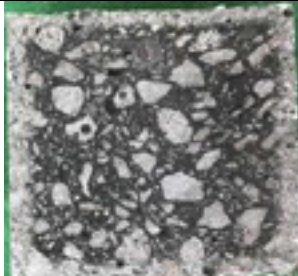
| | Cross-sections | Oxidation rate (%) |
|---|---|---|
| A2 | | 22.3 |


Fig. 6. Evaluation of oxidation resistance after applying oxidation inhibitor A

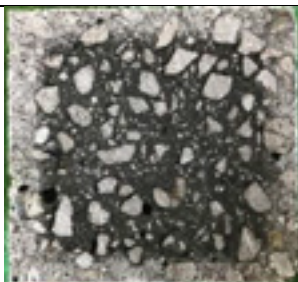
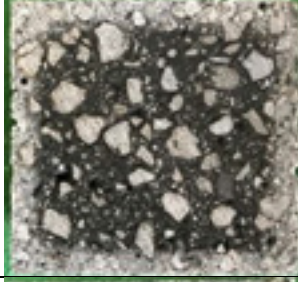
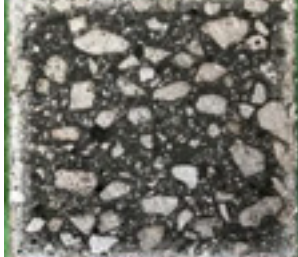
Fig. 7. shows the results of the oxidation resistance evaluation after applying oxidation inhibitor B. The order of oxidation resistance was B2 > B1 > existing product. For B2, we observed a 34.6% improvement in oxidation resistance compared with the existing level.






| | Cross-sections | Oxidation rate (%) |
|---|---|---|
| C | | 34.7 |
| B1 | | 31.7 |
| B2 | | 22.7 |

Fig. 7. Evaluation of oxidation resistance after applying oxidation inhibitor B

We found that the application of both oxidation inhibitors A and B improved oxidation resistance. Based on the evaluation results, we selected C and the mixtures with the best oxidation resistance (i.e., A2 and B2) for the erosion resistance evaluation. The A2 mixture showed a 21% improvement in erosion resistance while C2 remained similar to the existing level. Fig. 8 shows the results.

| Cross-sections | Sample and corrosion index |
|---|---|
|  | C 1.00 |
|  | A2 0.79 |
|  | C2 0.97 |

Fig. 8. Evaluation of erosion resistance after applying oxidation inhibitors

The mixture with increased SiC and a SiC–carbon ratio of 6, along with the application of oxidation inhibitor A, demonstrated excellent results in both oxidation and erosion resistance. Finally, we selected the A2 mixture for the field test.

## 4. FIELD TEST

For the field test, we applied the developed product to the main runner slag zone of Blast Furnace No. 3 at H Steel Mill in South Korea. The developed product and the existing product were used in equal quantity and throughput. Table III and Fig. 9 show the results. Compared with the existing product, our developed product resulted in an 8% improvement in the erosion rate and a 30% decrease in repair volume after use.

Table III. Comparison of remaining amounts and repair volume after completion

| | Existing product | Developed product | Notes |
|---|---|---|---|
| Throughput (tons) | 250,000 tons | 250,000 tons | - |
| Minimum remaining (mm) | 250 | 300 | ↑20% |
| Erosion rate (mm/1000 tons) | 1.76 | 1.61 | ↑8% |
| Repair material usage (ton) | 18.5 | 13.0 | ↓30% |

| Existing product | Developed product |
|---|---|
|  |  |
Fig. 9. Status of existing product and test product after completion

## 5. CONCLUSION

In this study, we sought to extend the slag zone lifespan of a blast furnace main runner by improving its oxidation resistance. We evaluated oxidation and corrosion resistance according to increases in SiC and the SiC–carbon ratio in the ASC material. We also adjusted the application and proportion of oxidation inhibitors according to the optimal SiC–carbon ratio. The conclusions are as follows:

1) With the increase of SiC content, the amount of $SiO_2$ film formed at high temperatures increased, leading to improved oxidation resistance. The best erosion resistance was observed using a mixture with a SiC–carbon ratio of 6.

2) When the boron-based oxidation inhibitor A was applied to the mixture, which had increased SiC and a SiC–carbon ratio of 6, we noted improvements of 35% and 21% in oxidation resistance and erosion resistance, respectively, compared with the existing product. It was crucial to control the amount of oxidation inhibitors added since excessive addition could lead to property degradation from excess moisture and construction issues.

3) We conducted a field test in the main runner slag zone using the developed product mixture. According to the results, the erosion rate improved by 8% owing to enhanced oxidation resistance compared with the existing product, and the volume of repair material used decreased by 30%. This made it possible to use the main runner more stably and improve the volume of repair material used. These outcomes can be attributed to improved oxidation and corrosion resistance through using the optimal SiC–carbon ratio and the application of oxidation inhibitors.

# INNOVATION IN CARBON FOOTPRINT REDUCTION AND SUSTAINABILITY IN THE MANUFACTURING OF INSULATION FIREBRICKS FOR LINING OF BLAST FURNACE STOVE

C. Natarajan, Ranjan Dey, S. Panneerselvam, S. Velappan, B. Raghavendra Pai, PM. Sivaram
Carborundum Universal Limited, Chennai, India

## ABSTRACT

Hot Blast Stove [HBS] is used to preheat air used in the Blast Furnace. HBS works as counter current regenerative heat exchanger which consists cylindrical steel structures lined with different kind of refractories includes Fire clay, Alumina, Silica and Insulation Fire bricks [IFB] having low bulk density, higher porosity and lower thermal conductivity.

IFB are manufactured by mixing the organic material such as saw dust, expandable polystyrene. Upon firing, organic material is burnt out and leaving pores in the finished bricks. These organic material burning have several negative environmental impacts due to release of harmful substances and generation of greenhouse gases. In order to have the sustainability & lesser carbon foot print, an innovative pore forming technology is introduced in the manufacturing of Insulation bricks.

Trials are carried out in ASTM 26 grade Insulation bricks in existing and new process for study purpose.

## IFB EXISTING MANUFACTURING PROCESS :

Insulating Fire bricks are made through different manufacturing process such as hand moulding, extrusion and slurry casting & slinger process. For this study, ASTM 26 grade is manufactured through slurry casting.

In the slurry casting process, expandable polystyrene is used as pore former.

This process consists of mixing refractory raw materials in appropriate proportion with expandable polystyrene and water and poured in the moulds and dried followed by Firing and finished with cutting operation.

## PROCESS FLOW CHART [Existing casting process]

## FOAMING PROCESS

In this process, the refractory slurry is prepared. The foaming agent is diluted with water and air and further mixed with refractory slurry. The slurry sets around the foam bubbles and this paste have sufficient strength to maintain its shape around the foam bubbles. It entrains 30-35 % of air by volume into the slurry and as a results low density foam structure is obtained.

Quality of the structure depends upon quality and type of foam used. Foaming agent is a material that facilitates formation of foam as surfactants. When foaming agent is added into the water in foam generator with proportion 1:30 to 1:40, a foam is generated.

## PROCESS FLOW FOR IFB MANUNFACTURING THROUGH FOAMING PROCESS

The bricks manufactured through existing process and foaming process are studied for various physical properties such as Pore size, Bulk Density, Apparent Porosity, Cold Crushing Strength and Thermal Conductivity.

## PORE SIZE

Pore size of foam based bricks are half the smaller in size which makes the product made out from foams are having micropores compared to existing process route product. These micropores helps to reduce the thermal conductivity

## BULK DENSITY

Existing process range: 0.84 to 0.88 g/cc. Foam process range : 0.82 to 0.86 g/cc.
## COLD CRUSHING STRENGTH

Existing process range : 1.7 to 2.1 Mpa. Foam process range : 2.3 to 2.5 Mpa.

Cold Crushing Strength (Mpa)
## APPARENT POROSITY

Existing process range: 61 to 68.3 %. Foam process range : 58.0 to 63.2 %

Apparent Porosity (%)

## THERMAL CONDUCTIVITY

Thermal Conductivity (W/mK)
## CARBON FOOT PRINT REDUCTION

Expandable polystyrene is derived from fossil fuels, primarily petroleum, and burning it involves the combustion of these carbon-based materials. The combustion process releases the carbon atoms present in polystyrene, combining them with oxygen from the air to form carbon dioxide.

The exact amount of $CO_2$ emissions produced from burning polystyrene can vary depending on factors such as the composition of the polystyrene, the efficiency of the combustion process, and the conditions under which it is burnt. However, as a general estimate, burning one kilogram of polystyrene can release approximately 3.3 kilograms of $CO_2$ emissions.

It's important to note that the environmental impact of polystyrene extends beyond just its $CO_2$ emissions from burning. The production of polystyrene also involves the extraction and refining of petroleum, which contributes to greenhouse gas emissions and other environmental concerns. Additionally, the disposal of polystyrene waste, whether through burning or other means, can have detrimental environmental effects, as discussed earlier

In the Foam process $CO_2$ emission is not experienced.

For 1 ton of ASTM 26 Mfg. CO2 emission [kg]
## CONCLUSIONS

The Insulating bricks produced through Foam process shows lower Bulk Density & Higher Mechanical strength and Lower Thermal Conductivity due to presence of appropriate pore size distribution.

In the regular process the $CO_2$ emission is 51.56 Kg of per ton of Insulation bricks where as in Foam process the emission is 0.06 Kg only.

The foaming agent is made from plants that are more readily available and easier to cultivate.

Processes based on foam are sustainable and good to the environment in terms of lesser carbon foot print

# DEVELOPMENT OF A NOVEL TAPHOLE CLAY WITH TOXICITY-FREE AND ODOR-LIGHTEN

Shougo Miyajima, Yuji Ootsubo, Katsumi Morikawa, Kiyoshi Goto, and Takashi Matsunaga.
Krosaki Harima Corporation, Kitakyushu, Japan

## ABSTRACT

Taphole cray is a key thermoplastic material to facilitate smooth filling from the taphole and to protect blast furnace hearth from erosion damage by molten pig iron or slag. As the plasticizer and the binder for the taphole clay, coal tar has been conventionally used widely due to its excellent thermal stability with high rate of carbon residual. In the usage of the coal tar, however, a serious deterioration of the working environment such as the carcinogenicity of polycyclic aromatic hydrocarbons (PAHs), the toxicity of volatile organic compounds, and the emission of bad odors with smoke. The taphole clay with the developed phenolic resin as the substitutin for the coal tar has exhibited better thermo plasticity than the taphole clay with the conventional phenolic resin, bringing in an expectation of improvement in plugging into the taphole when it applied practically in the blast furnace. The new taphole clay is also easy to handle with an excellent thermal stability, using the taphole clay working environment is significantly improved with elimination and lightnening of various burdens on the carcinogenicity, the toxicity and the odor/smoking.

## BACKGROUND

Figure 1 shows schematic image of a plugging process of the taphole clay. Plugging excutes using a clay gun with required of typically $200 \sim 500$kg taphole clay consumption. Such a large amout of the clay is for plugging intended to protect the inner wall of the blast furnace. The thermoplastic characteristics of the taphole clay is quite important to cover the inner wall of the blast furnace during plugging. Furthermore, extreme gap of temperature from 60 °C (taphole clay) to >1500°C (inner side of the blast furnace) tend to cause crack generation in the filled taphole clay. Stable and safety tapping of the pig iron through the taphole is an earnest requirement without cracking in the taphole clay during plugging. Coal tar is known as its superior thermoplastic property with slow volatilization by containing thermally stable wide variety of PAHs. Due to high toxicity and environmental harmfulness of the PAHs, in many countries they are prohibited or limited the usage of coal tar as refractory binder when the phenolic resin as substitute for coal tar is used for the taphole clay binder, rapidly hardening after filling into the blast furnace is an advantage to prevent cracking. However such early hardening property of the resin bonded clay often causes poor workability of the clay because of the difficulty of precise temperature control of the clay in actual operation. There are several patents to claim on some methods controlling the hardening property of the clay to solve this contradictory issues[1, 2]. Additionally, from the point of volatilization property of the heated resin bonded clay, there are several patents to claim on the enhancement of the volatilization behaviour of the clay for decreasing inner pressure after filling in the blast furnace[3, 4]. Those attempts for the resin bonded clay are aimed to the thermoplastic and volatilization properties to imitate those of the coal tar bonded clay. Our development policy also followed the previous attempts and aimed to develop thermally stable resin bonded clay realizing fine workability comparable to the previous attempts the coal tar bonded clay without toxicity and odor/smoking.

## CHARACTERISTICS AND CONCLUSION

Tab.1 shows hazardous component contained in the binders for taphole clays. Vaporized phenol from the resin bonded taphole clays was measured at approximately 70 °C by using Kitagawa gas detector tube; which can detect the concentration from 0.5 to 25ppm.

*Fig.1:Schematic image of a plugging process of taphole clay.*

Tab.1: Properties

| Binder property | Coal tar | Conventional resin binder | Developed resin binder |
|---|---|---|---|
| Carcinogen / ppm (Benzo[a]pyrene) | 7000 | Free | Free |
| Free phenol / % | — | >1% | <1% |
| Odor / ppm (Vaporized phenol) | — | >25 | Free |
| Taphole clay property | Coal tar | Conventional resin binder | Developed resin binder |
| Plugging | ++++ | + | +++ |
| Taphole depth | +++ | ++ | +++ |
| Tapping time | +++ | ++ | +++ |
| Handring | ++++ | + | +++ |
| Rapid hardening | + | ++++ | +++ |

Developed resin binder was free from both of carcinogen and vaporized phenol. Plugging performance of the developed clay was also compared with those of coal tar clay and conventional resin bonded clay as shown in Tab.1. Figure 2 shows comparison of hardening behaviour for each taphole clay with an uniaxial compression test at constant ambient temperatures. At 300 °C, developed taphole clay kept plasticity like a coal tar bonded clay in contrast, the conventional resin bonded clay hardened quickly. At 500 °C, the developed clay hardened quickly next to the hardening of conventional resin bonded clay. In contrast, coal tar bonded clay remained plasticity in the same time span. Such intermediate properties of the developed resin bonded clay between the coal tar and the conventional resin bonded clay is ideal for practice usage. Figure 3 shows schematic image of plugging test system[5] and Figure 4 shows results of plugging test of taphole clay after 3h calcination in the furnace. From the results of image analysis (use Image J software) for sectional image of specimens after plugging test, the developed resin bonded clay showed 2.2% of crack area close to the value of coal tar bonded clay. Uniformly filled plugging body shown in the cross section view gave us expectation to realize the satable tapping.

# REFRACTORY INNOVATIONS UNDER THE TARGET OF CARBON DIOXIDE PEAKING AND CARBON NEUTRALITY IN CHINA

Li Hongxia

Sinosteel Luoyang Institute of Refractories Research Co., Ltd., Luoyang 471039, China

**Abstract:**

Based on the target of carbon peak and carbon neutrality in China, the situation of carbon reduction and green development of the main high temperature industries under the background of double carbon will be introduced. The new technologies for the reduction of pollution and carbon in the iron and the key points of technological innovation of metallurgical refractories will be emphasized. The challenges and opportunities for refractories industry under the double carbon targets will be analyzed. The main innovation directions of refractories will be also pointed out.

Keywords: carbon peak; carbon neutrality; technological innovation of refractories; carbon reduction and green development

## 1 The development of the main high temperature industries served by refractories under the background of double carbon

At the Leaders' Climate Summit, President Xi Jinping announced that China will strive to achieve a carbon peak by 2030 and carbon neutrality by 2060. Carbon peak refers to the peak of greenhouse gas emissions in the country, and carbon neutralization refers to the balance between carbon production and carbon consumption, so as to achieve zero carbon load. China's commitment to achieve the time from carbon peak to carbon neutrality is far shorter than all the time of developed countries, which requires China to make arduous efforts. The '14th Five-Year Plan' is the critical period and window period for carbon peak. According to the decision-making and deployment of the central government, China will focus on building a clean, low-carbon, safe and efficient energy system. Actions to reduce pollution and carbon emissions in key industries will be implemented. Green low-carbon technology will achieve an important breakthrough. Green low-carbon policy and market system will be perfected. Green low-carbon life will be further advocated. Ecological carbon sink capacity will be improved.

According to statistics, in 2019, China's manufacturing industry accounted for 27.2 % of GDP. The total output value of typical process industries including petrochemical, chemical, iron and steel, non-ferrous, building materials, wafer manufacturing and other industries accounted for 51.98 % of the total annual output value of national enterprises.

The large-scale process manufacturing industry had caused huge carbon emissions, of which the $CO_2$ emissions of the basic raw material industry accounted for 70.0 %. The output of pig iron, crude steel, alumina, cement, ten kinds of non-ferrous metals, petrochemical and chemical industries with high carbon emissions in China's has ranked first in the world for many years. This is one of the main reasons why China's energy consumption per unit of GDP was 130 % of the world average and carbon emissions accounted for 28 % of the world's total. According to calculation, in order to make the energy consumption per unit GDP reach the world average level, China needs to reduce the consumption of 1 billion tons of standard coal every year. Therefore China 's energy saving and carbon reduction potential is huge. Therefore, high temperature industries such as electric power, iron and steel, non-ferrous metals, chemical industry and building materials are the key areas of energy saving and carbon reduction in China. At present, these high carbon emission industries have formulated and promoted carbon peak and carbon neutrality action plan and technology roadmap. Driven by the huge pressure of carbon neutrality and capacity reduction, the industry and product structure have been comprehensively adjusted, and scientific and technological innovation has been fully exerted, which promote the completion time of carbon peak and carbon neutrality ahead of the original schedule (2030 and 2060).

Refractories is an important support and indispensable part of high temperature industry. Its industrial development and technological innovation are closely related to the development of key high temperature industries and the path of energy saving and carbon reduction technology. The development of refractories is full of opportunities and challenges under the background of double carbon.

## 2 The development of iron and steel industry and the scientific and technological innovation of refractories for metallurgy under the goal of double carbon

China's refractories production ranks first in the world, and more than 70% of it is used in the metallurgical industry, which runs through metallurgy. The development and technological innovation of refractory industry depend on the development of iron and steel industry, technological innovation and technological progress.

According to statistics, China's pig iron and crude steel production in 2020 were 887.52 million tons and 1053 million tons respectively, an increase of 4.3 % and 5.2 % respectively. China 's steel production emits more than 1.96 billion tons of $CO_2$ per year, accounting for about 15 % of the total national greenhouse gas emissions [1], ranking second in the carbon emissions of the industry. The carbon reduction pressure of the iron and steel industry is huge, and it is the key area to reduce carbon emissions.

At the beginning of 2021, China Baowu Iron and Steel Group Co., Ltd. took the lead in releasing the goal of achieving carbon peak and carbon neutralization in advance to the society [2]. Strive to achieve carbon peak in 2023 by optimizing management and improving efficiency. Strive to reduce carbon emissions by 30% in 2025 and 30% in 2035 through technological innovation and process optimization. Strive to achieve carbon neutrality in 2050 through the path of process revolution and process reengineering. Baowu put forward the idea of green low-carbon development led by green development. The greenization of steel production process is realized by low-carbon metallurgy and intelligent manufacturing. The green use process of steel products is realized by high-quality products. Finally, contribute to the construction of carbon neutral society.

Hbis group has also issued a low-carbon green development action plan in the steel industry [3]. In 2021, a low-carbon metallurgical roadmap was released. In 2022, carbon will peak. In 2025, carbon emissions will be reduced by more than 10 % from the peak. In 2030, carbon emissions will be reduced by more than 30 % from the peak. In 2050, carbon neutrality target will be realized.

The energy saving and emission reduction of the steel industry is inseparable from technological innovation. China Baowu has explored and practiced the mode of low-carbon innovation and development and has made breakthroughs in non-blast furnace ironmaking technology. The OY furnace of non-blast furnace ironmaking process was built in Bayi Iron and Steel Co., Ltd. Based on the in-depth understanding and practice of COREX-3000, the technical research and re-innovation of non-blast furnace ironmaking process were carried out. In addition, China Baowu also built a low-carbon metallurgical innovation test platform. In 2019, the 430 $m^3$ blast furnace in Bayi was reconstructed into a hydrogen-rich carbon-circulating oxygen blast furnace, which, together with OY furnace and other auxiliary process equipment, became an innovative test platform for low-carbon metallurgy in Baowu. It was completed and put into operation on July 15, 2020. In 2020, the first stage test target of 35 % blast oxygen content was achieved, which broke through the oxygen-enriched smelting limit of traditional blast furnace. In addition, as early as August 2015, the original Baosteel Group proposed a metallurgical-coal chemical coupling theory and new process ideas. Those ideas closely combined metallurgical processes and chemical processes to convert metallurgical gas into chemical products for carbon sequestration, which can greatly reduce carbon dioxide emissions.

Hbis group has vigorously implemented hydrogen metallurgy technology, taking the lead in building the world's first 1.2 million

303

tons of hydrogen metallurgy production demonstration line in Zhangjiakou, Hebei Province, and building 1.2 million tons of production lines in Tangshan and Handan respectively. The demonstration and application of CCUS (carbon capture, utilization and storage) technology research and development was accelerated. The development and application of technologies such as imitation mantle molten iron bath was promoted.

The $CO_2$ emissions from the ironmaking process account for 70 % of the total emissions of the steel industry. Therefore, the ironmaking process is the key process for the steel industry to break through energy conservation and carbon reduction. About non-coking ironmaking, the University of Science and Technology Beijing and Jianlong Group proposed a new technology of hydrogen-based smelting reduction ironmaking (CISP), which avoided sintering and coking processes and realized the direct feeding of powder ore into the furnace. The process has strong adaptability to mineral powder and can deal with high phosphorus ore, vanadium titanium ore and so on. In the report of "Near net shape manufacturing technology under the background of carbon neutralization, "Academician Mao Xinping [4] introduced the SuSteel project proposed by the VAI in 2016. The project uses plasma hydrogen as fuel and reducing agent to realize direct steelmaking of iron ore, which can continuously produce crude steel without traditional steelmaking process. The technologies involved in this process include hydrogen plasma torch melting furnace, tail gas preheating and pre-reduction of iron ore.

At present, the research on new technology of non-coking ironmaking is a hot topic at home and abroad, mainly including high proportion pellet blast furnace ironmaking, low carbon ironmaking of full oxygen and hydrogen-rich blast furnace, gas-based shaft furnace hydrogen-rich direct reduction ironmaking, hydrogen-rich direct reduction ironmaking based on low rank coal, hydrogen-based smelting reduction ironmaking, and biomass ironmaking technology [5].

In addition, in China's steel industry, low $CO_2$ emissions of electric furnace short process accounted for less than 10%, far lower than the United States 62%, the European Union 39%, Japan 22% of the development level, also lower than the global average of 25.2%. The increasing amount of waste steel resources in Chinese society has provided favorable conditions for the development of short-process electric furnace steelmaking. It has become a consensus in the industry to promote the development of electric furnace steelmaking in China in an orderly manner. New steelmaking technologies include electric furnace steelmaking, $CO_2$ instead of $N_2$/Ar converter low-blowing technology cycle [5], cross-industry co-production technology and near-net-shape casting and rolling green low-carbon technology.

In summary, the iron and steel industry focuses on the following six key low-carbon metallurgical technologies in terms of how to reduce $CO_2$ emissions. 1) seeking the large-scale self-digestion of $CO_2$ in the long-process steel process [4]. 2) changing the steel manufacturing process and developing the short process electric furnace steelmaking and near net shape casting and rolling technology. 3) using non-fossil hydrogen metallurgy to reduce $CO_2$ emissions from the source. 4) applying metallurgical-coal chemical coupling to smelt direct reduction iron, exploring ironmaking to achieve negative carbon emissions. 5) researching and developing high-quality steel materials to improve life and reduce consumption. 6) Improving energy efficiency and reduce emissions through energy substitution and smart manufacturing.

Therefore, in order to achieve pollution reduction, carbon reduction and high-quality green development in the iron and steel industry, refractories should focus on the following six studies.

1) Study on long-life refractories for non-blast furnace ironmaking. Non-fossil hydrogen metallurgy technology should be paid attention to, including gas-based shaft furnace reduction and hydrogen-based smelting reduction ironmaking, full-oxygen hydrogen-rich blast furnace low-carbon ironmaking, biomass ironmaking etc.

2) Study on green functional refractories for converter furnace, electric furnace and refining technology. The bottom blowing of converter can effectively reduce the carbon and oxygen accumulation and improve the purity of molten steel. However, it will cause serious damage to the refractory at the bottom of the converter, especially when the life of the bottom blowing powder is less than 2000 heats. The new steelmaking technology for high-quality steel production makes the service environment of refractories more extreme and complex, including higher temperature, slag, molten metal, gas corrosion, mechanical wear, more severe thermal shock, higher pressure and high temperature vacuum. These harsh service environments pose a challenge to refractory workers.

3) Study on refractory for high quality steel efficient continuous casting. At present, the problems existing in the casting of high-quality steel include carburization (ultra-low carbon steel) and non-metallic inclusions, among which the problems of high-quality steel such as cord steel, bearing steel and rare earth steel are the most serious. Excessive alloying elements such as Mn, B, Ti, and rare earth lead to a decrease in the corrosion life of functional refractories, which will affect production efficiency. The submerged entry nozzle is easy to be blocked when casting Ti, Al and rare earth steel, which will affect the quality of steel. A series of high performance refractories for high quality superalloy production need to have better service performance.

4) Study on high quality refractory for near net shape continuous casting (ESP, thin strip continuous casting and amorphous thin strip production). Such as submerged entry nozzle, flow distribution nozzle, side sealing plate, nozzle, etc.

5) Study on a series of high-performance energy-saving refractory for thermal management of metallurgical high temperature devices.

6) Study on high value utilization of refractory and metallurgical slag.

## 3   Challenges and opportunities of refractory industry

A series of policies related to double carbon goal, green development, smart manufacturing, development and safety will further drive the technological innovation of high-temperature industry and promote the emergence of revolutionary high-temperature new technologies, which will greatly promote the technological innovation and industrial transformation of refractories. In addition, the calculation of carbon footprint in the whole life cycle of materials and the establishment of low-carbon green standards will make the development of refractory industry face great challenges and will also be full of opportunities and vitality. But in general, with the realization of the goal of high temperature industrial carbon peak and technological innovation, the general trend of the development of refractories is to reduce the quantity and increase the quality.

From the perspective of double carbon goal and low-carbon green high-quality development, there are some outstanding problems in China's refractory industry. The export of refractory raw materials in China accounts for a high proportion in the world, including various grades of magnesia, silicon carbide, brown corundum, white corundum, etc., resulting in high carbon emissions. The output of refractories in China is the first, among which the proportion of amorphous materials is low, the export volume of high energy consumption ordinary silicon bricks is large, and the proportion of green high quality materials is relatively low. The product structure needs to be further optimized. The manufacture of refractories is mainly based on fossil energy such as natural gas, which causes high carbon emissions. The energy efficiency and waste heat utilization rate of refractory manufacturing process need to be further improved. The utilization rate of refractories after reuse needs to be further improved.

Under the background of carbon neutrality and rapid development of new technologies in high temperature industries, the refractory industry is facing severe challenges. Carbon peak and carbon neutrality are not only the choice of technology, but also the reform of development right and development mode. Therefore, the refractory industry must: 1) implement new development concepts such as energy conservation and emission reduction, low-carbon green; 2) adhere to supply-side structural reforms, study raw material

decarbonization, energy reduction/decarbonization, production and manufacturing process decarbonization; 3) further improve energy efficiency and improve carbon sink capacity. The realization of the double carbon goal, the decarbonization of policies and regulations will gradually strengthen, decarbonization legislation, carbon quota, carbon trading, carbon tax, carbon negative list, carbon planning and so on will be stronger than the progress of science and technology in the short term, which needs the industry to attach great importance to.

In order to achieve low-carbon emission and carbon neutrality, the refractory industry also needs to deeply adjust the industrial layout and structure, not only to be close to raw materials but also to the market: 1) backward production capacity and high energy consumption equipment should be eliminated; 2) alternative raw materials for low-carbon emissions; 3) high life and functional materials should be developed to reduce resource and energy consumption; 4) key technologies for energy conservation and emission reduction should be developed and non-fossil clean energy should be used to improve energy efficiency; 5) The process flow should be optimized to promote smart manufacturing and green manufacturing; 6) the export of high-carbon emissions raw materials such as primary processing raw materials and low-end products should be curbed; 7) the technologies of carbon absorption and carbon consumption should be developed.

## 4 The direction of technological innovation in refractory industry

In order to comply with the high-end and intelligent manufacturing of high-quality carbon-reducing green development in the steel industry, refractories should achieve scientific and technological innovation. Firstly, we should focus on reduction and develop high-performance, long-life and lightweight products. Secondly, we should focus on functionalization and develop materials that are conducive to the production of high-quality steel and improve the energy efficiency of high-temperature industry. Thirdiy, we should focus on green environmental protection and develop environment-friendly, ecological and recyclable refractories with pollution reduction and carbon reduction. Fourthly, we should focus on the componentization of materials and improve the online detection and intelligent level of refractories. Science and technology of refractories should be considered from the aspects of material composition, structural design, preparation technology and material application engineering.

The first is the research of carbon reduction of raw materials. The main task is to innovate the preparation process of refractory raw materials. Alternative raw materials for low carbon emissions should be developed. The green calcination and enrichment and utilization technology of $CO_2$ of magnesite and dolomite based on product gas recycling should be developed. New heating technologies with low carbon emission should be developed to improve the efficiency of raw material preparation. Systematic research on replacing fused raw materials with lightweight high-strength microporous aggregates and sintered raw materials should be carried out. New green inorganic binders should be developed to replace organic binders with high carbon emissions such as phenolic resin and asphalt. Surfactants such as green additives and water reducer should be developed. Based on the innovation of raw material value chain of recycling, the proportion of high-quality recycling of used refractories should be improved. We should focus on improving the comprehensive utilization rate of low-quality raw materials. The improvement of comprehensive utilization rate of low-quality raw materials Attention should be paid to the improvement of comprehensive utilization rate of low-quality raw materials. The technology of replacing refractory raw materials with solid waste such as metallurgical slags is developed.

The second is the study of advanced high-temperature materials and the study of material components. The integrated design of structure and function should be innovated, and the research on cross-scale material compounding, gradient structure compounding, layered structure compounding and surface modification from nanometer to millimeter should be carried out to realize the optimal regulation of high temperature mechanical properties, thermal physics and functionality of materials. Long-life structure function integration high-temperature and high-transmittance wavelength furnace lining materials for new heating technologies and high-performance furnace lining materials for plasma heating, and refractories for waste incineration and industrial hazardous waste harmless treatment equipment should be studied. The key technologies of energy saving and emission reduction should be developed, and high performance and long-life green high temperature insulation materials should be developed to improve energy efficiency. To assist the field of new energy, new refractories with high efficiency, long life and green for coal gasification, and with high thermal shock resistance and high thermal insulation function for gas turbines should be studied. The innovation of multi-disciplinary cross-integration should be carried out, and materials, high temperature sensors, radar monitoring and computational simulation should be integrated to make high temperature materials modular and component-based, so as to maximize the online monitoring and service life of refractories.

The third is refractories evaluation and method innovation. The coupling mechanism of heat, force and corrosion medium of refractories under high temperature and complex service environment should be studied, and the service failure model and database should be established to predict the service life and service behavior, which provides a basis for the research and development of new and efficient refractory materials for different environments. The research on design and preparation of new materials based on the design of gradient materials and microstructure control should be carry out, and combining with thermodynamic simulation calculation, material genetic engineering and laboratory high temperature simulation verification to provide technical support for the development of a series of green refractory materials with excellent service behavior, long life and reliability. Finally, the synergistic improvement of key properties such as thermal shock resistance, permeability resistance, corrosion resistance and functionality of refractory materials is realized.

The fourth is the development of carbon reduction of preparation technology. The research on uniform forming and near net-shape preparation of refractories including complex shape of aggregates.should be carry out to solve the key common technology of structural functionalization, lightweight and complex shape material preparation of refractory materials. New equipment for shaped product to improve efficiency and reduce energy consumption should be researched and developed. New sintering technology and equipment, such as the use of microwave sintering technology, plasma sintering and other new technologies should be researched and developed. The energy consumption and heat loss of the process should be reduced, and intelligent manufacturing should be promoted to optimize the manufacturing process of refractory materials.

The fifth is to do a good job in carbon reduction infrastructure research. The calculation of the carbon footprint of refractories should be carry out by life cycle assessment (LCA). The carbon emissions of the industry should be accounted and verified. The total carbon emissions of the industry should be checked and ratified. The carbon market mechanism and carbon emission management should be improved. A series of standards for low-carbon development in industries such as carbon emission accounting standards should be formulated. These are the basic work to improve energy efficiency and low-carbon green development, are also green passes to enter the service industry, and play a major role in promoting the development of low carbon technology and standardizing market order to realize the greening of the whole life cycle of refractories and promote the high-temperature industry to achieve the target of carbon peak and carbon neutrality in China.

# NEW WAYS TO DESTROY REFRACTORIES – THE FUTURE OF GREEN STEELMAKING!

Thomas (Tom) Vert, Strategic Refractory Consulting Inc., Hamilton, ON, Canada.

## ABSTRACT

The "Carbon Challenge" that we are all trying to address is a major change in refractory customer manufacturing processes. Changes in steel plants to move to "green" steel will include removal or major modification of coke ovens, blast furnaces (BF) and basic oxygen furnaces(BOF); a shift to electric furnace (EAF) steelmaking with possible oxygen addition, direct reduced iron (DRI), liquid iron, hot briquetted iron (HBI); and the injection of hydrogen into any or all of these processes and/or any combination of all of the above!

A natural move from BOF wear rates of approximately 0.2mm/heat to EAF wear rates of 1mm/heat alone will increase refractory consumption regardless of any of the other technologies. The engineered move to each of the above changes and combinations thereof will increase the wear mechanisms of the refractories by an unknown factor also. Higher gangue ratios in DRI, use of EOF or Conarc furnaces, in the EAF technical space will raise major wear challenges to the refractories being used. And of course, it is still very early to see what the addition of high temperature hydrogen and/or steam as a byproduct will do!

This paper will attempt to predict the future of wear mechanisms and wear rates of "green steelmaking" with the prediction that no matter what...we will find new ways to destroy refractories! (and of course, new refractories to withstand these changes)

## WHAT IS GREEN STEEL?

Essentially, green steel is the manufacturing of steel without the use of fossil fuels.  So-called "green hydrogen" is one solution that could help reduce the steel industry's carbon footprint.

Hydrogen is labelled according to the source of underlying energy carrier used to produce the $H_2$ and whether carbon capture and storage (CCS) is employed, with green hydrogen as the ultimate goal.

With steel production making up ~7% of the world production of CO2, it is imperative to meet the climate change challenge, to reduce the use of fossil fuel usage.

As can be seen in Figure 1, the easiest and fastest way to meet this challenge is to move from BF/BOF production to EAF production[1].

Figure 1: Carbon emission intensity by steel production method[1].

A nice visual I like to use is the one from Midrex which shows the journey to green steel from the current state, as seen in the Figure 2[2].

Figure 2: Journey to green steel from the current state[2].

There are also numerous other pilot processes out there (e.g., HyBrit, Boston Metal, etc.) that may be a part of the solution, however, it is this author's opinion that the EAF will be the backbone of green steel future!

## HOW DO YOU WEAR OUT REFRACTORIES?

Refractories are worn by a combination of mechanisms which are summarized as "TMC".  TMC stands for thermal (T), mechanical (M) and chemical (C) wear mechanisms.  The general checklist that makes up the "TMC" analysis is shown in Table 1.

Table 1: TMC Wear Mechanisms

| Main Mechanism | Sub-Mechanism | Examples |
|---|---|---|
| **Thermal** | Peak temperature (T) | Tapping temperatures |
| | Thermal shock (delta T): Frequency and amplitude of changes | Heats/day and long outages |
| **Mechanical** | Impact | EAF door cleaning, force of scrap impact |
| | Abrasion | Stirring energy |
| | Applied stress | Mass of bricks sitting on the lowest layer of bricks (BOF stadium) |
| **Chemical (and Thermo-Chemical)** | Dissolution | Slag matrices attacked by chemically aggressive slags – especially at high temperatures |
| | Penetration | Fluid slag penetration |
| **Thermo-Mechanical** | Strain of thermal expansion | Expansion of lining |
| **Thermo-Mechanical (and Chemical)** | Spalling of the penetrated zones | Thermal expansion mismatch of penetrated zone vs virgin material |

A key to this analysis is also to evaluate from a refractory perspective. Refractory specialists are used for this as metallurgists usually understand the steelmaking process but do not understand refractory properties, and therefore cannot appreciate the effect of the former on the latter.

Besides to understand the refractories wear it is important to analyze current wear rates and predict them in the future.

## CURRENT WEAR RATES OF REFRACTORIES IN EACH PROCESS

### Blast Furnace Production

Refractories for blast furnaces include the initial lining (including stoves), repairs every 2 years on average (shotcrete and/or gunning and/or brick and/or castable repairs) (Table 2). Note that taphole clay is a metallurgical consumable and not a refractory so is therefore no included. Also, torpedo cars and/or hot metal ladles are not included as it is very plant layout dependent on wear rates but is not high enough to change the premise of this paper.

Table 2: BF Refractory Usage (no taphole clay)

| Initial lining (one time) | 1,000,000 | kg |
|---|---|---|
| Lining repairs every 2 years | 20,000 | kg |
| Trough refractories (~0.5kg/t) | 750,000 | kg |
| 20 year total kg usage | 16,200,000 | kg |
| Annual HM production | 1,500,000 | Tonnes |
| 20 year total HM production | 30,000,000 | Tonnes |
| Total BF refractory kg/t | 0.54 | kg/tonne |

Modern blast furnaces are a blend of carbon, silicon carbide, high alumina silicon carbide and high alumina bricks with zoning for key wear mechanisms.

Over time the trend has been to increase the usage of carbon and silicon carbide (SiC) type products to resist the high thermal loads and cycling in a modern BF operation. With a normally pressurized reducing atmosphere, the risk of oxidation has been low, and the lifetime of these refractories has increased. Modern carbon inclusive shotcrete materials have led to major increase in repair life. This has led to an increase in BF refractory life from 3 to 5 years in the 1980's to talk of a "perpetual" lining in future, with lives of over 20 years already documented without major relines.

### Basic Oxygen Furnace Production

Refractories for BOF's include the initial lining, the safety lining, gunning repairs and taphole changes are presented in (Table 3.)

Table 3: BOF Refractory Usage

| Area | kg/t | kg |
|---|---|---|
| Safety Lining | 0.01 | 14,727 |
| Working Brick | 0.09 | 141,029 |
| Gunning Repairs | 1.00 | 1,500,000 |
| Tapholes | 0.01 | 15,000 |
| Total Campaign Refractory usage | 1.11 | 1,670,756 |
| BOF Campaign Lifetime | 5,000 | - |
| BOF Average Heat Size | 300 | - |
| BOF Campaign Tonnage | 1,500,000 | - |
| Total BOF Refractory Usage | 1.11 | - |

Modern BOF's are mainly a blend of magnesia carbon brick, with zoning for key wear mechanisms (e.g., charge pad, trunnions, bottoms, etc.)

BOF life is highly dependent on operating and repair practices. USA BOF's have historically used slag splashing as a way to push BOF life to over 20,000 heats, though with the downside of lack of bottom stirring which adds other metallurgical costs including a higher usage of deoxidants.

Repair materials include basic gunning materials as well as patching with slags, used bricks, and/or bulk patching materials.

### Electric Arc Furnace Production

Refractories for EAF's include the initial lining, fettling and gunning repairs as well as taphole changes are presented in Table 4.

Table 4: EAF Refractory Usage (AC Furnace)

| Area | kg/t | kg |
|---|---|---|
| Hearth / Fettling | 1.50 | 225,000 |
| Working Brick | 0.60 | 90,000 |
| Gunning Repairs | 1.00 | 150,000 |
| Tapholes | 0.03 | 4,500 |
| Total Campaign Refractory usage | 3.13 | 469,500 |
| EAF Campaign Lifetime | 1,000 | - |
| EAF Average Heat Size | 150 | - |
| EAF Campaign Tonnage | 150,000 | - |
| Total EAF Refractory Usage | 3.13 | - |

Modern EAF's are mainly a blend of magnesia carbon brick, with zoning for key wear mechanisms (e.g., hot spot, above EBT, door area, etc.)

EAF life is highly dependent on operating and repair practices, even more so than the BOF. The variations on EAF sizes (from 20 tonnes to over 300 tonnes) as well as type (AC, DC, EOF, Conarc, etc.) make them very hard to generalize actual kg/tonne usage. The above calculations are for an average of AC type furnace.

From experience it is known that wear rates and higher refractory usage result from the following designs:

DC < AC < Shaft < EOF < Conarc

The major difference is in the amount of fettling and gunning repair required and again is highly dependent on foamy slag operations (which can cure many metallurgical sins!)

Wear rate is also affected by the type of scrap/iron charge from 100% scrap to large pieces of cold iron (from BF hot metal dumping) to HBI, DRI and even hot metal charging (up to 30% of the metallic charge. Note that the effect of these materials will be discussed more in the future state section.

## PREDICTED WEAR MECHANISMS/RATES OF REFRACTORIES IN EACH PROCESS WITH GREEN STEEL

### Blast Furnace Production

In the future, it is predicted that those companies that continue to utilize blast furnaces will try to inject hydrogen as one of the fuels. It is well known that hydrogen produces more water compared to other hydrocarbon fuels and may result in water vapor being present in the furnace atmosphere, which can lead to increased refractory corrosion for certain refractory compositions[3]. Modern day blast furnaces are composed of a combination of carbon, silicon carbide and alumina bricks with similar containing monolithic repair materials. The effect of $H_2$ and or $H_2O$ in these furnaces will lead to degradation of the refractory lining by the chemical reactions, as presented in equations 1 to 4:

| | |
|---|---|
| $2H_2 + C = CH_4$ | Eq. 1 |
| $2H_2 + SiC = Si + CH_4$ | Eq. 2 |
| $2H_2O + 2C = CO + CH_4$ | Eq. 3 |
| $2H_2O + SiC = SiO_2 + CH_4$ | Eq. 4 |
The blast furnace maintains as much as possible a reducing atmosphere when stable and under pressure, however, there are numerous times when the furnace is open to atmosphere for repairs and/or inspections. Also, water can enter the furnace through stave and/or plate leaks and/or snow/ice during winter months. All of these conditions will lead to higher wear rates, but it is unknown how high these wear rates may go.

It is this author's opinion that the initial lining wear rates for BFs with hydrogen injection will at least double due to the nature of attack mechanisms and operational conditions. Future predictions for refractory usage are presented in Table 5.

Table 5: BF Refractory Usage (no taphole clay) – FUTURE

| | | |
|---|---|---|
| Initial lining (one time) | 1,000,000 | kg |
| Lining repairs every **1 year** | **50,000** | kg |
| Trough refractories (~0.5kg/t) | 750,000 | kg |
| 20 year total kg usage | **17,000,000** | kg |
| Annual HM production | 1,500,000 | Tonnes |
| 20 year total HM production | 30,000,000 | Tonnes |
| Total BF refractory kg/t | **0.57** | kg/tonne |

It can be seen in Table 5 that overall wear rate only increases from 0.54 to 0.57kg/t due to the main refractory usage being in the BF troughs.

The key drop in refractory consumption, however, will be the major drop in the number of blast furnaces online which is expected to decrease at least 50% though this will vary widely by region due to economics, as seen in Figure 3[4]. For example, all North American steelmakers except Cliffs have committed to a switch to EAF production by 2040.

Figure 3: Global crude steel production by process route and scenario: 2019 to 2050[4].

**Basic Oxygen Furnace Production**

There is no mention at the current time of injecting hydrogen into the BOF and therefore there is assumed to be little change to wear rates of the BOF refractories.

As discussed with BF's, the key change in refractory consumption, will be the major drop in the number of oxygen furnaces online which is expected to drop by at least 50% though this will vary widely by region due to economics[4].

**Electric Arc Furnace Production**

Refractory wear for EAF's will increase in the future due to a combination of four factors:

1. Increased usage of combination oxygen/EAF furnaces such as EOF, Conarc and/or oxygen injection from bottom tuyeres.
2. Higher use of DRI/HBI and even liquid hot metal to meet final customer metallurgical requirements.
3. Injection of hydrogen into the EAF.
4. Usage of hot metal from other processes into the furnace.

Four factors will lead to an increase in refractory wear and usage, as follow:

1. As stated earlier in this paper, from experience it is known that wear rates and higher refractory usage result from the following designs:

    DC < AC < Shaft < EOF < Conarc

    As steel plants move to EAF's and push the envelope to meet stringent final customer demands for the move to more destructive designs will be natural. It is also expected that bottom stirring will be used with argon or potentially with oxygen to increase the process speed and lower tap to tap times. All of these will lead to higher refractory consumption.
2. The move to higher amounts of HBI, DRI and even hot metal charging will also lead to higher wear rates. It has been stated that the amount of higher quality DRI/HBI is dropping and therefore gangue materials will increase. This will lead to longer processing times, higher slag ratios and therefore more refractory issues.
3. Injection of hydrogen into the EAF with associated free $H_2$ and potentially $H_2O$ will again lead to refractory wear as the magnesia carbon brick will be destroyed quickly and need repairs. If the carbon is decreased in the brick, then the amount of thermal spalling will increase so for now there are not solutions to this challenge.

Table 6 shows this author's "crystal ball" projection of the >50% increase expected in refractory consumption!

Table 6: EAF Refractory Usage Future State (AC Furnace)

| Area | kg/t | kg |
|---|---|---|
| **Hearth / Fettling** | **2.00** | 300,000 |
| **Working Brick** | **1.20** | 180,000 |
| **Gunning Repairs** | **1.50** | 225,000 |
| Tapholes | 0.03 | 4,500 |
| Total Campaign Refractory usage | 4.73 | 709,500 |
| EAF Campaign Lifetime | 1,000 | |
| EAF Average Heat Size | 150 | |
| EAF Campaign Tonnage | 150,000 | |
| **Total EAF Refractory Usage** | **4.73** | **51% increase** |

**FUTURE REFRACTORY SOLUTIONS**

So, if the future will include some combination of more EAF's, more hydrogen, longer processing times and more aggressive slags, etc., than how do refractory designers move forward?

309

It should be noted that all refractory companies have started to work on the effects of hydrogen injection and what to do.

Some key work has been done and the key points are summarized as follows:

- From the Ellingham diagram, presented in Figure 4[5], it is possible to see that alumina, chromia and titania are the key oxides that are less affected by hydrogen at steelmaking temperatures.

Figure 4: Hydrogen Ellingham diagram[5].

This explains why very high purity alumina has been used in hydrogen atmospheres over time in other non-ferrous industries and why it is the refractory of choice in modern injection capable DRI facilities.

This will not be good enough for usage in an EAF of course as the carbon in the magnesia carbon brick, and the magnesia for basic slags are needed for survival.

Potential options are low carbon magnesia through the use of nano-carbon technologies, some forms of spinel (though chrome 6+ is still a major issue), or high temperature calcium aluminates (like hibonite).

We look forward to seeing the development of technologies to combat the newer and more aggressive steel plant processes!

**CONCLUSIONS**

1. "Green" Steelmaking will result in a shift from the BF/BOF route to the EAF route over the foreseeable future in order to get large gains in decarbonization.
2. The new process route will result in an increase of refractory usage by at least 90%. This is because the BF/BOF route uses 1.65kg/tonne and the EAF route uses more than 3.13kg/tonne.

3. The EAF route itself will generate additional refractory consumption due to process route, raw material, and injection changes towards more hydrogen.

# TRANSFORMATION TO HYDROGEN-BASED STEEL MAKING AND REFRACTORY CHALLENGES AT THYSSENKRUPP STEEL EUROPE AG IN DUISBURG

K. Kursch, Dr. B. Kohnen, Dr. M. Weinberg, thyssenkrupp Steel Europe AG, Duisburg

**ABSTRACT**

In 2045 tkSE wants to be climate neutral. To reach the goal the existing blast furnaces have to be replaced by direct reduction plants and smelters.

The change will be challenging for the plant site as well as for the refractory material. tkSE wants to use hydrogen gas for the production of up to 2,5 mio to/ a hot metal.

Already in 2019 tkSE started the first researches and development projects for new refractory materials together with several suppliers, universities, external labs and other industrial cooperation partners.

The behaviour of different materials under hydrogen atmosphere as well as under a mixed gas atmosphere with H2 and NG are investigated. Another big field of investigation is the smelter technology which works under a reducing atmosphere. Melting down a big amount of DRI (direct reduced iron) with an almost blast-furnace-like slag is not a common operation and also a challenging operation for the refractory.

## 1 INTRODUCTION

At tkSE AG, one blast furnace will be replaced by a DR (direct reduction) plant plus two smelters in the future. In one plant, 2.5 million tons per year of CO2-reduced hot metal are to be produced by melting $H_2$-reduced DRI (direct reduced iron). Due to structural conditions, tkSE has decided to use a SAF (submerged arc furnace) or ESF (electric smelting furnace) for the production instead of a conventional EAF (electric arc furnace). Due to the significantly lower power density compared to a conventional EAF, large melting units are required: in detail, the size of one smelter will be about 400 $m^2$.

tkSE would like to retain the steel mill route, including the conventional converter process, so that the almost carbon-free DRI produced will have to be carburized in the smelter.

On the one hand, this approach enables one-to-one production for all conventional grades in the steel mill produced by tkSE, i.e. the customer can rely on the usual quality. On the other hand, the slag produced by melting the DRI in the SAF has a similar chemical composition to conventional blast furnace slag, so that the cement and building materials industries, as customers of the granulated slag, can also continue to be supplied without restriction. Thus, no slags are produced, which can only be used as lump slag in road construction.

However, due to this plant combination tkSE faces completely new challenges with regard to the refractory lining of the above-mentioned aggregates.

## 2 H₂ – CORROSION IN DR-PLANTS

The DR plant planned by SMS is to be operated in the future, after a ramp-up period (natural gas operation), first with mixed gas (natural gas and $H_2$) and finally with 100 % $H_2$. In the plant, DRI will be produced under overpressure at gas inlet temperatures of up to 1100 °C. This process produces combinations of reactive gases, as well as hot water vapor.

### 2.1. Laboratory scale studies

In order to be able to assess the extent of possible damage by $H_2$ to the refractory lining, tkSE has already started testing different raw materials and products under operating conditions together with various institutes trand refractory suppliers at the end of 2019. An important project in this context is the RUHL (refractories under hydrogen load) project led by the University of Koblenz-Landau. In these tests, potential refractory products from Almatis, Refratechnik Steel and Steuler KCH are examined under varying conditions. Due

to extremely long delivery times for new test units, it has only been possible to test the materials in a pure $H_2$ atmosphere at various temperatures. Mixtures of water vapor and hydrogen could therefore not be tested so far.

Here, tkSE is paying particular attention to corundum-based materials, since this material represents a standard for DR systems currently in operation.

The corundum concrete described below, based on brown fused corundum, was subjected to 100% $H_2$ at 1200 °C for 200 h. This test was performed with three different specimens, each placed at different positions in a gas purging furnace, so that positioning effects on the strength of corrosion could be minimized.

After treatment, the concrete bar was prepared for examination under a scanning electron microscope. When viewing the polished surface, it is noticeable that macroscopically, unlike specimens of other materials, no corrosion zone is visible (Fig. 1).

*Fig. 1: Section of corundum concrete for SEM analysis.*

By means of element mapping, however, it can be shown beyond doubt, that the Si content decreases strongly towards the hot side (Fig 2).

*Fig. 2: EDX - Mapping for Si - distribution in the marked area.*

The physical properties also show a clear structural damage due to $H_2$ attack. The corundum concrete exhibits the lowest weight loss of all tested materials (Fig. 3), but shows the highest loss of cold bending strength with approx. 50 % (Fig. 4).

*Fig. 3: Overview weight loss*

*Fig. 4: Overview cold bending strength*

### 2.2. Results from practice

From other industrial plants with comparable conditions, samples from refractory linings were examined internally by tkSE. Some of them had been in use for many years. These are andalusite bricks with 35-40 % $SiO_2$ content.

In the cracking reactor of the Claus plant, an aggregate of the gas treatment of the coking plant, conditions with 1120 °C, 5 - 8 % $H_2$ and water vapor are similar to those in DR plants. Investigations of samples which were installed in a plant for five years each show a partly massive damage of the microstructure of the bricks (Fig. 5)

311

*Fig. 5: H₂-destroyed grate of the fission reactor v. 2018*

The specimens show the same corrosion mechanism as the laboratory specimens (Figs. 6 and 7): $H_2$ dissolves the silicate components from the microstructure on the hot side, reacts with $SiO_2$ to form $H_2O$ and $SiO$, which outgasses from the microstructure and leaves pores. Through these, new hydrogen can penetrate further into the structure and continue the process. What remains is a corundum fringe on the stone surface and a completely mullitic transformed microstructure inside.

*Fig. 6: Depletion of SiO₂ towards the hot side of 2018*

*Fig. 7: Depletion of SiO₂ towards hot side of 2020*

The examination of the strength showed that, although the microstructure was heavily attacked, the stone surprisingly exhibited a higher cold compressive strength than in the as-delivered condition (Fig. 8). The reason for this is not yet clear. It is assumed in the literature, that the combination of the outgassing SiO with water vapor forms a kind of gel on cooling and that this strengthens the microstructure again. [1].

*Fig. 8: KDF specimen with 99 and 117 MPa (unused 70-100 MPa)*

Refractory samples from a cowper were also examined (andalusite bricks, operating temperature approx. 1300 °C, 5-10 % $H_2$). Here, too, the same wear and corrosion pattern were found. Under the microscope, also secondary corundum could be found on the hot side, which would also be attacked and dissolved by $H_2$ in the further course. (Fig. 9)

*Fig. 9: Ground cowper brick with sec. corundum on the hot side*

### 3 CHALLENGES FOR SAF WEAR LINING

In the new melting units, the heat for melting the DRI is introduced via the slag to a greater extent than in EAFs. To get the DRI liquid, this process needs about 1650 °C operating temperature. Together with a slag basicity of 1.1 and reducing conditions, the FF lining is highly stressed. A conventional EAF lining will not withstand these conditions for a long time.

### 3.1. Laboratory scale studies

For carburization tests in a test furnace, it was necessary to investigate different FF materials for the melting vessel. For this purpose, crucibles were made from different materials and filled with blast furnace slag and DRI. Thus prepared, they were heated for 20 h at 1650 °C (later operating temperature of the smelter) under a slightly reducing atmosphere. The results show that most of the tested materials would not have reached 10 h operating time.

Initially, bricks were tested that are also in use elsewhere at tkSE and perform very well there, as well as the grade used as the standard lining for the test vessel. Figs. 10-12 list the crucibles that showed the best resistance.

Only three crucibles of the stone products reached 20 h of exposure without breaking through laterally, but here the microstructure is also heavily infiltrated and at least washed out.

*Fig. 10: Mg-Cr (20 % Cr₂O₃), slag is completely infiltrated*

*Fig. 11: Al-C-SiC (10 % SiC), DRI and slag completely infiltrated, microstructure heavily washed out*

*Fig. 12: Andalusite, DRI not, slag little infiltrated, microstructure on the right almost broken through*

The microstructure of a pure corundum stone was completely destroyed (Fig. 13+14).

*Fig. 13+14: Corundum stone with 99% Al₂O₃, completely infiltrated and broken through*

As well as a corundum mullite stone with 9 % $SiO_2$, or a C-corundum chromite stone with 10 % $Cr_2O_3$ (Fig. 15+16).

*Fig. 15: Corundum mullite stone*
*Fig. 16: C-corundum chromite stone*

The results for the monolithic products are also sobering. Even a corundum concrete, which has been used for decades (at least 15 years) in the blast furnace floor as a prefabricated part, was completely destroyed after 20 hours (Fig. 17).

*Fig. 17: Corundum prefabricated concrete of the blast furnace floor*

These results lead to the conclusion, that the use of a freeze lining in the slag zone will be of elementary importance for the high durability of the selected furnace design.

## 4  SUMMARY

DR –Plant:
*   refractory samples of comparable plants all show a strong attack, up to a massive damage of the microstructure by $H_2$
*   The refractory material of future DR plants should have a minimum content of $SiO_2$

Smelter:
*   Conditions in a smelter used for hot metal production (acid slags with basicity of 1.1, 1650 °C, reducing atmosphere) are highly aggressive for the lining
*   Conventional EAF refractory concepts cannot be easily adapted, partly because of the reducing atmosphere
*   Freeze lining is of high importance for the durability of the refractory of a smelter

Next Steps:
➢   Tests must be carried out with mixed gases and hot water vapor
➢   Samples from DR facilities already operating in a conventional manner are to be examined
➢   Temperature gradient existing in real application due to freeze-lining requires modified tests
➢   New refractory products must be developed in close cooperation with the suppliers over the next two years

# DECARBONISATION OF STEEL INDUSTRY AND ITS IMPACT ON FUTURE SLAG

Olena Volkova, Institute of Iron and Steel Technology, TU Bergakademie Freiberg, Freiberg, Germany

## ABSTRACT

The current transformation of the steel industry is presented. The latest and planned measures for $CO_2$ reduction in steel production are exhibited. Two possible production routes, hydrogen-based direct reduction with an electric arc furnace (DR-EAF) and hydrogen-based direct reduction with a basic oxygen furnace via a smelter (DR-smelter-BOF) are explained. Possible changes in future slag and metallurgical treatment, such as desulphurisation and dephosphorisation, are addressed.

## INTRODUCTION

Steel is an indispensable material in our modern society. In 2022, 1878.5 million tons of crude steel were produced worldwide [1]. Only in Germany last year, 36.8 million tons of crude steel were manufactured [2]. This makes Germany the largest steel producer in the European Union. The most important German steel producers with the largest output are thyssenkrupp Steel Europe AG, ArcelorMittal Germany Holding GmbH, and Salzgitter AG.

Today, steel is usually produced mainly in two ways: an integrated route using raw materials (iron ore, limestone, coal, etc.), and a secondary route based on the re-melting of metal scrap. For the integrated route, often called as the primary route, $CO_2$ gas in the amount of 1,880 kg/t crude steel is directly emitted from the coke plant, sinter plant, blast furnace (BF), basic oxygen furnace (BOF), and following continuous casting and forming processes [3]. Herewith, BF has the highest share of $CO_2$ emissions.

With the scrap-based secondary steelmaking route, often called as the electric arc furnace (EAF) route, only a portion of the $CO_2$ emissions is directly associated with the production site. Meanwhile, the most of $CO_2$ emissions are attributed to the generation of electrical energy, which serves as the main source of heating in this route. For instance, crude steel from the EAF route emitted 410 kg/t, assuming the $CO_2$ emissions for the electrical energy production of 300 g-$CO_2$-eq/kWh [3]. If the $CO_2$ load of the electrical energy increases, the $CO_2$ emissions of the secondary steelmaking route would increase immediately. Depending upon the source, the generation of 1 kWh of electrical energy produces 295 to 1005g of $CO_2$ [4]. According to [5], the average $CO_2$ load of electrical energy in the last 5 years was 473 g-$CO_2$-eq/kWh in Germany and 819 g-$CO_2$-eq/kWh in Poland.

Direct reduced iron (DRI) production began its commercial introduction in the late 1950s [6]. DRI was seen as a niche material for use in EAF applications, where large quantities of steel were not required or where sufficient scrap stocks were not available [6]. Currently, about 4.8% of total steel production is made through the direct reduction (DR)-EAF route, using predominantly natural gas, and thus producing lower $CO_2$ emissions compared to the integrated route [7]. For example, the $CO_2$ emissions from DR-EAF route were calculated as 993kg/t crude steel [3]. The top 5 DRI producing countries in 2021 were India, Iran, Russia, Saudi Arabia, and Mexico [8].

The EAF route provides approx. 28% of world steel, accounting only for 8% of the $CO_2$ emissions generated by the steel industry [4]. On the other hand, the integrated route produces almost 72% of steel but is responsible for 92% of the $CO_2$ emissions [4]. In total, the iron and steel industry is the second largest global industrial $CO_2$ emitter, contributing 7-9% of global $CO_2$ emissions [9].

In 2011, a roadmap to achieve a competitive low-C economy in Europe by 2050 was developed [10]. It shows that European industries will have to reduce their $CO_2$ emissions by 80-95% in absolute terms by 2050 compared to 1990 levels, which is a significant challenge. The answer to this challenge is the development and implementation of key pathways for $CO_2$ reduction, such as smart C usage (SCU) and C direct avoidance (CDA) in the iron and steel industry.

SCU includes incremental actions/optimisations for the conventional primary route of steel production and $CO_2$ reduction, involving end-of-pipe technologies, such as $CO_2$ capture and storage (CCS) and C capture and usage (CCU). Examples of SCU are actual processes and technologies developed recently, such as Carbon2Chem from thyssenkrupp steel Europe [11], Steelanol from ArcelorMittal together with Primetals, LanzaTech, and E4tech [12]. CDA includes the scrap-based secondary route of steel production (electric furnace) and the Fe ore-based direct reduction electric furnace route with natural gas and/or hydrogen as a reducing agent, avoiding the use of coal and coke.

Unfortunately, there is a shortage of scrap to fully meet the demand for iron and steel via the EAF route [5]. Moreover, this route cannot be used for all steel grades due to quality restrictions. For example, the production of flat products is still hardly possible in EAFs [13]. The production of manganese-free high-silicon electrical steels is also hardly conceivable via this route. Copper (Cu), Tin (Sn), Chromium (Cr), Molybdenum (Mo), and Nickel (Ni) contaminations of scrap are a vital problem for EAF production of several grades of steel, Fig. 1. In 2019, the average copper content of scrap was 0.34 mass%, exhibiting a clear increase from 0.22 mass% Cu in 1982, and is expected to rise further with continued recycling [4].

Fig. 1: Copper equivalent for different steel groups (adapted from [14]).

Examples of CDA are planned, developed, and researched projects, such as SALCOS® from Salzgitter AG [15], HYBRIT® from SSAB/LKAB/Vattenfall [16], and H2Future from voestalpine [17], etc. Thereby, the conventional blast furnaces will be replaced with direct reduction units, involving hydrogen ($H_2$) as a reducing agent.

## HYDROGEN STEELMAKING

Using $H_2$ as a reducing agent is not a new concept. Direct reduction with a high proportion of $H_2$ has been proven in a MIDREX Shaft Furnace [6]. The Ferrominera Orinoco MIDREX Plant in Venezuela used a steam reformer, resulting in an $H_2$/CO molar ratio in a range from 3.3 to 3.8 [6]. For comparison, in a MIDREX process with natural gas, the typical reducing gas consists of 55 mol% $H_2$ and 36 mol% CO. In 1986, several test campaigns utilized a very high hydrogen content ($H_2$/CO=4.2) [6] in one pilot plant. However, the main aim of today's transformation processes in steelmaking is the renouncement of coal and natural gas and a complete transition to the use of $H_2$ in iron production.

### Two ways of steelmaking with hydrogen

Currently, there are two strategies for implementing hydrogen-based steelmaking, Fig. 2:

- One-step process includes direct reduction unit with EAF (DR-EAF-route), and
- Two-step process contains direct reduction unit, smelter, and BOF (DR-smelter-BOF-route).

The one step process (DR-EAF) with natural gas (NG) direct reduction is the most widespread strategy, especially in countries rich in NG, such as Saudi Arabia, United Arabic Emirates (UAE), Iran, and Mexico [18]. The two-step process (DR-smelter-BOF) with coal based direct reduction has proven to be successful in processing ilmenite- or titanomagnetite-based sponge iron, e.g., in South Africa or New Zealand [18].

In their decarbonization strategies, steelmakers such as ArcelorMittal Germany Holding GmbH [19] and Salzgitter AG [20], rely on the one-step process strategy for implementing hydrogen-based steelmaking. Thereby, capacity of EAF can be up to 250 tons of tapping mass. But Germany's largest steelmaker, thyssenkrupp Steel Europe AG is developing the two-step process [21]. The reasons for the different decisions will be elucidated further.

*Fig. 2: Two strategies for implementing hydrogen-based steelmaking*

Depending on the iron content, iron ore can be classified as [5]:
- high grade iron ore, if its Fe content exceeds 65 mass%,
- medium quality, if its Fe content is from 58 mass% to 65 mass%, and
- low-grade iron ore with Fe content less than 58 mass%.

Typical impurities of iron ore are $SiO_2$, $Al_2O_3$, CaO, MgO, MnO, $P_2O_5$, $TiO_2$, $V_2O_3$, and sulphur. The amount of impurities (gangue) is different for different grades of iron ore. The low grade one can contain more than 19 mass% of gangue, whereas iron ore with Fe>67 mass% (high grade) has less than 3mass% gangue [5].

Most gangue oxides cannot be reduced with hydrogen in direct reduction units, remaining as oxides in DRI (direct reduced iron), Fig. 3. Depending on the degree of metallization, a minor fraction of iron can also remain as an oxide in DRI. As DRI is melted in EAF, gangue oxide and unreduced iron form slag, to which other slag formers, such as lime, dololime, or $SiO_2$ holders/formers, should be added in order to achieve the desired chemical composition and desired basicity ($CaO/SiO_2$) of the slag. The use of iron ore with high gangue content within the one-step process (DR-EAF) leads to an increase in slag amounts in EAF, higher consumption of slag formers (flux), higher electrical energy usage, and increased refractory wear. All these issues contribute to the increased operation costs for the EAF. For example, when using iron ore with 58 mass% of Fe and 19 mass% of gangue, assuming a degree of metallization during DR of 90% and metallic yield in EAF of 95%, more than 530 kg of slag/t crude steel would be produced only from DRI. This simple calculation does not take into account the use of a binder by pelletizing, e.g., bentonite, or the addition of slag formers for necessary metallurgical tasks. Because of this, the total amount of gangue in oxide pellets for DR-EAF process should not exceed 3-4 mass% [22]. Tab. 1 shows the practical and preferred chemical quality for iron ore for the one-step process. However, only a small percentage of global seaborne iron ore (about 3%) comes close to these requirements [7].

The two-step process was proposed for processing DRIs from low grade ores. Specifically, as the first step, a submerged arc furnace (SAF), i.e., a smelter, is utilized to melt and accomplish final reduction. Then, the melt is refined in a BOF. This technological route, involving a split into two separate units, enables efficient separation of the melt from the slag within the first step by the

smelter. Furthermore, the slag obtained from the smelter may be further used for the cement industry [5].

Tab. 1: Chemical composition limits for iron ore by one-step process (DR-EAF), (adapted from [22])

| Sources | Practical limits [mass%] | Preferred limits [mass%] |
|---|---|---|
| Fe | 66.0 min | 67.0 min |
| $SiO_2+Al_2O_3$ | 3.5 max | 2.0 mas |
| CaO | 2.5 max | - |
| MgO | 1.0 max | - |
| $P_2O_5$ | 0.03max | 0.015max |
| S | 0.025 max | 0.015 max |
| $TiO_2$ | 0.35max | 0.15 max |

*Fig. 3: Change of the standard Gibbs free energy for reactions of hydrogen with different oxides of iron ore. Calculated with FactSage 7.2 (FtOxid, all database)*

The disadvantage of the two-step process is a need of two metallurgical units, leading to elevated operation costs. The benefits of the two-step process are:
- possibility of using low-grade iron ore,
- using existing periphery of an integrated steel plant (BOF, casting ladles, ladle furnaces, vacuum degassers, stirring station, and continuous caster),
- ability to produce a wide range of steels, with strict requirements for chemical composition,
- usage of smelter slag for the cement industry.

Many integrated steel plants in the world, as well as in Germany, operate with a tapping mass capacity of 300-400 tons from BOF. The two-step process is expected to be especially attractive for these large-scale units.

Smelter is still named differently by various authors and companies. For instance, the following terms can be found in the literature: submerged arc furnace (SAF), open bath furnace (OBF), or open slag bath furnace (OSBF). Smelter configuration can be circular or rectangular. A rectangular furnace design, considering inner dimensions of 36 x 14 m and six-in-line electrodes (Soederberg electrodes), can reach annual production rates of up to 1.5 Mt/year of DRI charges to the smelter [5]. The electrodes are submerged in the DRI and carbon mixture, resulting in melting upon the application of Joule heat to the burden. A circular smelter, for production capacity of 0.9 Mt/year, having an internal shell diameter of 20m, MgO conductive lining, and three 1700 mm Soederberg electrodes, was presented in [23]. When compared to EAF, the smelter is expected to have a much longer campaign life,

lowering logistic measures of relining (crane, building, frequent downtime, etc.) [24]).

In addition, a larger area of bath surface leads to a lower slag rise. The operation costs for Soederberg electrodes are less than those for graphite electrodes [24]. Tab. 2 provides a comparison of these two strategies.

Tab. 2: Comparison of one- and two-step process strategies for implementing hydrogen-based steelmaking (adapted from [5] and [24])

| | DR-EAF | DR-Smelter-BOF |
|---|---|---|
| **Iron ores** | High grade iron ore pellets | Flexibility for using low grade iron ore pellets |
| **Charge materials** | From 100% scrap to 100% DRI, depending on target steel quality | 100% DRI in smelter, scrap as coolant in BOF |
| **Slag** | Foaming slag with minimum weight and basicity of 1.6 to 1.8, maintaining EAF yields and refractory wear | **Smelter:** slag with low basicity of approx. 1.0; use of existing slag granulation facilities. **BOF:** Typical BOF slag with basicity of 3.6 and higher |
| **Slag usage** | Only minor application known for such slag, worst case: landfilling of the slag is required | **Smelter:** usage in cement industry. **BOF:** Typical usage of BOF slags, higher P content might also allow extended use as fertilizer |
| **Metallic Yield** | High slag amount in combination with high FeO content of the slag results in high Fe losses and thus low yield | **Smelter:** reducing atmosphere in smelter and long setting time ensure low Fe and FeO contents of slag. **BOF:** High FeO content of slag but low slag amount. High metallic yield for the two-step process |
| **Metallurgical tasks** | Limited possibility of Dephosphorization. Desulfurization after EAF during secondary metallurgy | **Smelter:** very good desulfurization. Desulfurization of hot metal before BOF. **BOF:** Very good dephosphorization |

The transformation process to direct reduction assumes many variations in possible technological solutions. Competing companies for steelmaking facilities offer their customers diverse systems. For instance, Tenova and Danieli have jointly developed the ENERGIRON technology, which attracted one of the largest German steel companies, Salzgitter AG (signed a memorandum of understanding, MOU, in 2022) to build a new plant. Accordingly, the plant is designed to have an annual capacity of 2.1 million tons of directly reduced sponge iron [25]. Alternatively, MIDREX technology is attracting new investments. Both technologies for DRI production involve the shaft furnace; however, MIDREX operates at lower pressures compared to ENERGIRON and utilizes a reduction gas generated in an external reformer. Another technology in the DRI market is HYFOR (Hydrogen-based Fine Ore Reduction) developed by Primetals. The world's first HYFOR pilot plant fabricates DRIs from fine concentrates of iron ore after beneficiation. Notably, no additional agglomeration, such as sintering or pelletizing, is required. This approach allows the processing of iron ore concentrate fines that are 100% smaller than 0.15 mm in particle size. Furthermore, it can handle a broad range of ores, including but not limited to hematite and magnetite [26].

## Impact of strategies for implementing hydrogen-based steelmaking on future slag

In contrast to the BF, a DR unit does not separate gangue from iron ore. The gangue is brought into a melting unit within DRI and ends up in the slag after melting. This increases a demand for slag formers and energy consumption. Thereby, an amount of slag formed in EAF via the DR-EAF-route and its chemical composition depend on:

- iron ore grade (gangue oxides: amount, type) and binder used for pelletizing,
- metallization degree in DR-unit,
- charged mixture of materials (DRI, scrap),
- scrap quality,
- added slag formers,
- metallic yield and produced steel quality.

The slag in EAF has a high FeO content, which lowers its desulfurization ability. Desulfurization takes place in a casting ladle during secondary metallurgy on a ladle furnace (LF), stirring stand, or vacuum degassing (VD/VOD) after deoxidation and decarburisation. This can lead to an extended steel processing in a ladle, increased heat losses, increased taping temperatures, an increase in heating during LF, and to an increase of ladle refractory wear.

For proper slag foaming in EAF, no CaO-rich slag should be adjusted, which, together with poorer mixing conditions of EAF compared to BOF, limits dephosphorization. The $Al_2O_3$, $TiO_2$, and $V_2O_3$ from gangue and binder would end up in EAF slag and further worsen dephosphorization [27].

In Tab. 3, the amount and chemical composition of the slags from the conventional scrap-based EAF route and DR-EAF route are compared. The values for the DR-EAF route are from [18], where they were obtained using the mass- and energy balances model by FactSage[tm]. As a results, the higher amount of slag is exhibited for the DR-EAF route.

Tab. 3: Comparison of steelmaking slags for conventional scrap-based route and one-step process strategies for implementing hydrogen-based steelmaking (* quality steel)

| | EAF, scrap-based route* [28] | EAF (DR-EAF-route) | |
|---|---|---|---|
| | | High-quality DRI [18] | Low-quality DRI [18] |
| **Slag [kg/t-CSt]** | 100-200 [29] | 207 | 496 |
| **CaO [mass%]** | 20-35 | 30 | 31 |
| **SiO$_2$[mass%]** | 10-20 | 19 | 19 |
| **Al$_2$O$_3$[mass%]** | 5-15 | 9,6 | 6,2 |
| **MgO [mass%]** | 4-7 | 10 | 10 |
| **FeO [mass%]** | 30-50 | 31 | 32 |
| **CaO/SiO$_2$** | 1-3.5 | 1.6 | 1.6 |

Tab. 4: Comparison of ironmaking slags for conventional integrated route and two-step process strategies for implementing hydrogen-based steelmaking

| | BF [30] | Smelter | |
|---|---|---|---|
| | | High-quality DRI [18] | Low-quality DRI [18] |
| **Slag [kg/t-HM]** | 150-300 [31] | 94 | 276 |
| **CaO [mass%]** | 37-42 | 46 | 37 |
| **SiO$_2$ [mass%]** | 32-38 | 38 | 33 |
| **Al$_2$O$_3$ [mass%]** | 10-15 | 13 | 17 |
| **MgO [mass%]** | 6-12 | 1.4 | 11 |
| **FeO [mass%]** | <1 | 1.3 | 1.1 |
| **CaO/SiO$_2$** | 0,97-1,3 | 1.2 | 1.1 |

The amount of slag formed in a smelter and its chemical composition would depend only on iron ore grade, gangue oxides, binder used for pelletizing. The smelter slag would have the

chemical composition near to BF slag, Tab. 4. This slag would have high desulfurization ability and can be used in the cement industry.

**Processing magnetite ore without oxidising**

Enrichment of magnetite ore via magnetic separation is generally more efficient than that of hematite ore. However, magnetite ($Fe_3O_4$) has lower reducibility compared to hematite ($Fe_2O_3$) [4]. From this reason, magnetite would be converted to hematite before charging into a reduction unit. Herewith, pellets from magnetite ore undergo the oxidation roasting process, encompassing four different stages: drying, preheating (800-900°C), induration (1200-1350°C) and cooling. Purohit et al [4, 32] reported an increase in magnetite reducibility through combining magnetite with lime. Specifically, thermal treatment (approx. 950°C to 1000°C) with fluxes and other additives transforms magnetite to an intermediate reducible form, exhibiting a formation of the $CaFe_3O_5$ phase. This new phase is highly beneficial for increasing the further reducibility and mechanical strength of pellets. As a result, up to 150 kg $CO_2$/t crude steel can be saved [4].

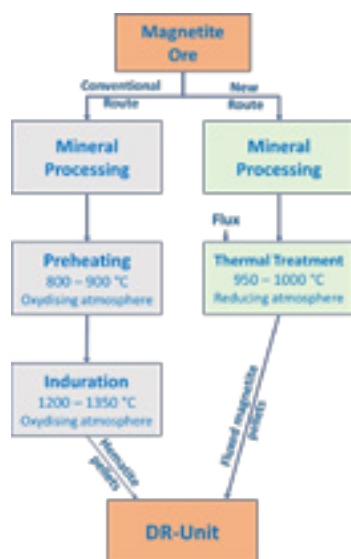

*Fig. 4: Magnetite ore processing route (adapted from [4])*

**CONCLUSIONS**

Steel industry is again in transformation. It will become $CO_2$ neutral in the future. The ongoing transformation of the steel industry introduces new challenges and consequently new tasks for further research. These include the design of iron ore pellets, smelter design, recycling of new slags, refractory design for new steelmaking processes, and more. Currently, manufacturing steel in a completely carbon-free manner remains a significant technological challenge. The Electric Arc Furnace (EAF) requires carbon for proper mixing through the formation of CO bubbles, for slag foaming to reduce energy consumption and refractory wear, and for alloying. Small quantities of carbon will also be used in the smelter. Nevertheless, it is probable that new solutions will be discovered for these issues.

# INNOVATIVE DESIGN AND INSTALLATION TECHNIQUE FOR SLAG DOOR OF CONARC FURNACE – A UNIQUE APPROACH FOR PERFORMANCE HIKE-UP

Prof. Dr. Helge Jansen, Dr. Thomas Schemmel*, Dr. Ujjwal Sengupta, Yarra Prasad, Dr. Murugesan Sathiyakumar & Dr. Debasish Chandra
Refratechnik Steel GmbH, Düsseldorf, Germany, steel@refra.com

ABSTRACT

More vigour refractory design for critical application in steel plant operation plays an important role to control final performance. A smart way of performance augmentation to achieve low specific refractory consumption by suitable refractory quality, lining design and right application/installation practice should be attempted. This paper deals in identification of critical area followed by suitable solution of CONARC furnace to achieve higher performance. CONARC furnace may be sub-divided into micro-zones based on criticality and operational parameters – and slag door has found to be the most critical area due to thermo-mechanical and chemical stresses especially during slag cleaning. An attempt has been made for designing and making a pre-engineered shape cluster at slag door area of CONARC furnace to achieve high structural strength to eliminate brick damage and fall during running, targeting higher and consistent lifetime. Special focus has been made to improve abrasion resistance while designing and special installation technique to address thermo-mechanical issue during operation. A suitable design of refractory, its quality and its installation for good structural strength is thereby most important. Such unique approach has been successfully used in an Indian steel plant. The success based on a case-study has validated the effectiveness of the thought process and the development as well in order to reduce specific refractory consumption.

INTRODUCTION

Apart from operational parameters in any specific steel melting shop[1], appropriate design and installation are the important success keys to achieve high refractory performance. Challenge for the refractory designers is to establish an effective corelation between refractory performance, installation design, shop operational parameters and quality of refractories. Proper corelation helps correct choice of quality to get the intended performance. Each steel plant has their standard operating practices, which may not be largely favourable to refractory lifetime in general. Therefore, designing refractory to suit the existing shop operating practice and logistics should be the approach of refractory designer to move hand-in-hand with the user in order to achieve intended lifetime. Apart from providing the effective product for improvement, proper installation of the product becomes very important. So, refractory designers and manufacturers often acts as a total solution provider which starts from designing refractory and ends up with the intended performance as per shop floor demand.

DEVELOPING MOTIVATION FOR AN INNOVATIVE APPROACH

Performance of refractories is the final measurement of success of a refractory supplier in front of any customer. Performance issues acts as motivation for improvement or development of products,

approaches, or processes as a scope of improvement.

Existing performance issues of CONARC furnace in steel melting shop are –

- Inconsistent performance with uncertainty of lifetime
- Difficulty in planning at shop floor to achieve targeted production with desired productivity and minimum down time
- Sudden failure resulting unsafe situation
- High specific consumption of refractories

EXISTING MECHANISM FOR PERFORMANCE LIMITATION

Like all high temperature process vessels, CONARC furnace also has different zones (Fig. 1) with respect to its unique criticality and quality requirements. They are bottom, side wall, slag door, co-jets, hot spot, and nose. In slag door area slag deposition is quite common phenomenon as after slag draining, it sticks to the refractory of slag door by temperature drop resulting increase in viscosity[2].

Fig 1: Major zones and challenges for refractories in CONARC furnace

The deposition needs to be cleaned intermittently, mostly by mechanical means (say, by using forklifts). Probable mechanical impacts from back side loosens the slag door lining structure due to obvious reason. It was observed that the long bricks used to come out from working lining and fall inside furnace during campaign, limiting the lifetime potential of refractory. This forces intermittent on-line repairs with refractory masses, which not only incur financial loss but also results inconsistent lifetime pattern as well as higher specific consumption of refractory masses with productivity loss which is not desirable. Additionally, it also results un-utilisation of high life potential of other zones.

HOW WE THOUGHT…. THE ROADMAP

It is inevitable that slag temperature comes down after slag dumping followed by metal tapping which increases the viscosity of slag, deposited on slag door refractories-create jamming and difficult to clean smoothly without disturbing refractories and its structural stability. It is also inevitable that for cleaner operation and better control, operators keep on cleaning that area manually by poking with forks of a forklift. This process results inconsistent performance due to many uncontrolled factors.

Special considerations while design –

- To increase unit weight of brick, it is to be pre-assembled structure of different big blocks with interlocking design expected to have better resistance to abrasion by mechanical abuse during slag cleaning in comparison to existing practice.
- To design better brick-to-brick locking
- Blocks are to be installed by special glue at site to have better structural strength.
- User-friendliness by lifting arrangement for individual assembly conforming site facilities
- Size of the blocks by pre-assembling were designed to optimize easy handling, user-

friendly installation, and improvement of structural strength in staggered manner.

Such big blocks are more resistant in loosening from working lining due to higher weight with proper locking during installation and bond formation between blocks by special glue influenced by thermal effect during operation. The assembly has been done by special refractory glue and the joints have tested and found high strength after curing during production process (Fig. 2).

Fig. 2: Brick assembly in production process with special refractory glue
Fig. 3: Brick assembly lifting arrangement designed for easy handling during installation

Lifting arrangement (Fig. 3) has been also designed to have user-friendly installation. Additionally, from the schematic diagram (Fig. 4), pre-assembled structure design clearly indicates the basic concept for improved structural strength of slag door.
Fig. 4: Brick pre-assembled structure design and total assembly

Quality of refractory has been designed in a unique way to optimise between resistance to abrasion, corrosion by slag and thermal spalling by judicious combination of dosage of flaky graphite with high purity magnesia.

Table 1: Refractory quality contributes to performance

| Corrosion by slag | Slag door is used to drain slag, corrosion in brick rather stimulate slag sticking; hence better non-wetting character is required |
|---|---|
| Thermal spalling resistance | Slag door is exposed in thermal stress continuously during the total campaign lifetime-hence graphite plays important role for to improve resistance to thermal cycling |
| Resistance to abrasion | Periodic slag draining, mechanical aberration in cleaning-high strength product is required |
| Optimization of flaky graphite & high purity magnesia | Both raw materials have discrete roles but physical properties are opposite; balancing them in recipe is the design challenge for optimum performance |

Property data of the brand has been tabulated in Table 2.

MANUFACTURING PROCESS AND INSTALLATION

Designed shapes were pressed in high-capacity hydraulic press followed by efficient tempering to achieve high bulk density and low AP with high CCS- both as such and after coking which indicates proper carbon bond in the product. The bricks are then glued during production as per the design (Fig. 2). The assembled bricks are then packed according to the BLOCK numbers for easy identification & installation. The lifting arrangements (Fig. 2) for all assembled blocks are placed as designed and strapped. The concept was tried to prove the worth of the same in an Indian integrated steel plant. The pre-assembled blocks were installed in slag door of CONARC furnace as per the design without any difficulties (Fig. 4). Perfect design includes exact shell profile, and the execution was also satisfactory without any adjustments. High level of dimensional accuracy made things even easier. Performance was found to be quite encouraging. Table 2: Property data of the brand

Table 2: Brand property data

| Physical Properties | As supplied | Coked ASTM C831 |
|---|---|---|
| Bulk Density [g/cc] | >3.00 | >2.95 |
| Apparent Porosity [Vol-%] | <4 | <10 |
| Cold Crushing Strength [N/mm$^2$] | >40 | >20 |
| Carbon Content [Wt-%] | >11 | |
| **Chemical Analysis of Magnesia** | | |
| MgO [%] | >97.8 | |
| Al$_2$O$_3$ [%] | < 0.2 | |
| Fe$_2$O$_3$ [%] | < 0.6 | |

PERFORMANCE AND EVALUATION:

It is obvious that operational parameters have the paramount importance (Table 3) over refractory performance. The performance was satisfactory and shown in Table 4. Due to robust design the refractory, mass consumption is also lower by

approximately 15 t in a single campaign and the lifetime has been improved by >8%.

PERFORMANCE FEEDBACK

A few glimpses of photographs (Fig. 5 & 6) during installation are shown below for better understanding.

Fig. 5: Photograph of installed blocks

Fig. 6: Photograph of installed blocks

Major operational parameters with respect to the specific field trial are as flows:

Table 3: Major Operational Parameters of CONARC furnace during the campaign

| Operational Parameters | |
|---|---|
| Heat Size [t] | 188 |
| Holding time [min] | 60 |
| Arcing time [min] | Arcing 20-22, Blowing 30-35 |
| Tapping $O_2$ [ppm] | 900 |
| Lining Thickness [mm] | 650 |
| Number heats/day | 20 - 22 |
| **Slag Chemistry** | |
| CaO [%] | 30 - 35 |
| MgO [%] | 8 - 12 |
| $SiO_2$ [%] | 10 - 12 |
| FeO [%] | 25 - 30 |

Table 4: Performance detail of trial in CONARC furnace

| Lifetime (heats) | 387 |
|---|---|
| Repair | No repair at Slag Door |
| Gunning consumption standard In trial | 0.5 kg /Ton LM |

The furnace was terminated by plan without any issue of slag door damage. No sign of loosening of slag door structure was observed during operation of full campaign.

The benefits for such design are as follows –

i. Reduction in gunning mass consumption by more than 27%. This has good impact on overall commercials as the gunning mass consumption at slag door area had the lion share

ii. Overall improvement of campaign life by more than 7%

iii. Consistent lifetime, which is safe and predictive from operation point of view

SUMMARY AND CONCLUSION:

Innovative design in slag door of CONARC furnace has proved its efficiency for higher lifetime in CONARC furnace. The salient features of design and performance are as follows:

i. Optimized size of block design to have good resistance to abrasion during slag cleaning

ii. Efficient interlocking between blocks

iii. Unique glue to impart better locking during installation

iv. Better structural strength

v. Quality of refractory has been designed in tailor made way to take care of all issues in slag door

vi. Less specific consumption of gunning mass and proper utilization of other zones to achieve higher lifetime observed in field trial in an Indian steel plant

Finally, it may be concluded that it is possible to design slag door with smart technology to take care of operational issues leading low specific consumption of refractory.

# NOVEL MICROPOROUS MGO–BASED HIGH–TEMPERATURE THERMAL INSULATOR

Rafael Salomão, Leandro Fernandes

São Carlos School of Engineering, Materials Engineering Department, University of São Paulo, São Carlos, Brazil

Luís Carlos Simão

Fibertechnic Ltda., Valinhos, Brazil

## ABSTRACT

This study addresses the development of a novel MgO-based thermal insulator (Nanoxtherm®) whose temperature-resistant microporous structure was engineered to introduce controlled packing flaws amongst their highly asymmetric particles during the compacting. Hard-burnt MgO and dolomite particles were dry-mixed with exfoliated expanded aluminum phyllosilicate and fibers, before being sprayed with colloidal silica. The mixture was uniaxially pressed as boards ($400 \times 100 \times 20$ mm) and dried overnight (120ºC). Samples were thermally treated at different temperatures (120-1100ºC) for the evaluation of their physical properties (compression strength, rigidity, permanent dimensional thermal variation, solid density, total porosity, thermal conductivity), crystalline phases, and microstructure. The microporous microstructure generated during pressing was not significantly affected by thermal treatment below 1100ºC. Samples' thermal conductivity, total porosity, and compression strength varied between 0.20-0.14 W.(m.K)$^{-1}$, 54-56 %, and 29-15 MPa in the 200-1000ºC temperature range, respectively.

## INTRODUCTION

Microporous refractory ceramics are effective thermal barriers for high-temperature insulation due to a useful combination of features. Their microstructure contains pores with a careful balance between volumetric fraction (50-80 %), diameter distribution (0.5-5 microns), and geometry and degree of interconnection (ideally isolated spheres) [1]. The solid ceramic phase surrounding such functional pores shows significant corrosion and densification resistance for avoiding microstructure changes, extending materials' service life, and preventing maintenance operations. In comparison to ceramic fiber-based insulators, microporous refractories show straightforward manufacturing and installation and do not produce hazardous particulate debris [2]. They also show lower thermal conductivity and diffusivity above the temperature range at which heat loss by infrared radiation becomes significant (600-800ºC).

Several combinations of raw materials and processing techniques result in microporous ceramic structures. As an example, the addition of organic particles (e.g., starch and other synthetic polymers) or foams to stable particles' suspension produces cellular ceramics whose total porosity levels can be as high as 90 % [2]. On the other hand, aqueous dispersions of $\alpha$-$Al_2O_3$, solid inorganic porogenic agents ($\alpha$-$Al(OH)_3$, $Mg(OH)_2$, $CaCO_3$), and binders ($\rho$-$Al_2O_3$, calcium aluminate cement) formed castable systems which evolve to microporous refractories of $\alpha$-$Al_2O_3$, $Al_9Si_3O_{13}$, $MgAl_2O_4$, and $CaAl_{12}O_{19}$, after sintering. Since such compounds are intrinsically densification-resistant, they are good candidates for applications that require long exposures to high temperatures [3-6].

This study employed a novel approach based on the production of controlled packing flaws during compacting for generating a microporous MgO-based (MMB) thermal insulator with a large fraction of micropores and preventing their disappearance during service at high temperatures (Nanoxtherm®) [7]. Mixtures of different types of ceramic raw materials containing a large fraction of inner pores and comprised of highly asymmetric particles were shaped as boards by uniaxial pressing assisted by a bonding spray of colloidal silica. In comparison to the other porogenic methods presented, the strategy shows energy-saving straightforward processing, since the structures produced require no previous thermal treatment to attain sufficient strength and porosity for use.

## EXPERIMENTAL

Flat boards of Nanoxtherm® ($400 \times 100 \times 20$ mm) were produced dry-mixing as-received coarse dolomite (($Mg.Ca)CO_3$) and hard-burnt magnesia (MgO) particles with inorganic and polymeric fibers and exfoliated expanded aluminum phyllosilicate (($Mg,Fe^{2+},Fe^{3+})_3(Al,Si)_4O_{10}(OH)_2.4H_2O$). After receiving a short spray of colloidal silica, the mixture was uniaxially pressed (50 MPa, 60 s) and dried overnight at 120ºC. The main boards were then sliced as $100 \times 40 \times 20$ mm prisms and $20 \times 20 \times 20$ mm cubes. Before and after isothermal treatment (200-1100ºC, 2ºC.min$^{-1}$ heating rate, 5 h hold, 10ºC.min$^{-1}$ cooling rate), the samples' dimensions and mass were measured for the calculation of geometric total porosity and permanent dimensional thermal variation. Solid density was measured by Helium pycnometer method in equivalent samples after grounding and cubic samples were used for cold-crushing strength measurements. Fractured surfaces were observed by optical stereoscopic and scanning electron microscopy and the samples' thermal conductivity was measured by the calorimetric method (200-1100ºC). The crystalline phases formed were identified by X-ray diffraction.

## RESULTS AND DISCUSSION

The structure attained after pressing showed a heterogeneous microstructure containing two phases. In the follicular one (Figs. 1a-c), the lamellar particles of phyllosilicate are oriented perpendicularly to the pressing direction surrounding the granular one comprised of MgO and dolomite particles (Figs. 1d-f).

*Fig. 1: Cross-section of as-produced f MMB thermal insulator (Nanoxtherm®): a-c) follicular and d-e) granular phases.*

In comparison to other studies, significantly higher levels of total porosity (54 %) and compression strength (28 MPa) were observed for green-dried samples (Figs. 2a-b) before any thermal treatment. Differently from [3-5] in which porogenic mechanisms were triggered by dehydroxylation reactions, the very small pores observed at the cross-section of the MMB structure were formed due to packing flaws during pressing. Therefore, after the early drying stages, the material is already highly porous and can behave as a thermal insulator.

*Fig. 2: Evolution of physical properties of microporous MgO-based thermal insulator with thermal treatment up to 1100ºC.*

An increase in the thermal treatment temperature of up to 700ºC promoted no significant changes in TP, dimensions, CS, and thermal conductivity (Fig. 2c). The XRD results (not shown here) showed no significant chemical reaction occurred up to that temperature. In the 700-1000ºC range, the decomposition of phyllosilicate and $CaCO_3$ promoted an increase in their solid density. Since those particles were inserted in a non-reactive and rigid MgO scaffold, their volume reduction increased the pore content of the structure [3]. Above 1000ºC, early sintering and formation of small portions of the liquid phase (Fig. 3) led to a densification-related shrinkage and gain of strength. Such results suggest 1100ºC is the maximum temperature of use for the composition in contact with a primary source of heat.

*Fig. 3: Cross-section of MMB thermal insulator of follicular (a-c) and granular (d-e) phases after 5 h at 900ºC.*

Interestingly, a significant reduction in thermal conductivity followed the microstructure changes, and a total porosity reduction was observed between 900-1100ºC, differing from the behavior observed for ceramic fibers blankets, which showed higher thermal conductivity as temperature increased. Such behavior indicates refractory structures containing micropores can scatter infrared electromagnetic heat waves, which are the dominant heat transfer mechanism above 600ºC. In the same temperature range, fiber blankets were less effective in block heat flow due to their excessive pore fraction, which increases the mean free path for photons throughout the structure. Besides superior thermal insulation capacity for the same lining thickness, the novel microporous MgO-based material showed excellent compression strength despite its large pore fraction. Such a synergetic combination of useful properties is due to the fact that the ceramic particles employed show intrinsically high refractoriness and their inter-particle pores are densification-resistant and Taylor-made for scattering heat waves in a wide temperature range.

## CONCLUSIONS

This present study addressed the characterization of a novel microporous MgO-based thermal insulator (Nanoxtherm®) which presented two strategies for thermal insulation. In the first and most significant one, controlled compacting flaws promoted by highly asymmetric phyllosilicate particles became pores of sub-micrometric dimension after demolding and, during the initial heating, the decomposition of hydroxyl-carbonated compounds generated pores at the particles' surfaces. Therefore, up to 600ºC, the large fraction of thin pores reduced thermal conduction through phonons. Secondly, between 600-1100ºC, the slight total porosity reduction observed also favored photon scattering, reducing the thermal conduction that occurred by irradiation of infrared waves. In comparison to other classes of insulators, such as ceramic fiber blankets, the low thermal conductivity and high compression strength levels observed enable his novel material to be employed as self-supporting thinner insulating linings in steel ladles and runners and as other pieces of equipment for primary aluminum processing, petrochemical units, and cement kilns.

## ABSTRACT

Consumption of Electric Arc Furnace (EAF) basic monolithic gunning refractory products will increase with the projected green steel transformation from Blast Furnace-Basic Oxygen furnace (BF-BOF) route to Direct reduced Iron-Electric Arc Furnace (DRI-EAF) route. Dead Burned Magnesia (DBM) is the primary raw material used in the basic monolithic gunning refractory products. Production of DBM from magnesite ore significantly contributes to the greenhouse gas (GHG) emissions. One sustainability approach is to replace the DBM with recycled refractory materials to reduce the carbon footprint of the monolithic gunning products. However, the availability of these recycled materials is limited, and process requires significant investment on the refractory waste sorting systems to control the quality. The approach in this study explores the use of a sustainable and low carbon footprint natural mineral in a monolithic EAF gunning product. Results showed that this approach could reduce GHG emissions by around 30% compared to a standard gunning material comprising only DBM. Mechanical and physical characterization, slag corrosion tests supported with thermochemical simulations and electron microscopy, demonstrated that a product using the natural refractory mineral could exhibit refractory properties comparable to a gunning material comprising only DBM.

## INTRODUCTION

The Iron and steel industry has a significant role on carbon neutrality to achieve the Paris climate agreement's long-term temperature goal of limiting global temperature increase to well below $2^0C$, while pursuing efforts to limit the increase to 1.5 °C. The Global steel industry is responsible for around 11% of global carbon dioxide ($CO_2$) emissions and 7% of global Greenhouse gas (GHG) emissions [1,2]. According to the World Steel Association figures, 28.2% of the crude steel was produced by Electric Arc Furnace (EAF) route and 71.5% was produced from Blast Furnace – Basic Oxygen Furnace (BF-BOF) route in 2022 [3]. Steel decarbonization scenarios of International Energy Agency (IEA) estimate that EAF steel production to double in next 30 years and become the dominant steelmaking technology in the world, as it offers a wider range of decarbonization options compared to the BF-BOF steelmaking to meet mid-century net zero emission goals [1,2].

Magnesia (MgO) based refractory products are the primary refractory materials used in the working lining of both BOFs and EAFs. Demand on these refractories will continue to increase as the steel demand is projected to rise 30% by 2050 [4]. On the other hand, transformation of the steelmaking route from BOF to EAF would result in the additional increase in the consumption of MgO-based refractories because of the expected increase in Direct Reduced Iron (DRI) usage in the commercial EAF processes and with the introduction of new DRI-EAF based technologies like 100% Hydrogen ($H_2$). The DRI-EAF is an important technological pathway for the carbon neutral steel sector with over 15 projects officially announced in Europe for roll out up to 2030 [5].

Dead burned magnesia (DBM) and fused magnesia (FM) are the main raw materials used in the MgO-based refractory products used in EAFs. In 2021, world production capacity of DBM and FM from magnesite ore was $8.85 \times 10^3$ kilotons and $2.15 \times 10^3$ kilotons respectively [6]. DBM production from magnesium carbonate ore ($MgCO_3$) significantly contributes to the GHG emissions which is mainly caused by carbonate decomposition ($MgCO_{3(s)}$ + heat = $MgO_{(s)}$ + $CO_{2(g)}$) and fossil fuel combustion. As a benchmark for natural low-iron DBM production, direct emissions for a modern gas-fired shaft furnace are around 1.65 t CO2-eq/t MgO, while for an old coal-fired shaft furnace, these emissions could increase to around 2.50 t CO2-eq/t MgO [7].

Magnesia containing shaped and unshaped basic refractories are the most widely used refractories in the steel industry. They also have the highest environmental impact among the refractories used in the steelmaking furnaces due to the higher carbon footprint of the virgin raw materials (DBM & FM) used and higher amount of spent refractory waste generation after use. Spent refractories are mostly recycled by using them in open-loop applications such as roadbed aggregates and slag conditioners. Closed-loop recycling of spent refractories is increasing and has potential to generate more economic and environmental benefits by replacing the virgin raw materials. Targets to lower cost and increase sustainability of the refractory products have created a strong demand for closed-loop refractory recycling [8]. However, the supply of these recycled spent refractories is limited and estimated to cover only 7% of the raw material demand for refractories. Since the supply is limited, the price of these recycled aggregates has started to increase in the recent years due to the higher demand in the market. On the other hand, spent refractory waste management market is still under development to meet the quality requirements from refractory producers. To meet these requirements, production processes for recycled aggregates will require higher investment cost sophisticated sorting systems for proper removal of slag, iron, and other impurities to avoid variations in the aggregate quality [9].

Electric arc furnaces have still the highest refractory wear among the steelmaking furnaces. Specific consumption of MgO based refractories in a modern scrap based EAF can be reduced to around 2.0 kg/ton steel in average with application of good refractory maintenance practices. MgO based monolithic hot gunning repair materials play an important role in refractory maintenance to extend the furnace lifetime, to decrease overall refractory costs and finally increase productivity. Another advantage of these hot gunning repair materials is the utilization of higher percentage of recycled aggregates to reduce the carbon footprint of the products for sustainability. However, as outlined in the previous paragraph availability of these recycles is limited at present.

As an alternative approach for the improved sustainability of refractory products and EAF steelmaking, the purpose of this study is to characterize and evaluate refractory properties of an experimental EAF hot gunning product that use a lower carbon footprint natural mineral.

## MATERIALS

Two different silicate bonded EAF hot gunning products designated as A and B were examined and compared. Product A contains only DBM. Product B has a forsteritic type natural refractory mineral as a partial replacement to DBM to reduce the carbon footprint of the product. Table 1 shows chemistries of the products together with the relative carbon footprint of the products calculated based on the direct emissions from DBM usage.

As part of the study two different types of industrial EAF slag sampled before tapping were used for evaluation of slag-refractory interaction. Slag 1 was from an EAF charged with 30% scrap-70% DRI that produce high carbon rebar and construction steel grades. Slag 2 was from an EAF charged with 100% scrap that produce low carbon specialty steel grades. Chemistry and basicity of the slags are shown in table 2.

Tab. 1: Chemistry (on ignited basis) and relative carbon footprint of experimental gunning products

|  | Product A | Product B |
|---|---|---|
| Composition | DBM | DBM / Mineral |
| Chemistry | % | % |
| MgO | 88.6 | 74.9 |
| CaO | 1.8 | 1.8 |
| SiO$_2$ | 6.2 | 17.8 |
| Fe$_2$O$_3$ | 1.8 | 3.8 |
| Al$_2$O$_3$ | 0.9 | 0.6 |
|  | % | % |
| Relative carbon footprint[1] | 100.0 | 70.3 |

[1]: Calculations are based on direct emissions from DBM. Product A that composed to have only DBM is referenced as 100%.

Tab. 2: Chemistry and basicity of the slag 1 and slag 2

|  | EAF Slag 1 | EAF Slag 2 |
|---|---|---|
| Chemistry | % | % |
| MgO | 11.8 | 4.1 |
| Al$_2$O$_3$ | 5.5 | 5.1 |

| B2 | 1.40 | 3.48 |
| B4 | 1.57 | 2.59 |

B2 = CaO/SiO$_2$, B4 = (CaO+MgO)/(SiO2+Al$_2$O$_3$)

## METHODS

Mechanical characterization of the refractory gunning samples was performed by hot modulus of rupture (HMOR) and cold crushing strength (CCS) tests, with variations in temperature ranging from 1000 °C to 1600 °C. Additionally, physical properties such as permanent linear change (PLC) and apparent porosity (AP) were determined from samples treated under the same temperature range.

Static slag corrosion test (cup test) was used to evaluate slag corrosion of the gunning samples. Samples were filled into cylindrical steel moulds by casting with 10% water to form hollow refractory cups. Cups were first dried at 110 °C for 24 hours and then pre-fired at 1200 °C for 3 hours before the corrosion tests. After pre-firing, each cup was filled with 40 g of pulverized slag up to the middle of the hole and then fired at 1600 °C for 3 hours to complete the corrosion test. The test cups were dissected for the visual examination of the slag penetration into samples. Slag penetration area was calculated by using the Image J software. Scanning electron microscopy supported with energy-dispersive X-ray spectroscopy (SEM/EDS) was used for mapping of the interacted zones between samples and molten slag. Thermochemical simulations were performed by using "Equilib" module of FactSage 7.0 to simulate counter-cross inter-diffusion reactions at interface between refractory gunning samples and slags. "Phase Diagram" module was used to estimate the monoxide saturation in the slags. FToxide database was selected for both modules to forecast the possible solid and liquid solution phase formations. Viscosity module was also used the calculate the viscosities of the slags.

## RESULTS AND DISCUSSION
### Mechanical and physical properties

The HMOR test results (figure 1a) indicated that both product A and product B had high and similar strength values at 1000⁰C and 1100 ºC. However, their strength suddenly dropped at 1200 °C and continued decreasing as the temperature increased. Product A's strength decreased at a faster rate than product B's when transitioning from 1100 °C to 1200 °C and stayed relatively stable between 1200 °C to 1500 °C before it reached its lowest value at 1500 °C. Product B showed higher strength values at all temperatures after 1200 °C compared to product A and a sharp decrease after 1300 °C was noted until it reached its lowest value at 1500 °C.

The CCS test results (figure 1b) showed a linear change in the strength values of product A at temperatures ranging from 1000 °C to 1600 °C. Product B also had a linear increase in strength values between 1000 °C-1400 °C, but a slight decrease was observed after 1400 °C. Product B had higher strength values between 1000 °C-1400 °C compared to product A, before strength values for both of the products reached to very close numbers at 1600 ºC.

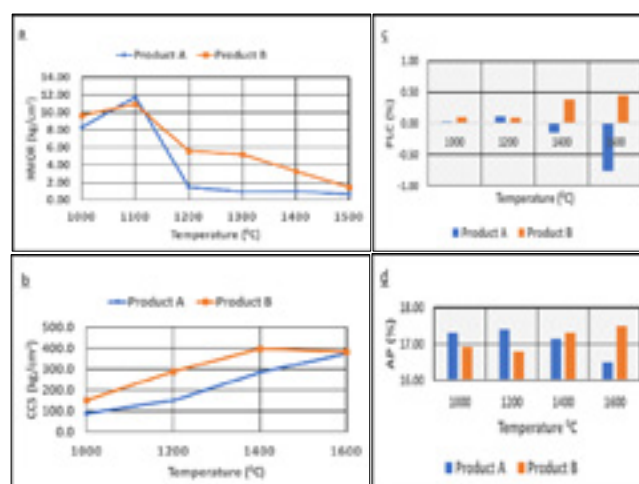

Fig. 1: (a) Hot modulus of rupture (HMOR), (b) Cold crushing strength (CCS), (c) Permanent linear change (PLC) and (d) Apparent porosity (AP) of the samples in the temperature range from 1000 °C to 1600 °C.

PLC and AP test results are given in figure 1c and figure 1d. According to the results, product B showed a positive PLC at temperatures after 1200 °C, while product A showed a negative PLC. As a result of these changes in the PLC, an increase in the AP of product B was observed for temperatures between 1400 °C and 1600 °C, while the AP of product A decreased. The reason for the thermal expansion in Product B is that the SiO$_2$ in the mineral used in its composition is converted into forsterite (Mg$_2$SiO$_4$) by reacting with the MgO in the DBM used. This conversion and the additional sintering resulted from this conversion allowed product B to have higher HMOR and CCS strength values than product A in the temperature range of 1200 °C to 1400 °C. However, at temperatures after 1400 °C, the AP increase in product B decreased its strength and the strength values of both products were found to be close to each other at 1600 °C with strength of product B was still slightly higher.

### Slag corrosion cup tests

After conducting slag corrosion tests, the cross-sectional surfaces of the samples (figure 2) were examined. Overall, it was observed that slag 1 caused less penetration compared to slag 2. This is evident from figures 2a and 2c, where slag 1 remained still in the cup while Slag 2 almost completely penetrated and rarely remained in the cup, as seen in figures 2b and 2d. The calculated slag penetration areas shown in figure 2 revealed that there is no considerable difference found on the corrosion profiles of product A and product B when reacted with both type of slags.

327
*Fig. 2: Slag penetration into samples after slag corrosion cup test at 1600 °C for 3 hours, (a) Product A – Slag 1 (b) Product A – Slag 2 (c) Product B – Slag 1 (d) Product B – Slag 2*

MgO saturation lines calculated by Factsage for both slag 1 and slag 2 are shown in the phase diagram in figure 3. Diagram indicated that slag 2 is in the undersaturated region in terms of MgO dissolution. However, slag 1 is in the saturated region. In addition, the viscosity values calculated by Factsage presented in figure 3 confirmed that slag 2 (0.124 Poise) has considerably lower viscosity than slag 1 (0.327 Poise). Given its high fluidity and insufficient MgO saturation, slag 2 caused more penetration and corrosion in the samples than slag 1.

*Fig. 3: MgO saturation lines of slags at 28% CaO and 35% CaO in the system $CaO-SiO_2-FeO-MgO-5\%Al_2O_3$ and slag viscosities calculated by Factsage at 1600 °C 1 atm.*

To better understand the mechanisms behind the slag corrosion, the interaction of each gunning sample with slag 1 and slag 2 was evaluated separately by thermochemical simulations and SEM/EDS examinations.

**Interactions of Product A with Slag 1 and Slag 2**

According to the thermochemical simulations in figure 4a and b, when slag mass % increases at 1600 °C, the percentage of the solid monoxide phases MgO (MeO_A#1) and solid forsterite (Fo) in product A decreases linearly and continues to dissolve in the liquid phase (SLAGA#1). During this dissolution MgO reacts with the FeO in the slag to form a secondary solid phase called magnesiowustite (MW) as symbolized as FeO (MeO_A#1) in the graphs.

Comparison of the two interactions shows that MW solid phase in product A- slag 2 graph reaches its maximum value at a slag mass ratio of 50% (figure 4b), while product A-slag 1 graph shows a higher starting point of MW phase dissolution at a slag mass ratio of 70% (figure4a). This is because of the higher FeO content of slag 2 compared to slag 1 (table 2) and explains why slag 2 caused higher dissolution of MgO from product A compared to slag 1 in the slag corrosion cup tests. Another important difference between two

interactions is the presence of the FeO(MeO_A#1) and MgO (MeO_A#1) phases in solid form in the graph for slag 1 on the 100% slag axis, while complete dissolution of these phases is observed in the graph for slag 2 which also indicates the higher corrosive behaviour of slag 2.

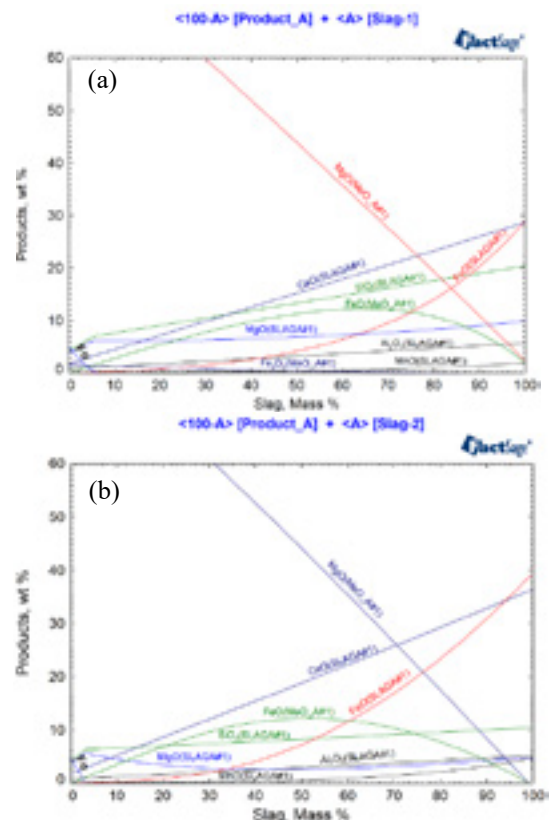

*Fig. 4: Percentage of products (phases) formed versus slag-refractory mass ratio in the refractory-slag system at 1600 °C 1 atm determined by Factsage (a) Product A – Slag 1 reaction, (b) Product A – Slag 2 reaction.*

Figure 5 shows SEM images and EDS analysis of the slag-refractory interaction zones for product A-slag 1 (figure 5a) and product B-slag 2 (figure 5b). Iron (Fe) was mapped in blue colour on the images for better distinction between the interacted zones. EDS analyses were performed on three zones marked in yellow on the images with zone 1 serving as the initial reaction area between refractory and slag, zone 2 as the intermediate reaction area and zone 3 as the refractory zone. High levels of Mg and Fe were detected in zones 1 and 2, together with other elements (Ca, Si, Al and Mn) mostly originating from the slag. It was also observed that Fe content increased from zone 3 (refractory) towards zone 1 where the initial

*Fig. 5: SEM images and EDS analysis of the interacted zones on the samples after slag corrosion test, (a) Product A – Slag 1, (b) Product A – Slag 2*

reaction with slag and refractory had occurred. These findings are in line with the MW formation shown in corrosion models predicted by the Factsage thermochemical simulations given in figure 4.

**Interactions of Product B with Slag 1 and Slag 2**
According to the thermochemical simulations in figure 6a and 6b, the corrosion modeling of product B shows differences compared to Product A given in the previous section. The main reason for this difference is the higher forsterite ($Mg_2SiO_4$) phase presence resulting from the use of refractory mineral in product B. Simulations in graphs showed that with the increase in the percentage of slag, the solid forsterite (Fo) dissolves and passes into the liquid phase (SLAGA#1). Complete dissolution of the forsterite occurs at a slag mass ratio of 26% for the slag 1-product B reaction (figure 6a), while this dissolution occurs at a slag mass ratio of 18% for the slag 2-product B reaction (figure 6b). This difference explains why Slag 2 caused more corrosion in product B compared to Slag 1. During forsterite dissolution some of the MgO in the forsterite is transformed into the solid MW phase by reacting with the FeO in the slag, while some of it passes into the liquid phase with the SiO2 in the forsterite.

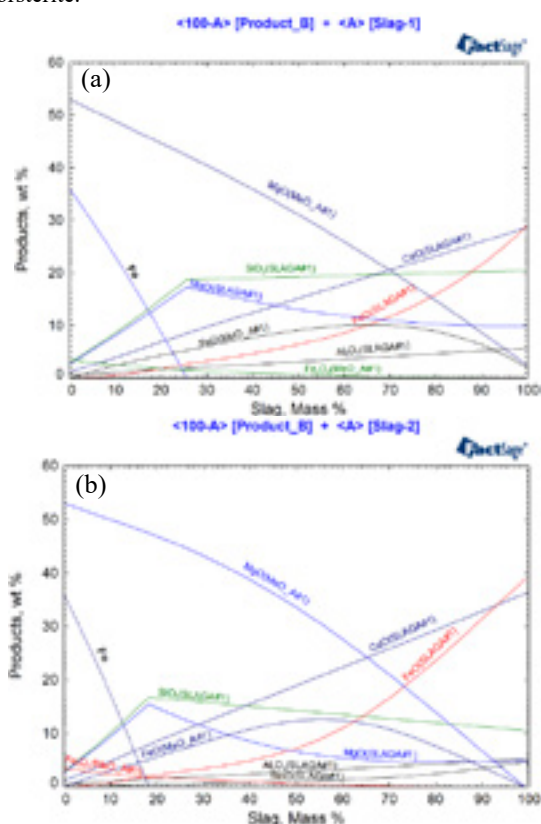

*Fig. 6: Percentage of products (phases) formed versus slag-refractory mass ratio in the refractory-slag system at 1600°C 1 atm determined by Factsage (a) Product B – Slag 1 reaction, (b) Product B – Slag 2 reaction.*

As seen in the SEM images and EDS analyses given in Figure 7, high percentage of Silicium (Si) was detected in the regions where the first interaction with the slag and refractory took place (zone 1). This confirmed forsterite dissolution in slag which was also predicted with the thermochemical simulations. In addition, in the areas where slag penetration took place, refractoy grains that were not fully dissolved (zone 2 and zone 3) in the slag were also detected. The Mg and Si peaks detected in EDS scans indicated that the chemistry of these grains are in line with the to the forsteritic type of composition and some Ca and Fe were also found on the grain boundiries which is an indication of grain dissolution started in the slags (zone 2 and zone 3 in figure 7a).

*Fig. 7: SEM images and EDS analysis of the interacted zones on the samples after slag corrosion test, (a) Product B – Slag 1, (b) Product B – Slag 2*

**CONCLUSIONS**
This study has shown that the utilization of a lower carbon footprint natural mineral in EAF gunning products is viable option in improving sustainability. Product B, which contains the lower carbon footprint mineral has given a 30% reduction in GHG emissions. This lower carbon footprint product displays notable refractory properties with good high temperature strength, physical properties, and slag corrosion resistance when compared to a standard gunning material comprising only DBM.

The study has revealed that product B exhibited higher HMOR and CCS than product A at temperatures ranging from 1200 °C to 1600 °C, with a slighlty higher AP at 1600 °C due to the thermal expansion in product B related to forsterite formation. Although product B has a higher AP than product A at 1600 °C, the slag penetration areas of both products were found to be similar, and MgO stauration and viscosity of the slags were the significant factors in slag corrosion of both products. The thermodynamic simulation outcomes were consistent with corrosion test results and SEM/EDS investigations, with the formation of magenesiowustite (MW) and forsterite dissolution determined in the slag refractory interaction zones.

Further research is intended to gain a more in-depth understanding of the corrosion mechanism. It is also proposed to carry out field trial assesments in different EAF operating conditions to understand the performance of the Product B.

# REFRACTORY SOLUTIONS TO "THE CARBON CHALLENGE"

*Yawei Li, Ning Liao, Shaobai Sang*

The Key Laboratory of Refractories and Metallurgy, Wuhan University of Science and Technology, Wuhan, 430081, China
National-Provincial Joint Engineering Research Centre of High-Temperature Materials and Lining Technology, Wuhan, 430081, China

## ABSTRACT

Nowadays the global demand to lower $CO_2$ emission brings new opportunities and challenges to the refractory industries. Refractories as traditional materials are much concerned by its end users of high temperature industries, such as iron and steel making, cement producers. Of course, the transformation to green, lower $CO_2$ emission and new technologies in these high temperature processes will bring much impact on the refractory materials and lining concept of the furnaces. In present paper, several solutions are addressed to the above challenges, including recycling of solid wastes into lightweight mullite aggregates, optimization of cement bonded unshaped refractories and application of layered structure compounds into carbon containing refractories.

## 1 INTRODUCTION

Refractories are key materials for high temperature industries, such as cement, metallurgy, and petrochemical. In fact, the $CO_2$ emission of these conventional industries plays an important role for the global carbon emissions. Therefore, it is of great importance to design superior refractories to tackle the carbon emission challenges. Generally, several solutions are proposed: 1) recycling of solid waste as raw materials for high value-added refractories 2) reducing carbon sources from carbon containing refractories; 3) promotion of the application of monolithic to reduce $CO_2$ emissions during production, application and recycle after use.

Recently, much attention was paid on the above topics. As for recycling of solid waste or mineral tailings, especially for aluminosilicate, much effort were spent on preparation of dense or lightweight mullite clinkers by utilizing coal gangue, fly ash, and kyanite tailings, etc. In addition, the green and low carbon technologies to produce cement bonded unshaped refractories were widely used in many high temperature applications due to their good handleability, high green and hot strengths. In most cases, CaO content should be reduced for better high temperature performances of unshaped refractories. Therefore, several additives with high specific surface area, such as zeolite, M-S-H, hydrotalcite are proposed to stimulate the hydration of cement phases and subsequently optimize the comprehensive properties.

For carbon containing refractories, nano carbon technology can reduce the total carbon content while improving the elevated temperature properties, especially the thermal shock resistance. More recently, investigations focus on the replacement of traditional graphite flake with layered structure compounds, including BN, $Ti_2AlC_3$ and $Cr_2AlB_2$. These compounds have much better oxidation resistance and their by-product during structure transformation could further enhance the refractories, similar to graphite's well-known deformation, strengthening and toughening mechanism.

In present paper, we summarize several research works from our group regarding the topic of green and low-carbon refractories.

## 2 SOLUTIONS TO $CO_2$ CHALLENGES

### 2.1 Recycling of solid wastes into lightweight mullite aggregates

As a matter of fact, million tons of aluminosilicate solid wastes are dumped every year globally. One promising application is the recycling of valuable alumina and silica and make them into mullite-based materials (mostly used below 1500°C due to certain impurities). For our works, the chemical compositions of raw materials are listed in Table 1. As a reference, 95.6% grade III bauxite and 4.4% microsilica (named as M) are mixed and fired at 1400-1600 °C for 3h. In comparison, new batch with 51% grade III bauxite, 34 % fly ash and 15% reactive alumina powders (named as M-F) are prepared [1]. The microstructures of obtained specimens are shown in Fig.1. The mullite crystal size increases with the rise in temperature, and the fly ash containing specimens (M-F) present remarkable growth of mullite. Therefore, it is reasonable to see that the specimens M-F have higher strengths than those of the specimens M. In addition, the higher firing temperature brings no further contribution to the enhancement due to the abnormal growth of mullite and the generation of more liquid phase. Consequently, the proper developed mullite structure contributes to optimized/refined pore structure and thus decreases the thermal conductivity to a certain content, where the lowest value reaches 0.616 W/(m·K) (at 1000 °C) for the fly ash containing specimens fired at 1500 °C. It should be noted that the firing temperature above 1500 °C would increase the thermal conductivity significantly due to the enhanced liquid sintering behaviour.

Table 1. Chemical composition of raw materials (wt.%).

| Raw material | $SiO_2$ | $Al_2O_3$ | $Fe_2O_3$ | CaO | MgO | $K_2O$ | $Na_2O$ | $TiO_2$ | LOI |
|---|---|---|---|---|---|---|---|---|---|
| Grade III bauxite | 26.94 | 55.97 | 1.74 | 0.15 | 0.25 | 0.36 | 0.03 | 2.65 | 11.28 |
| Fly ash | 50.52 | 36.84 | 3.13 | 4.07 | 0.56 | 0.25 | 0.07 | 1.23 | 2.77 |
| Coal gangue | 45.48 | 34.88 | 0.37 | 0.89 | 0.15 | 0.11 | 0.01 | 0.52 | 17.58 |

*Fig. 1: Microstructures of the obtained mullite specimens fired at: 1400 °C (a), 1500 °C (b), 1600 °C (c).*
*Fig. 2: Mechanical properties of different specimens (a) and thermal conductivity of obtained mullite specimens at 1500 ℃ (b).*

Furthermore, the combination of coal gangue and fly ash is also feasible to prepare lightweight mullite with low thermal conductivity. Three batches with coal gangue : fly ash : reactive alumina ratio at 60:10:30, 50:20:30, and 40:30:30 (named as F10, F20 and F30, respectively) were fired at 1500 ℃ for 3 hours. The results (Fig.3) show that the increase of fly ash promotes the growth of mullite, while it also improves the thermal conductivity from 0.512 W/(m·K) to 0.719 W/(m·K) (at 1000 ℃). Therefore, the content of fly ash should be elaborately designed to achieve lower thermal conductivity with good mechanical properties.

*Fig. 3: Microstructure (a, b) and thermal conductivity (c) of mullite specimens fired at 1500 ℃.*

In addition, kyanite is regarded as one of important aluminum silicate ($Al_2SiO_5$) minerals in refractory field, which accompanies volume expansion during the heating-up process and exhibits excellent alkali attack resistance due to the structure feature of mullite-high silica glass phase after its complete mullitization [2]. In our experiments, zircon containing kyanite tailings ( 54.01%$Al_2O_3$, 33.13%$SiO_2$ and 7.63% $ZrO_2$) were used to prepare lightweight mullite at 1400-1650 ℃. The phase composition indicates that kyanite finishs its mullitization process at 1400 ℃ and zircon decomposes into $ZrO_2$ and $SiO_2$ above 1500 ℃. Consequently, lightweight mullite and high silica glass composite with a great number of close pores (nearly 20%) can be prepared at 1600 and 1650℃ (Fig.4). Additionally, the alkali attack test (in mass change ratio) shows mullite and high silica glass composite has good potassium vapor alkali attack resistance (Fig.5).

*Fig. 4: Microstructure of lightweight mullite specimens fired at 1650 ℃.*  *Fig. 5: Relationship between porosity and alkali attack on specimens.*
## 2.2 Optimization of cement bonded unshaped refractories

Calcium aluminate cement (CAC) is an important binder for unshaped refractories with the advantages of excellent green strength, good handleability, and good high temperature properties. In fact, the hydrates in cement hydration process determine the early strength, microstructure evolution and comprehensive properties [3]. Generally, metastable $CAH_{10}$, $C_2AH_8$ hydrates will transform into stable $C_3AH_6$ and $AH_3$ (Fig.6), resulting in deteriorated mechanical properties and coarser pore structures [4]. In the last decades, researchers have been trying to stimulate the formation of stable and laminar hydrates such as $C_2AH_8$ and to hinder the formation of granular $C_3AH_6$ ones. As for the formation of $C_2AH_8$, our previous works find out that silicates such as zeolite can stimulate the hydration of cement and induce the formation of $C_2AH_8$ (Fig.7) [5]. Similar to $C_2AH_8$, $C_4AcH_{11}$ as another similar layered structure compound, can enhance remarkably the performances of castables because it could construct the most complicated pore structure both at early stage and elevating temperatures. Our recent work finds out that Mg-Al hydrotalcite (M-A-H) can accelerate the hydration and stimulate the formation of $C_4AcH_{11}$. Besides, another layered structure compound, magnesium silicate hydrate (M-S-H), can promote the hydration of cement and the formation of $CAH_{10}$ and $C_2AH_8$. With the combination of M-S-H with CAC, the mechanical properties of lightweight mullite castables can be further improved (Fig.8). In order to further reduce the thermal conductivity, the air entrainer is also incorporated. The results show that the introduction of 0.01% or 0.02% of air entrainer can remain a high strength, while further optimized pore size distribution (especially between 4~40 μm) can be obtained. With the presence of abundant close pores, the thermal conductivity is obviously reduced, where the lowest one for the 0.02% of air entrainer containing castables can be 0.601 W/(m·K).

### 2.3  Application of layered structure compound into carbon containing refractories

Carbon containing refractories were widely used as functional component for converter, ladle, and continuous casting. The presence of carbon mainly in form of graphite is important for thermal shock resistance and slag corrosion resistance. However, the drawbacks are the poor oxidation of graphite and risk of carbon pick up in clean steel-making process. Therefore, many efforts were made to reduce carbon content in refractories. At the beginning of 21$^{st}$ century, nano structured matrixes were proposed by the addition of nano carbon and oxides into refractories, which include nano carbon black, carbon nanotubes, graphene, expanded graphite, *in-situ* catalytic growth of nano carbon and whiskers, nano alumina, and spinel powders. These additives can reduce total carbon content and dramatically optimize the thermal shock resistance and toughen the refractories by the aid of crack bridging, crack deflection, and whisker pull-out mechanisms.

Recently, non-carbon-based compounds with layered structure, such as *h*-BN [6], $Ti_2AlC_3$ [7] and $Cr_2AlB_2$ [8] were used to replace flaky graphite (Fig.9). These compounds could improve oxidation resistance while their layered structure toughened the mechanical properties. Howerver, the toughening mechanisms are completely different from each other. BN remains its structure even at high temperature, while $Ti_2AlC_3$ transforms into a mullite-$Ai_2TiO_5$-TiC/$TiO_2$ core-shell structure. Similarly, scattered BN, $Cr_2O_3$, and $Cr_3C_2$ was generated within the matrix with the addition of $Cr_2AlB_2$ (Fig.10). These structure transformations contribute to obviously optimized pore structure and induce the growth of whiskers, which eventually improve the fracture behaviours of alumina-carbon refractories. As shown in Fig.11a, the introduction of 0.5 wt.% BN (Fig.11a) can improve the displacement of $Al_2O_3$-C refractories remarkably, while the further increase of BN can still increase the toughness and remain good strength. Besides, the addition of 1 wt.% $Ti_2AlC_3$ contributes to larger displacement (2.6 mm to 3.5 mm) and all the three batches obtain comparable fracture loads (Fig.11b). It should be mentioned that excess addition of these layered structure compound would decrease the bonding strengths like conventional graphite flake.
*Fig. 9: Microstructure of several additives with layered structure.*

*Fig. 10: Microstructure of $Al_2O_3$-C refractories (1400 °C*3h) with addition of graphite (a), BN (b), $Ti_2AlC_3$ (c) and $Cr_2AlB_2$ (d) respectively.*

*Fig. 11: Load-displacement curves of $Al_2O_3$-C refractories (1400 °C*3h, room T wedge splitting test) with addition of graphite, BN (a), and $Ti_2AlC_3$ (b).*

## 3. CONCLUSIONS

Refractory technologies can contribute significantly to reducing global $CO_2$ emission. Recycling of coal gangue, fly ash, and kyanite tailings can be adopted to prepare lightweight mullite clinkers for low thermal conductivity refectory products. As for carbon containing refractories, several non-oxides such as BN, $Ti_2AlC_3$ and $Cr_2AlB_2$ could replace flaky graphite in order to remarkably improve the thermal shock resistance as well as oxidation resistance. Besides, as for the unshaped castables, the additives such as zeolite, M-S-H, and M-A-H with high specific surface area and different functional groups would accelerate the hydration of CAC and induce the formation of layered structure hydrates $C_2AH_8$ and $C_4AcH_{11}$, which decrease the demand of cement and improve the high temperature properties.

# PREFABRICATED SLAG DOOR SOLUTION – TO SOLVE A WELL-KNOWN OBSTACLE TO INCREASE EAF PERFORMANCE

Bernd Buchberger*, Dietmar Jammernegg, Mario Valdes, Andreas Viertauer,
Mayerton Refractories Ltd, UK
Sreedharan Unni Chakkungal, Asif Ahmad, Muhammad Abubaker
National Steel CO. LTD., KSA

## ABSTRACT

One of the bottlenecks for high performance of EAFs is extended refractory wear in the slag door area. This often limits the lifetime of the complete vessel. Problems are mainly related to grade selection, lining process/installation, and process conditions.

To overcome this issue Mayerton developed solutions with preassembled slag doors. The given example describes the implementation of such a slag door at National Steel (NASCO) in Saudi Arabia. NASCO is operating a split type EAF, which gives the opportunity to place such a preassembled slag door into the furnace.

Detailed engineering of the overall situation of the EAF (condition of furnace shell, installation equipment in steel plant, space for the block) is mandatory and has to be taken into account. For the correct choice of the refractory grade the knowledge of process parameters is essential as well. Specifics about the refractory detail engineering, grade selection, installation and performance results will be given in-depth in the paper.

## INTRODUCTION

Under the umbrella of Al Ittefaq Steel Products Cooperation. (ISPC), National Steel Cooperation. (NASCO) was established in 2004 with an annual capacity of 0.5 million metric tonnes (MT) of steel billets. Since then, NASCO has strategically enhanced its capacity to achieve 1.0 million MT production in 2014 through technical upgrades to maintain the quality and meet the increasing demand.

NASCO is a steel melt shop that produces steel billets for the ISPC group. They mainly produce construction steel grades through EAF-LF-CCM route. Steel scrap and direct reduced iron (DRI) are used. A state of the art, highly productive EAF with continuous DRI feeding system and advanced auxiliary equipment to ensure consistent production of quality steel is the primary facility. Novel is that an induction furnace (IF) with twenty ton capacity runs in combination with the EAF to increase overall output in a cost-effective manner. One ladle furnace (LF) is taking care for refining to ensure the desired quality is achieved. The steel is cast at a four strands billet continuous casting machine (CCM) with very high level of automation capable of producing billet sections of 130 mm to 180 mm[1]. The product mix spans from low-, medium- to high carbon grades. The official equipment manufacturer was Siemens-VAI.

The EAF is producing 24 – 28 heats per day. Due to the planned plant utilization and planned maintenance stops the lifetime is around 400 heats. After the end of the campaign the whole furnace is taken out with a heavy crane and replaced by a newly relined or repaired vessel which is directly taken into operational mode. One of the obstacles to extend the lifetime and to reduce the number of maintenance cycles is the high pre-wear at the slag door.

RESULTS AND DISCUSSION

The EAF is lined in a common lining configuration. Above the three layers of permanent lining which are fired magnesia bricks a hearth ramming mass for the bottom and banks is placed. The side wall is lined with different MgO-C grades in respect of balanced lining, especially for the hot spot areas.

Fig 1. Lower shell of the EAF with refractory lining included.

The slag door area is the clearly defined weak point and is the main reason to take the furnace out of operation due to high pre-wear compared with the rest of the lining. Notable is the additional downtime for gunning the slag door area. It was decided to select a new refractory material together with a custom-fit engineered slag door solution.

Refractory selection:

For choosing the best refractory material in an EAF, especially in the slag door area, several facts have to be taken into account: The atmospheric conditions as this area has a close contact to the normal atmosphere outside the furnace, thermal shocks and regular contact with slag. On the one hand high carbon content would increase resistance against slags but would on the other hand decrease oxidation resistance of the material. Antioxidants increase corrosion resistance but decrease hot strength of the refractory material.

The finally chosen refractory grade is based on the furnace operating conditions. The chosen material is based on high purity fused magnesia (FM 98) with a C/S ratio >2, a carbon content of around 15%, and a resin bond. For restrengthening the brick structure a well-known combination of metal powders was added to the brick (metallic Al and Si)[2,3], dense pressing of the bricks was chosen as the densifying method to prevent steel and slag infiltration into the brick's microstructure. For the final assembly of the slag door the single bricks were glued with a glue based on polyurethane with oxidic additions to give a maximum strength to the final piece part. The preassembly assures a perfect fit of every single brick in this critical area, avoiding steel or slag penetration into brick joints.

Slag door detail engineering:

There are some main facts to consider. Most importantly, the upper part must be separably from the lower part of the kiln shell. This gives the opportunity to set a prefab solution into the furnace from above. Furnace steel shells which have been in operation for several years normally show thermos-mechanical deformation. This deformation has to be considered for the detailed design engineering.

NASCO runs an EAF split type vessel which gives the opportunity to set a preassembled slag door solution in one piece with a crane into the furnace during maintenance or refractory rebuilt. Figure 2a shows the slag door refractory design with the handling slings. The jamb bricks (Fig. 2b) will be settled separately after setting the block to close the gap to the wall lining (Fig. 1).

(a)                          (b)
Fig. 2. (a) Prefab slag door with lifting slings,
(b) with jamb bricks set in place.

Before setting the prefab slag door into its final place the flatness of the surface was checked (Figure 3 a). To avoid steel and slag penetration in the horizontal gap between standard lining and the prefab block it was decided to use a mortar between the seating pad and the prefab block (Figure 3 b).

(a)                          (b)

Fig. 3 (a) check the flatness, (b) mortar patching.

Figure 4 depicts the prefab block manipulation on the lifting device before setting. It has to be noticed that the mortar layer brings an additional benefit for the fine adjustment of the block due to the reduced friction.

Fig. 4. Setting in place the preassembled slag door block.

Essential for the stable mechanical fixation are large vertical pilar bricks, which are set left and right of the slag door block (Figure 5 a and b). The necessary tolerances/gap between the pilar bricks, jam bricks and upper shell are essential for mounting the upper shell and to compensate the brick elongation during furnace operation (Figure 6). The gap between bricks and water cooled panels was closed with conventional patching mortar.

(a)                          (b)
Fig. 5. after setting the upper shell (a) left and (b) right pillar bricks were set as connection to the wall lining.

Fig. 6. Prefab slag door solution after mounting the upper shell.

The complete newly relined furnace with the prefab slag door went into operation directly after completion of the maintenance on October 12th 2022. The EAF campaign duration was scheduled for exactly 3 weeks with high plant utilization with very limited time for gunning. Figure 7 gives an impression about the furnace refractory after 20 heats while Figure 8 shows the status at 338 heats after gunning.

336
Fig. 7. EAF after 20 heats.

Fig. 8. EAF after 338 heats.

The furnace was taken out of operation after 422 heats. The expectation of achievable lifetime, maintenance service activities and residual lining thickness was more than fulfilled. Figure 9 shows the lower shell area after dismantling from the upper shell with the slag door directly before wrecking. The remaining thickness of the prefab slag door would allow additional approximately >100 heats. This positive result with the residual thickness is the ignition to modify the whole lining configuration to extend the planned EAF operation.

Fig. 9. After demounting the upper shell – lower shell with slag door area.

In a further trial the target of 450 heats has been reached without any problems in the slag door area.

CONCLUSION

Besides safe handling and fast mounting the prefabricated slag door solution showed its main benefit – debottlenecking a critical area of refractory service life and therefor extend the furnace operation with reduced downtime for gunning which led to higher plant productivity and reduced OPEX. Nevertheless, the right choice of the refractory material was essential as well.

# IMPROVE FURNACE LIFETIME AND OPERATIONAL SAFETY BY ROBOTIC GUNNING REPAIR

Christian Wolf, Velco GmbH, Velbert Germany

## ABSTRACT

The hot gunning repair of furnaces, ladles, RH degasser snorkels is a well-established procedure to increase the refractory lifetime and avoid break outs. However during the repair, the aggregate will not be available for production. It is the steelmaker's intention to reduce the time loss for the gunning repair, and to perform the repair efficient and with the highest standards for operational safety. This paper describes the recent developments in robotic gunning with the help of integrated TV cameras and laser scanners.

## LADLES

The refractory wear at ladles is mainly in the slag zone and the lip area. At plants with secondary metallurgy the slag zone wears out even more quickly. Sometimes the top of the lining, the lip ring, becomes damaged due to slag removal with a breaking out machine. Consequently, a ladle can be put back into operation very quick after a hot gunning repair focussed only on the slag zone. The most convenient location to carry out a hot repair is the tilting stand, where the slide gate is repaired. It is possible to use a manual gunning lance but this results in high physical stress for the worker.

When using a gunning robot the gunning repair is:

- Quicker, because of higher gunning rates.
- More efficient, because of the well directed jet.
- Easier because there is no physical stress for the worker.

Velco has built different solutions for this task, depending on the plant layout and if the ladle is in horizontal or vertical position. One version is a fixed installation consisting of a rotating lance that can move in and out, running on a beam structure. For each repair stand one robot is required (Fig. 1)

Fig. 1 Stationary ladle gunning installation

The second version is a gunning lance which is mounted on an electric trolley that can drive from a parked position to one, or more repair positions. Fig. 2 shows a manipulator at a ladle with a liquid content of approximately 150t of steel, for the repair of ladles which are in a tilting stand, at voest alpine in Linz, Austria.

Fig. 2 Mobile lance trolley for ladle gunning

## ELECTRIC ARC FURNACES

In the past 25 years Velco has supplied 22 gunning robots for electric arc furnaces. However, due to the different layouts of the melt shops no two robots are alike. It has to checked for collisions with T&P robot, oxygen lance or door ram.

In between the vessel exchange sequences, hot gunning is the preferred solution to keep the furnace operative. When using hand lancing a pipe of typically 6 to 8m in length is introduced through the slag door. The gunning rate is only 60 to 80 kg/min. Handling the pipe is hard work and not all areas at the furnace can be reached, especially close to the slag door.

There is the option to install a CCTV camera in the gunning head (Fig. 3), so that it is possible to watch and record the gunning repair. The operator can stay safely in the pulpit.

Fig. 3 Video of gunning with Camera in gunning robot head

The new design developed in 2021 is called METOP. It has a pure mechanical lift system by an electro-mechanical cylinder. No hydraulic required Fig. 4.

Fig. 4 new design of Metop

Next step of improvement is the use of pre-programmed gunning programs. The operator can pre-select areas to be gunned on a touch screen. He can save different gunning programs depending on the gunning strategy and furnace life. The robot then automatically repairs only the selected locations (Fig. 5)

Fig. 5 Zone selection for automatic gunning

Lucchini Industries Steel Plant in Lovere /Italy was looking for a new gunning manipulator to improve operational safety, but had no space near the electric arc furnace. They decided for the crane held gunning manipulator PNEUTOP. Which is parked approx. 40m away from the furnace in a special structure. For the gunning repair, the manipulator is picked up by the overhead crane (Fig.6) and lowered from the top into the furnace. The PNEUTOP is connected to a pressure vessel machine.

Fig. 6 PNEUTOP robot moved by a crane

The refractory gunning material is supplied in BIG BAGs that are filled into the pressure vessel via a filling hopper. Via a radio remote control the operator moves the lance to the desired location, starts and stops the pressure vessel machine and controls the gunning water flow.

Using the gunning manipulator the repair is quicker and the operational safety is improved (Fig. 7) .

Fig. 7  hot gunning repair with PNEUTOP

**LASER SCANNER**

In cooperation with IMSI (Industrial Measuring Systems Inc., Toronto, Canada) it has been developed a design where a high speed laser scanner with its own swing arm is attached to the boom of the gunning robot.
The laser arm is mounted very compact onto the gunning robot boom and requires no extra space on the shop floor. During parking and gunning operation the laser and the arm  head towards the robot base. Only for the measurement the arm swings over the furnace shell (Fig. 8a, b). The laser is protected against heat and dust by enclosures, heat shields and air cooling. The laser scans the shape of the refractory lining, compares with the initial brick lining and gives recommendations where gunning should take place. So the gunning repair can be performed automatically.

Fig. 8 a, b Gunning robot with laser scanner arm in parking, resp. scanning mode

## RH-DEGASSERS

The high quality demands of the automobile industry, leads to an increase in the proportion of melts routed via the vacuum degasser. Snorkel lifetime is an important factor in achieving high availability, of the RH-degasser. Due to the reaction with steel and slag, the snorkel wears out both internally and externally. Often the outside lining is damaged by slag removal with scrapers or de-bricking machines. It is of primary importance to keep the system safe and to avoid break outs of hot metal, but the service time is limited as the sequences of the steel plant have priority. Any unplanned exchange of the snorkels should be avoided. Outside gunning is a common practice. However, the workplace is exposed to heat and the operator likes to stay away from the snorkel, so the gunning is not always well directed and has high rebound losses.

Some steel plants have a service car to which a platform for hand gunning is attached. So the distance is smaller and the rebound lower. Nevertheless, inside gunning is not possible because of the danger of dripping hot steel or slag from the RH-vessel.

Hence, using a gunning robot is beneficial for outside repairs, because the gunning is better directed and the physical stress on the workers is eliminated. A robot is essential for the inside repair of the RH snorkel. If gunning is performed well, consumption is in the range of 0.5kg/t steel. Typically gunning takes place after 6 to 8 treatments.

Most robots have two gunning lances, one for inside and one for the outside repair. Lances and lifting arm are based on a frame that can rotate by 180° (Fig. 9 a, b). One lance can repair the inside of snorkel A, while the other is doing the outside repair of the snorkel B. When this is finished, the main base rotates, so snorkel A is repaired on the outside and snorkel B is repaired on

the inside.

Fig .9 a, b Gunning manipulator with 2 lances

The advantage of placing the scraper and the gunning robot on the same service car is the time saving in handling. The complete operation of snorkel cleaning and inside/outside gunning can be performed in approx. 12 -15 min. (Fig 10).

Fig. 10 service car with scraper and gunning robot (picture SMS group)

For the inspection and documentation of the wear pattern it is possible to attach a camera on the robot (Fig. 11). Instead of the inner gunning lance, a water cooled camera is driven into the snorkel. A video can be made of the snorkel or the lower vessel area. Using positioning encoders, the area of robot in the video can be exactly determined (Fig. 12). The video can be stored and the wear can be documented. By this process the lifetime can be optimised. The inspected areas can be precisely repaired with the robot.

Fig. 11 water cooled inspection camera

Fig. 12 Inside picture of RH-snorkel

The operator can either use automatic programmes or may control the maintenance process via a radio remote control (manually).

**CONCLUSIONS**

Gunning robots help to increase productivity and the safety of the refractory brick lining. In combination with cameras and laser scanner they bring a new level of operational safety to the steel mill.

# EFFECT OF MAGNESIA GRAIN SIZE COMPOSITION ON INTERNAL PORE STRUCTURE IN MAGNESIA CARBON REFRACTORY BRICKS

Tetsuya Furukawa, Gaku Shimada and Eiji Ishihara
Shinagawa refractories Co., Ltd., Bizen, Japan

## ABSTRACT

The permeability of MgO-C brick is highly influenced by its pore structure, a three-dimensionally connecting complex structure. It was indicated in the author's previous study that the permeability of MgO-C brick is influenced by not only the apparent porosity but also other factors. The particle size distribution coefficient corresponding to the Fuller index of the Andreasen's equation is defined as the apparent q value ($q_{AP}$). Relations between $q_{AP}$ and the specific surface area of inner pores as well as the tortuosity factor of pores were examined in this study. It was clarified that there exists a correlation between the $q_{AP}$ value and specific surface area of inner pores as well as between the $q_{AP}$ value and tortuosity factor of pores. The tortuosity factor of pores was found to be the parameter which most considerably influences the permeability of MgO-C brick.

## INTRODUCTION

One of the deterioration mechanisms of MgO-C brick which is exposed to elevated temperatures is oxidation-reduction reaction between MgO and C, namely, MgO-C reaction. A series of reactions which were proposed by R. J. Leonards et al. [1] in the earliest investigation study work on MgO-C reaction are (1) decomposition of MgO to Mg and O, (2) attachment of generated oxygen (O) on C surface, (3) generation of CO on C surface and (4) reduction of MgO by generated CO gas. In each reaction the transfer of gas components, attachment/detachment of gas components and interface reactions are engaged.

A backscattered electron image of MgO-C brick structure is shown in Fig. 1. MgO-C brick structure is composed of magnesia particles, scaly graphite and a great number of pores with various sizes which are extended in magnesia and graphite particles.

*Fig. 1: Backscattered electron image of MgO-C brick structure*

Influenced by the morphological feature of being composed of magnesia and graphite particles, as well as by particle size distribution and the filling factor of raw materials, these pores are three-dimensionally connected to demonstrate a complex pore structure. The pore structure influences the ease of internal gas movement, which is indexed with a parameter of "permeability" expressed with equation (1) [2], [3].

$$K_p=\varepsilon^3/2\tau^2 S_v^2(1-\varepsilon)^2=f(\varepsilon, \tau^{-2}, S_v^{-2}) \tag{1}$$

Where,
  $K_p$: Permeability[m$^2$]
  $\varepsilon$ : Apparent porosity
  $\tau$: Tortuosity factor of pores
  $S_v$: Specific surface area of inner pore[m$^2$/m$^3$]

While, as expressed with equation (2), tortuosity factor of pores, $\tau$, is defined as the ratio between actual distance and shortest distance.

$$\tau=l_e/l \tag{2}$$

Where,
  $\tau$: Tortuosity factor of pores
  $l_e$: Actual distance[m]
  $l$: Shortest distance[m]

Controlling the pore structure in MgO-C brick is thought to be quite important with the prospect of lowering permeability contributing to suppression of MgO-C reaction. Relations between apparent q value ($q_{AP}$) and various physical properties of MgO-C brick examined in the authors' previous study presented at the UNITECR 2022 by G. Shimada et al. [4] by introducing particle size distribution expressed as apparent q value ($q_{AP}$), which is defined referring to the Fuller index in Andreasen distribution [5], one of the theoretical formulas used for filling particle bodies. As shown in Fig. 2 and Fig. 3, it was clarified that, in accordance to lowering of $q_{AP}$, the permeability of MgO-C brick was lowered and a marked change was observed in the apparent porosity of MgO-C brick at approximately 0.28 of $q_{AP}$.

*Fig. 2: Relation between $q_{AP}$ value and permeability [4]*

*Fig. 3: Relation between $q_{AP}$ value and apparent porosity [4]*

Since lowering the permeability of MgO-C brick, which was observed in the previous study work, cannot be explained simply by change of apparent porosity, it is inferred that permeability is influenced by other factors of pore structure expressed in right-hand side of equation (1). In addition to the apparent porosity, influences of other parameters of pore structure, namely, specific surface area of inner pores and tortuosity factor of pores, on

permeability of MgO-C brick were studied by examining relations between $q_{AP}$ and these parameters.

## EXPERIMENT

Five (5) different MgO-C brick samples were prepared with varying particle size distributions of raw material MgO particles. Blend compositions of each MgO-C brick sample are comparatively shown in Fig. 4, along with particle size distribution, which, similarly to the previous study work, is expressed as apparent q value ($q_{AP}$). Portions of fine and middle particle size magnesia particles in each MgO-C brick sample were elaborately adjusted so that MgO-C brick samples A-E exhibit around 0.28 of $q_{AP}$, at which a marked change in apparent porosity was observed in the previous study.

| Coarse → Fine | | | | | |
|---|---|---|---|---|---|
| Sample name | A | B | C | D | E |
| $q_{AP}$ | 0.289 | 0.282 | 0.276 | 0.270 | 0.258 |
| MgO — Coarse grain (Upper 1mm) | a | a-c | a-2c | a-3c | a-5c |
| MgO — Fine grain (Under 1mm) | b | b+c | b+2c | b+3c | b+5c |
| C | Fixed amount | | | | |
| Binder | Changed by surface area of MgO | | | | |
| Additive | Fixed amount | | | | |

a: 0~40, b: 40~80, c: 0~5

*Fig. 4: Blend compositions of MgO-C brick samples*

Each MgO-C brick sample was prepared by a combination of raw material mixing with high-speed mixer and shaping with uniaxial pressing machine. After firing the MgO-C brick samples embedded in coke breeze at 1500°C, their physical properties, specific surface area of inner pores and tortuosity factor of pores, were evaluated. These physical properties were measured by mercury porosimetry in accordance with JIS R1655 (Test methods for pore size distribution of fine ceramic green body by mercury porosimetry). The specific surface area of the inner pores ($S_v$) and tortuosity factor of pores ($\tau$) of each MgO-C brick sample were calculated with equation (3) and equation (4), respectively.

$$S_v = -Y_s \Sigma P \Delta V / W_s \gamma \cos\theta \tag{3}$$

$$\tau = \{D_{avg}^2 / 96 K_p (1 - Y_s V_{tot}/W_s)\}^{1/2} \tag{4}$$

Where
$S_v$: Specific surface area of inner pore[m²/m³]
P: Injection pressure of mercury[N/m²]
V: Injection volume of mercury[m³]
$\gamma$: Surface energy[N/m]
$\theta$: Contact angle[deg]
$Y_s$: Apparent density of sample specimen[g/m³]
$W_s$: Weight of sample specimen[g]
$\tau$: Tortuosity factor of pores
$D_{avg}$: Weighted average pore size[m]
$K_p$: Permeability[m²]
$V_{tot}$: Whole volume of injection mercury[m³]

## RESULTS

The relation between the apparent q value ($q_{AP}$) and specific surface area of the inner pores is shown in Fig. 5.

*Fig. 5: Relation between $q_{AP}$ value and specific surface area of inner pores*

In association with the lowering of $q_{AP}$, the specific surface area of the inner pores in the MgO-C brick sample increased with a strong correlation. The relation between $q_{AP}$ and the tortuosity factor of the pores is shown in Fig. 6.

*Fig. 6: Relation between $q_{AP}$ value and tortuosity factor of pores*

In accordance with the lowering of $q_{AP}$, the tortuosity factor of the pores increased with moderate correlation.

## DISCUSSION

Equation (1) indicates that permeability is in proportion to apparent porosity and permeability is in inverse proportion to the squared value of the specific surface area of inner pores and tortuosity factor of pores. That is, permeability of MgO-C brick is influenced by its apparent porosity as well as by its specific surface area of inner pores and tortuosity factor of pores. The relation between permeability and specific surface area of inner pores is shown in Fig. 7, and the relation between permeability and tortuosity factor of pores is shown in Fig. 8.

*Fig. 7: Relation between specific surface area of inner pores and permeability*
*Fig. 8: Relation between tortuosity factor of pores and permeability*

Both figures affirm that permeability of MgO-C brick is in inverse proportional to the squared value of both specific surface area of inner pores and tortuosity factor of pores. When comparing the correlation of these two factors, it can be concluded that influence of the tortuosity factor of pores on permeability is bigger than that of the specific surface area of inner pores. It is safe to conclude that the highest influencing factor on permeability of MgO-C brick is the tortuosity factor of pores.

**CONCLUSIONS**

The follwing are conclusions attained in this study

- The specific surface area of the inner pores
  increases with a strong correlation to the lowering the $q_{AP}$ value.

- The tortuosity factor of pores increases with
  moderate correlation to the lowering the $q_{AP}$ value.

- The permeability of MgO-C brick is influenced by
  the apparent porosity,specific surface area of
  inner pores and tortuosity factor of pores.
  The highest influencing factor on permeability is
  the tortuosity factor of pores.

**ABSTRACT**

One of the most important strategies for the development of converter steel production technology is achieving high resistance of the working lining, which corresponds to the minimum unit cost of refractories and eliminates the downtime associated with repairs [1,2].

The choice of the optimal lining treatment system during a campaign is formed, ultimately, for reasons of reducing unit costs and process requirements [3,4].

When assessing the prospects for the development of the refractory market for steel-smelting complex of Ukraine, we can assume the further development of the tendency to reduce the specific consumption of refractories per 1 ton of steel by increasing the operational durability of the converter's linings. This is evidenced by indicators of persistence in Europe, Japan, China and the United States, one and a half to two times or more surpassing the average indicators achieved in Ukraine.

Modern technologies allow performing "hot" repairs of the converter lining without its decommissioning during the working campaign. The main methods of refractory restoration: gunning (semi-dry, flare), patching (molded products, masses), remaining (modified) slag blowing with nitrogen [5-7].

Such methods, as a rule, are not long-lasting (5-35 minutes) and, with considerable efficiency, keep up the rhythm of the production process in the workshop.

By results of laboratory researches the hot repair self-flowing mass "GIR-RB-X" and flux-modifier "GIR-MBF" on the basis of secondary, domestic raw materials, were developed.

Obtained results were employed for the improvement of skull coating process and hot repairing method of the converter lining at several metals works of Ukraine.

Industrial tests of the self-flowing, hot repair magnesium mass, and flux-modifier on lining of heavy-load converters in the conditions of PJSC "DMK" and PJSC "MK "Azovstal" are carried out.

The LLC "GIR-Engineering» company organized serial production of self-flowing magnesium mass "GIR-RB-X" brand and magnesium flux-modifier "GIR-MBF" brand on production capacities in Ukraine (Dnipro region)

## Introduction

Nowadays, at least two dominating approaches to the production run of converters refractory lining, are existent. One of them ("North-American") is based on the principle of continuous maintenance of the refractory lining and assuring its maximum permissible lifetime, so-called "everlasting lining". The second ("European") approach of steelmaking process is principally focused on the maximum steel output through minimum heat cycle. In this respect, all maintenance activities on the refractory lining are minimized and rigidly scheduled. Converter lining lifetime with this approach, amounts to 5-7 thousand heats. Ukraine steelmaking companies have embraced "European" approach with particular modifications into the maintenance strategy, specifically, scheduling of specially treated slag splashing by nitrogen. The method of local hot repairs BOF lining using magnesium self-flowing masses is also widely used.

It is known that the converter refractory work is subject to uneven wear during the campaign. This is due to a number of factors, the main of which are the corrosive effect of slag and the erosive effect of the circulation flows of the gas-slag-metal emulsion. Due to the characteristics of the hydrodynamics of the converter process and the specificity of its cyclicity (filling-sampling-discharge), i.e. constant tilting of the unit with products of melting, zones of advanced wear of the lining are formed. These are mainly the zones of the lower bell, the trunnions zones, the drain zone and the tap zone. A diagram of the zone masonry of the converter and an example of the topography of the uneven wear of the lining is presented in Figure 1.

*Fig. 1: Zonal lining of a 350 - ton converter and an example of non-uniformity of wear: 1 - tap area; 2 - axle zones; 3 - zone of the lower cone. Color on topography - residual lining thickness: blue - max, red - min.*

One of the most efficient technologies for increasing the lifetime of BOF refractories all over the lining is "Slag Splashing". Slag coating on the lining surface exercised by means of nitrogen jets that splash specially treated slag with special magnesium flux-modifiers / additives during 2-8 min. This skull serves as a consumable refractory layer – "secondary lining", which protects BOF refractory brickwork against adverse process factors (wear). Chemical and mineralogical composition of the splashing slag, is thoroughly selected for particular manufacturing conditions of the given enterprise. The selection of the optimum slag composition, is normally based on the concentration of two compounds: iron oxide $FeO_x$ and magnesium oxide MgO, which is followed by the selection of the required low-melting and high-melting phases mix. Low-melting phases secure firm binding of the slag and the refractory, while high-melting phases promote the "backbone" formation assuring its strength and refractory properties.

There are two main methods of hot repairing the most "difficult" areas of advanced wear of the trunnions and tap-hole zones lining. This is a method of gunning (semi-dry, flare) and patching by self-spreading mass. At the same time, gunning is carried out using special equipment, which requires preparation and adjustment before the operation, which entails considerable time costs that disrupt the production schedule. So, the time spent on gunning, comes to 30-50 minutes. Often, saving time (reducing exposure time, reducing mass consumption) for such an operation adversely affects the quality of repair and reduces the durability of the restored section.

The most promising alternative to the gunning of local wear, which does not require special equipment and personnel training, is a patching by self-spreading, magnesium masses.

The raw-material base of Ukraine metals sector, is notable for the absence of high-quality magnesium raw materials. The solution to this problem is the development of manufacture using secondary magnesium raw-material for slag-forming mixes and repair masses.

345

**Procedures for evaluation of slag physical properties meant for skull coating**

Skull layer formation is governed by certain thermophysical conditions, among those are thermal field distribution of the primary and "secondary" lining (heat removal), volume ratio of solid phases, thermal effect of solidification, temperature range of melting, adhesion, etc. Slag viscosity, its amount, lance design, its height above the bath level, liquid bath depth, blowing modes, etc., exert profound influence on the skull layer formation [8].

The offered procedure on qualitative evaluation of physical and chemical properties of the skull layer, comprises 4 steps.

At the first step, emphasis was laid on the preparation of refractory "pads" samples that model the facility lining. To attain adequate resemblance to the refractory material surface, the samples were annealed in the furnace to enable surface carbon release and simulate the first wear stage. The annealing process was exercised by thermal-cycling method (1000↔1600 °C) for 1 hour (2-3 thermocycles) in the oxidizing medium. Further, the "pad", under converter process temperatures, was soaked with slag, to simulate the second wear stage of the refractory. Finally, the required (similar) refractory surface was obtained, akin to the actual surface susceptible to wear in the course of converter campaigns. Figure 4.1. shows outer appearance of the refractory pad treated sample of 30x30x30 mm.

*Fig. 2: Treated refractory pad modelling converter lining (30x30x30 mm), A – depth of slag penetration into the refractory.*

Activities at the second step included immediate modification of the BOF slag by a number of magnesian materials of different chemical and mineralogical composition. Figure 3. represents the second step in the graphic form.

*Fig. 3: Overview of the equipment employed in the second modelling step. 1 – electrical motor; 2 – rack; 3 – molybdenic shaft with spindle; 4 – bearing assembly; 5 – copper water-cooler; 6 – molybdenic crucible with molten slag; 7 – thermocouple; 8 – Tamman furnace; 9 – logging unit with analog-digital converter; 10 – computer, 11 – refractory sample – pad.*

Basic slags exhibit low viscosity at steelmaking temperatures (1550–1650°C). Basic slags viscosity raises together with the increase of CaO content and MgO content in particular. A substantial rise in the slag apparent viscosity is observed at the presence of 1-5 mm non-dissolved particles (e.g.,periclase "grains") bringing about a marked increase of internal friction. Figure 4. demonstrates empirical relation between the viscosity of final converter slag and the volume of dispersed solids ("grains").

*Fig. 4: Relation between treated slag viscosity and non-dissolved "grains" volume (WT %).*

It is evident from the diagram that the increase in the volume of dispersed solid (non-dissolved) phase in the slag, results in the viscosity growth. At reaching some 6-8% by the "grain" phase, the slag displays "satisfactory" viscosity for splashing process. Whereas at gaining 10% and over by the "grain" phase, a dramatic rise in the slag viscosity occurs, stemming from the melt heterogenization. These data correlate well with the physical (cold) modelling of splashing process as considered above.

Based on the studies performed at this step, we have formulated a conceptual approach to physical and chemical properties of modifying fluxes meant for treating slag to be further splashed. Thus, the presence of low-soluble components in magnesium-containing materials at the amount of 0.65-0.35 (WT %), min. 80% of those having 2-6 mm fraction, promotes their uniform distribution over the entire volume of the molten slag as early as within first seconds of nitrogen purging. It is attained thanks to the presence of readily-soluble, fine components in the material that contribute to the dispersion of additions. The said additions upon coming into contact with the slag, are assimilated (dissolved) in a speedy manner, thus increasing MgO content in the slag. This ratio of low-soluble and readily-soluble components leads to the formation of a considerable amount of high-melting ferritic phases in the treated slag, and formation of a firm "backbone" in the cooled skull layer due to non-dissolved fractions – "grains".

To verify and corroborate the above-mentioned approach to slag modification for further splashing, the third step dealt with the evaluation of adhesion of the treated skull to periclase-carbon refractories. The adhesion was assessed in terms of limiting wetting angle of the "pad" by a slag droplet, as we as thermal resistance (low fusibility) of the cooled layer.

The diagram representation of the third simulation step is given in Figure 5.

*Fig.5: Relationship of the limiting wetting angle and FeO content in the slag.*

On a treated refractory corner heated to temperature of a converter lining prior to purging (1500°C), Figure 6 (a), a droplet of modified slag was placed. By means of dimensional scaling of photo- and video-recordings of the wetting process, limiting wetting angles of slag droplets of various chemical composition, were determined.

It has been established that the main parameters guiding the wetting, are FeO and MgO content in the slag.
*Fig. 6: Schematic representation of skull layer adhesion to the refractory "pad".*

As such, at FeO content of over 25% and MgO content of 6-7%, the wetting angle is under 10°, i.e., very small (nearly no wetting). With FeO content decrease, wetting angle grows and at some 5% FeO content, it is averaging 90°. It is noteworthy that the rise in MgO content in the slag, results in the wetting decline of periclase-carbon material, herewith, the degree of wetting angle elevation, depends heavily on the slag oxidation. At FeO content of 25%, MgO content gain from 6 to 16% brings about wetting angle increase from 10 to 25°, at FeO content of 15%, similar MgO content gain would cause wetting angle change to 90°.

Together with support of limiting wetting angle (θ) that reflects efficient "bonding" of the skull with the lining surface, we have managed to achieve high refractoriness of the protective layer. To estimate the temperature range of treated skull layer melting, the "pad" sample with a slag droplet thereon, was put into a horizontal heating furnace. In addition, the "corner" was placed in the horizontal position (Fig. 6 (b)). Once the design temperatures (1550 – 1650°C), were reached, the sample was turned at 90° angle, thus simulating vertical wall of the converter lining (Fig. 6 (c)). By means of continuous photo- and video-recordings, concurrently with temperature assessment, the evaluation of the skull lifetime within the temperature range of converter heat, was performed.

Figure 7 illustrates a skull layer sample with high adhesion characteristics to the refractory and high thermal resistance.

*Fig. 7: Skull layer behaviour in the melting temperature range. I. – high adhesion and low fusibility (>1680°C; II. – high adhesion, low refractory properties (1646°C), minor skull "crawling" is reported; III. – low adhesion, unsatisfactory refractory properties (1596°C), skull "crawling".*

As indicated in the figure 7 (I.) *(flux-modifier "GIR-MBF" brand)*, at attaining high temperatures at the final stage of the converter heat (1680°C and over), the skull layer sample has not reached the melting point and has not lost the adhesion to the "corner", i.e., the "crawling" of the protective layer is not reported. On the second case (figure 7 (II.)) near 1638 °C, observed the surface melting of skull sample, and rise of temperature to 1646 °C led to minor skull "crawling" down to vertical wall. Unsatisfactory quality of skull sample shown on fig. 7. (III.). The sample of modifier slag in the range of 1580 – 1596 °C is fully crossed in liquid phase and trickle down.

This result can reasonably prove the quality of the skull layer and demonstrate the correctness of the agent chemistry selection to be used for slag modification before splashing.

As mentioned earlier, the optimum slag chemistry is attained upon reducing FeO content and supersaturating slag with MgO. Slag oversaturation with MgO has a fundamental importance for slag treatment before splashing, since it binds Fe oxides into high-melting magnesia-ferrites displacing low-melting calcium ferrites.

Slag solidification (loss of mobility) and skull formation are reported when the volume ratio of solid phases solidifying therein, crosses the boundary required for their percolation, thus forming robust framing within the molten slag. Consequently, the "penetration" of solid components from the modifying agent into the slag ("under-dissolved grains"), enhances this process.

Experiments have shown that the optimum slag composition is reachable upon reducing FeO content down to 13-15%, slag oversaturation with MgO to 10-12% and introducing of low-soluble fractions (2-6 mm) of 6-8% weight ratio into the modifying agent. This correlation secures adequate volume of high-melting phases, while the presence of non-dissolved fractions (low soluble components) in the slag, results in the formation of the "binding backbone" within the skull layer. It is attributable to the origination of the protective skull layer featured with wear-resistance, mechanical strength, and high adhesion to the refractory lining surface.

Based on the obtained results, flux-modifier "GIR-MBF" brend for final converter slag was developed and tested in the industrial environment, the flux-modifier being of magnesia-based, produced from available domestic materials comprising both low-soluble and readily-soluble components. With regard to the above mentioned, 2-6 mm fractions made up min. 80% of the total volume of low-soluble components.

As a result, industrial testing modifier additives to optimize the cost and implementation of the developed "mini-regulations" in PJSC "MK AZOVSTAL" overall, the total consumption of magnesium materials for melting (at the end of the campaign 2000- 2936 heats.) was reduced by 20 % (compared to the beginning), and decrease unit costs of steel production at 0,85 \$/t

**Procedures for evaluation of self-flowing magnesium mass for local hot repair BOF lining**

In order to test and optimize the physico-chemical properties of the welding mass, a technique has been developed. A unit for the experiments was a rotary-type heating furnace. The layout and appearance of the experimental installations is presented in Fig. 8.

*Fig. 8: General view (a) and installation diagram (b, c) of an experimental test bench of a rotary type furnace: 1 - engine;*

347

*2 - furnace body; 3 - gas-oxygen burner, 4 - drive shaft; 5 - heat insulation; 6 - periclase-carbon lining (converter refractories); 7 - welding mass of the "GIR-RB-X" brand; 8 - working surface of the refractory (impregnation with melting products);*

The experimental research methodology was divided into three stages.:
- *first stage;* preparation of refractory samples for patching. Melting in the cavity of the furnace slag metal emulsion. The temperature of the liquid bath is 1630°C. Forced wear of the internal space was carried out by rotating the furnace around its axis with a frequency of 10-12 revolutions/min. The uneven wear of the internal space was achieved by tilting the furnace relative to the horizontal axis. Prolonged contact (3.5 hours) of the working surface with a slag-metal emulsion imitated erosion and corrosion wear of a periclase-carbon brick with infiltration of liquid smelting products into the refractory, which corresponded sufficiently to the mechanisms of wear in actual conditions of converter smelting. After rendering adequate properties of the working surface of the refractories, they moved to the second stage - patching the worn area with the "GIR-RB-X" developed mass.
- *second stage;* filling with the repair weight of the zone ahead of wear. Before filling the mass into the cavity of the furnace, the melting products tapped. The temperature of the working space after the melting tapping is 1450°C. The mass was fed in heat into the inner space on the worn area of the lining. Mass consumption per operation is 0.5 kg.
The test of the "mobility" of the mass was evaluated when the furnace was rotated around the horizontal axis by reversing it in two directions by 45°. The filling of the worn area occurred evenly, without premature sintering of the mass. Then the furnace was returned to its original position and held for 15 min, until the sample was fully heated and sintering (Figure 9 a)).

*Fig. 9: a) - uniform filling of the worn area, b) - patching after reheating and erosion-corrosive wear.*

The degree of mass adhesion after sintering to the surface was evaluated by rotating the furnace around a horizontal axis. The mass was sintered in a dense monolith with a lining, did not crumble and did not flake off.
- *third stage;* reheating of the furnace to a working temperature of 1630°C; testing of erosion and corrosion resistance of the welding mass.
After evaluating the adhesive properties and sintering rate, the workspace was reheated to the converter melting temperature. At the same time, new portions of metal and slag were loaded into the working space before the formation of a liquid bath (1/3 of the internal volume of the furnace) 4-5 kg. Continuous rotation of the furnace with slag-metal emulsion lasted for 1 hour, to simulate the erosive and corrosive wear of the patching conglomerate. Then the products of melting were tapped again from the furnace. The appearance and residual amount of the patching mass after reheating and wear of the slag metal emulsion is shown in Fig. 9 b). After a qualitative assessment of the behavior of the patching mass, the degree of its adhesion to the periclase-carbon brick, the sintering time and corrosion and erosion resistance, the furnace was cooled to room temperature. The inner lining was dismantled and the sintered mass was separated from the surface of the refractory. After mechanical preparation of the sample conglomerate, the compressive strength was measured on a laboratory press. As a

result, this parameter amounted to 38.5 MPa, which fully satisfies production requirements and corresponds to the indicator of foreign analogues. Figure 5 shows a sample of a sintered "GIR-RB-X" mass conglomerate after destruction by a press.

*Fig 9: A sample of a "GIR-RB-X" mass conglomerate*

Figure 5 shows the dense structure of the sample of the welding mass, which is also confirmed by the number of large fragments after destruction by the press. Strength at compression (after sintering 1600 ° C) not less then 35 MPa.
Based on the tests, the following results were obtained on PJSC "Kamet-Steel". Specific consumption of the repair mass was 0.089 kg/ton, with the standard - 0.092 kg/ton

## CONCLUSIONS
A unique technique for assessing the physico-chemical properties of a slag coating modified with various additives has been developed.
Based on the obtained results, flux-modifier "GIR-MBF" brend for final converter slag was developed and tested in the industrial environment, the flux-modifier being of magnesia-based, produced from available domestic materials comprising both low-soluble and readily-soluble components. With regard to the above mentioned, 2-6 mm fractions made up min. 80% of the total volume of low-soluble components.
Based on the developed methodology using available domestic raw material, a self-flowing magnesium hot repair mass "GIR-RB-X" brand has been developed.
The main quality indicators of the material are as follows: - grain size distribution; grading fraction of 0-8 mm, selected so as to ensure the most dense packing of grains after sintering. - chemical composition; MgO content 80-85 % by mass (on ignition basis) to ensure maximum erosion resistance after sintering.

# DEVELOPMENT OF LOW CO₂ EMISSION REPAIR MATERIAL AT BASIC OXYGEN FURNACE (BOF) APPLICATION

Patrícia Alves Silva de Resende Brum, Vladnilson Peter de Souza Ramos, Douglas Fernando Galesi, Ariovaldo do Nascimento, Haysler Apolinário Amoroso Lima, Hamilton Cesar Guimaraes of Shinagawa Refractories, Vinhedo, Brazil

## ABSTRACT

Steel market across the globe is increasingly facing a decarbonization challenge due to the pressure to reduce its carbon footprint and have more sustainable processes and products. Step forward, steel producers have the mission to estimate, evaluate and establish economically and technologically feasible plan to decrease carbon dioxide emissions. Shinagawa Refractories' strategy is aligned to prioritize projects which are focused on these sustainable guidelines. In a Basic Oxygen Furnace (BOF), the corrosion caused by high FeO content slag and high oxidation are the most critical conditions for maintenance of refractory lining integrity. Because of all technologies and innovations taken by Shinagawa, the durability of refractory products applied at BOF lining is improved and it is possible to reduce the quantity of repair material throughout the campaign which leads carbon dioxide emissions reduction. The present work will show the significant in one of our customers results of low CO₂ emission basic repair material applied in BOF with gain in performance related to flowability, adhesion to work lining and curing time.

## INTRODUCTION

The expansion of more technological processes increases the pressure on steel producers claiming for higher quality products consistent with the rise of restricted sustainability measures. Refractories products has a relevant position on steelmaking industry due to its effect on manufacturing costs and product quality as they are applied on harsh operating environments to endure high temperatures and wear conditions [1].

Steel production needs high amount of energy, and it is responsible for 11% of overall global carbon emissions [2]. In the 21st century, climate change is the most important concern for steel producers and as it was agreed at the aims of Paris Agreement [3] the steel industry is committed to reduce greenhouse gas emissions in a short time to achieve a climate neutral world by 2050 from its operations and the use of its products.

Blow Oxygen Furnace (BOF) is a crucial step at steelmaking process, as it is defined as an asset whose availability directly impacts steel mills productivity. A BOF with low production level led to a series of undesirable consequences, such as higher number of cycles of available BOFs, an increase on demand for steel heating up processes consuming energy and a lower final product yield. Currently, one of the factors with the greatest impact on BOF availability is the maintenance of refractory lining. Regularly steel mills have 2 or 3 BOF equipment and, if 1 of them stops its operation to change refractory lining, it means a reduction of 33 to 50% in the steel production. Normally, this replacement time is in between 60 and 100 hours, having a significant impact on production. In addition, hot repair techniques for refractory lining consume equipment downtime, between 40 and 100 minutes, and therefore it also impacts on asset availability [4].

The wear of the working lining of BOF converters is associated with the characteristics of the material of the refractory lining, the slag and steel of the BOF, in addition to the interaction between them, also temperature and oxidizing atmosphere inside BOF.

The most common refractory lining repair technique performed to reduce the wear rate is hot repair which can be divided into slag splashing, slag coating, pouring and projection. In these processes there is a formation of a protective layer (coat) that will be effective against all wear mechanisms (abrasion, corrosion, erosion and thermoclase). A correct operation will provide this result, avoiding the removal of this layer and, in fact, contributing to the formation of a protective layer. Hot repair technique should be selected based on the wear mechanisms present in each region. Considering operational parameters, the lowest cost and shortest time countermeasures are preferred, as they lead to greater availability of the asset for production, since productivity is the factor with the greatest impact from a refractory point of view on operating costs in a plant BOF [4].

Even Magnesia-Carbon (MgO-C) bricks are widely used in BOF due to their desirable resistance to chemical corrosion and mechanical stresses, hot repair is required to improve the total lifetime of the converter lining. Traditionally, the application for hot repair BOF and ladle slag line have been filled with basic dry gunning mixes since the 1970s, when mostly phosphate-bonded materials were utilized. A continuously growth on lower-carbon steel demand has caused severe operating conditions to converters as previously mentioned on this paper. Therefore, MgO bricks and repairing mixes needed to be redesigned [5,6].

When the hot repair mix is applied into the BOF at high temperature it is needed some time to burn up the volatile matters with an origin on carbon content coming from raw materials used on the mix composition. A defined quantity of fumes emission can be originated from this volatile burning which reduction is the main propose of this paper. Hot repairing mix presented on this paper was developed to maintain the required properties of its compatibility with MgO-C bricks and allowing self-flowing application. But most important focus is on lowering suspended particles and gases emissions.

## MATERIALS AND METHODS

### Formulation

The composition of basic self-flow mix was based on its compatibility with basic bricks to allow the hot repairing and it was formulated using high grade calcined magnesia of different grain sizes to contribute not only for densification but also to endorse good fluidity needed to product installation. To guarantee the increase of mechanical resistance at high temperatures, some additives were incorporated in the formulation.

Table 1 presents chemical composition results of the basic self-flow mix in which % of MgO and other compounds were performed following the ABNT NBR 12860 standard. Carbon content was measured at Combustion Analyser LECO CS230CH.

Tab. 1: Chemical composition of basic self-flow mix for hot repair

| Composition | % |
|---|---|
| MgO | 88.5 |
| C | 7.0 |
| Others | 4.5 |

### Physical Properties

Prismatic samples (160 mm x 40 mm x 40 mm) were obtained by performing the mixing step according to an internal mixing procedure. After moulding, the samples were baked at 200°C and 1,400 °C at reducing atmosphere, cooled down and tested. Apparent Density and Apparent Porosity were conducted according to the ABNT NBR 16661 standard. Cold compressive strength and module of rupture tests were conducted at Universal Testing Machine KRATOS (model: KE-30.000/E MP) according to ABNT NBR 10059 and 5014, respectively.

### Hot Modulus of Rupture (HMOR)

The Hot Modulus of Rupture (HMOR) measurements were conducted following ASTM C583 standard under three-point bending tests at 1,400°C. The samples were moulded in a prismatic format (150 mm x 25 mm x 25 mm), heated at 1,400 °C and in reducing atmosphere during the test.

349

**Rheology of mix**

Fluidity is an important property for self-flow mix as great quantity of mix needs to flow correctly and be deposited to cover the worn area of BOF refractory lining for repairing. During BOF operations for steel refining, after converter tapping, the temperature inside it is between 1,200 °C and 1,400 °C and when the curing of hot repair mix is concluded the temperature lowered to 1,000°C. Because of that conditions, thermal fluidity of the repair mix was fixed at 1,000°C [6].

**Field Tests**

After lab trials, two pilot trials were conducted in a BOF (denoted here as BOF#A) with a capacity of 220 ton of a Brazilian steel producer, aiming to validate developed mix performance at field conditions. Total quantity was 1,500 kg divided in two big bags of 750 kg each. Hot repair mix was installed with the help of a crane's arm to put the mix big bag inside the converter.

**RESULTS AND DISCUSSION**

Table 2 presented the results of physical properties measured after baking at 200 °C and after heating at 1,400 °C conducted at basic self-flow mix for hot repair.

Tab. 2: Physical and rheological properties of basic self-flow mix after baking at 200 °C and after heating at 1,400 °C.

| Properties | Basic Self-Flow Mix |
|---|---|
| | After baking at 200 °C |
| Apparent Density (g/cm³) | 2.43 |
| Apparent Porosity (%) | 19.3 |
| Cold Crushing Strength (MPa) | 15.1 |
| Module of Rupture (MPa) | 4.4 |
| | After heating at 1,400 °C |
| Apparent Density (g/cm³) | 2.39 |
| Apparent Porosity (%) | 26.6 |
| Cold Crushing Strength (MPa) | 11.1 |
| Module of Rupture (MPa) | 2.0 |
| HMOR (MPa) | 9.42 |
| Self-flow (mm) | 173 |
| Self-flow after 15 beats (mm) | 190 |

Table 1 shows that basic self-flow mix presented good properties of density and porosity with expected results after curing and heat treatment which are in accordance with other basic hot repair mixes developments [6,7]. The basic mix also shows great mechanical properties on both temperatures and the most important a high hot module of rupture which can indicate a good field performance of enduring mechanical impact of liquid metal on BOF converters.

Figure 1 presents the aspect of the mix after self-flow test and demonstrate the good thermal fluidity after a test at 1,000°C which indicates a good workability of this hot repair mix with a good potential to be applied at converters refractory lining.

Fig. 1: (a) Self-flow test; (b) Thermal flow at 1,000 °C.

At first field test, 1 big bag of 750kg of mix were put at tapping area of converter and, after 90 minutes curing time, it was sintered maintaining attached at correct region for 16 heats, as shown in Figure 2. For the second trial, 1 big bag of 750 kg of the mix was put at the same region, but after 120 minutes curing, it was attached for 42 heats (Figure 3). In both scenarios, fluidity and adherence at refractory wall were validated.

Fig. 2: First field trial (a) BOF#A tap region before hot repair; (b) Basic self-flow mix adhered after 16 heats.

Fig. 3: Second field trial (a) BOF#A tap region before hot repair; (b) Basic self-flow mix adhered after 42 heats.

**CONCLUSIONS**

High mechanical resistance at high temperatures (HMOR) and thermal fluidity properties of basic self-flow mix presented in this paper were measured in lab scale but also validated by an excellent performance field trial. Not only the good workability and sintering of hot repair mix were noticed but also a reduction on articulate emissions by steelmaking company's workers as positive feedback, achieving one of main purpose of mix this product development. Shinagawa Refractories has a continuously efforts to reduce not only the particulate material, as well as to decrease carbon footprint and $CO_2$ emissions of hot repair mix.

# STEEL LADLE LINING MANAGEMENT: COMPARISON BETWEEN DIFFERENT MAINTENANCE TECHNOLOGIES TO INCREASE PERFORMANCE, REDUCE REFRACTORY CONSUMPTION AND WASTE DISPOSAL OF USED MATERIALS

Luca Folco, Alan Kranjc, Seven Refractories d.o.o. Divača, Slovenia

## ABSTRACT

Nowadays steel ladle is the main vessel for secondary metallurgy, and this means that long service life and stable performance play a key role on final quality and quantity of produced steel.

During the years have been proved that zoning the different areas of the steel ladle, with specific refractory materials, it is the most effective and safe approach, optimize the service life and currently steelmakers rely basically on two concepts of refractory lining.

Most of them trust on bricks (MgO-C, AMC, Doloma, etc), that give good high temperature resistance, strong slag protection, easy heating up and reliable service life.

Others have switched to monolithic solutions based on alumina-spinel, with high thermal stability, good hot strength, excellent resistance to thermal spalling, low carbon pick and lower thermal conductivity important for production of ULC steels and energy savings respectively.

Both concepts have problem of uneven wear of refractories at different zones.

Higher corrosion of slag zone, high wear in impact zone, blocked purging plugs and need for their replacement. Therefore, at these stoppages, decision needs to be made to replace complete lining in low wear zones and consequently loosing high amount of perfectly good material or to continue with existing lining and risk potential breakthrough.

Repair with sprayable materials emerges as a good solution to increasing number of heats before complete relining is needed and assures low risk of breakthrough. This can be done with shotcrete, which gives very good performance, but requires expensive equipment or gunning where performance of installed material is much lower or new emerging technology called ShotGun that shows much higher performance than gunning at lower installation cost compared to shotcrete. It promises to be a good option specially for smaller steel shops, where slightly higher performance of shotcrete just cannot outweigh its limitations.

## INTRODUCTION

Steel ladles play a critical role in steel production, serving as vessels for transporting liquid steel through various stages of secondary metallurgy. The refractory lining of these ladles is subjected to chemical, thermal, and mechanical wear during the refining processes. Making it essential to carefully select type of refractories, installation technique, and maintenance of the lining. There is no one-size-fits-all solution due to the wide-ranging requirements set by steel shop managers, including durability, balanced performance, low consumption, resistance to slag attack, safety, ease of installation, quick heating-up, capacity optimization, insulation properties, flexibility, and cost-effectiveness. Finding the best compromise with those complex requirements is a continuous challenge.

While MgO-C bricks have long been favoured for ladle lining due to their high-temperature resistance and reliable service life, the steel industry is increasingly recognizing the potential of alumina-spinel monolithic refractories. Research conducted over two decades ago revealed that these monolithic products not only compete with traditional lining materials but also offer additional benefits, such as increased ladle capacity and reduced thermal losses. [1]

Recent reports and articles have further supported these findings, highlighting the advantages of alumina-spinel monolithic refractories. Lower operating costs and improved consistency in carbon content, particularly for ultralow carbon steels, make these refractories appealing to steelmakers seeking enhanced efficiency and higher-quality steel production. Furthermore, transitioning from MgO-C bricks to alumina-spinel monolithic refractories can contribute to a reduction in $CO_2$ emissions, both during refractory production and operation, making it an environmentally sustainable choice. Another advantage of monolithic refractories is their ability to minimize waste generation by allowing targeted repairs instead of complete demolition and relining, optimizing resource utilization in the steelmaking process. [2] [3] [4] [5]

**Summary of article from 2020**

A previous article presented at ICR 2020 showcased Seven Refractories' innovative cyclic shotcreting repair technique for steel ladle management. This summary provides a connection between the new advances and the previous work. [6]

The cyclic shotcreting repair approach involves applying protective layers of monolithic castable onto an existing brick lining in a repetitive manner. By combining the advantages of monolithic and brick linings, this method offers a flexible and reliable solution for ladle lining repair.

The shotcreting technique, known for its flexibility and ability to create refractory linings with similar technical features as traditional casting methods, is utilized in this application. A castable mix is sprayed at high pressure onto the surface, where it rapidly sets, allowing for targeted repairs without complete demolition and relining.

A comparison between the typical brick lining cycle and the cycle with shot repair reveals the advantages of the shotcreting application. (Tab.1.) Without steel zone repair, the slag line can be replaced only once before complete relining becomes necessary. However, with shot repair in the steel zone, the slag line can be changed multiple times before complete relining is required.

The shotcreting application extends the campaign life of ladles, reduces specific consumption and costs, all while maintaining the use of traditional brick linings. The shotcreting layer takes on wear, while the original bricks remain intact.

This technology offers significant benefits, including prolonged ladle campaign life, easy visual wear control, and reduced waste of refractory lining. It leads to substantial reductions in specific consumption and operational costs without compromising the availability, reliability, and safety of ladle management.

In conclusion, the cyclic shotcreting repair technique provides a cost-effective and efficient solution for extending the lifespan of steel ladle working linings while capitalizing on the advantages of both monolithic and brick linings.

## MORE EXAMPLES OF IMPLEMENTATION OF SHOTCRETE REPAIRS

Since 2020, shotcreting repair has become a standard solution applied in numerous steelworks. The increased number of ladles repaired has led to the optimization of cleaning techniques, installations, and heating curves, resulting in more reliable ladle management. This article presents the results obtained from two steelworks.

On average, the slag line bricks are replaced after approximately 40 heats. Ladle then survive another 40 heats. The ladle then continues to operate for another 40 heats. However, at around 82 heats, the bricks in the steel zone become too worn to complete another slag zone cycle, resulting in the complete demolition of the ladle. In the new campaign life cycle, the introduction of two repairs in the steel zone and two replacements of slag zone bricks extends the ladle's campaign life by 50%. (Tab.2)

| Phase | Standard Procedure | Shotcreting Application |
|-------|--------------------|------------------------|
|  | Description | Description |
| 1 | New brick lining (complete) | New brick lining (complete) |

Tab. 1: Comparison between the standard steel ladle life cycle and the one with included shotcrete repair.

**Steelworks 1**

| Capacity of steel ladle | 350 t |
|-------------------------|-------|
| Nr. of ladle campaigns (2020-23) | 350 |
| Tonnage of bricks for steel zone | 26,5 t |
| Tonnage of bricks for slag zone | 14,3 t |
| Avg. quantity of Shot material per repair | 4 t |
| Nr. of heats without repair | 82 |
| Nr. of heats with 2 repairs | 123 |

Tab.2. Average performance of steel ladles in steelworks 1

**Steelworks 2**

| Capacity of steel ladle | 160 t |
|-------------------------|-------|
| Nr. of ladle campaigns (2020-23) | 690 |
| Tonnage of bricks for steel zone | 16 t |
| Tonnage of bricks for slag zone | 6,3 t |
| Avg. quantity of Shot material per repair | 3 t |
| Nr. of heats without repair | 100 |
| Nr. of heats with 2 repairs | 185 |

Tab.3. Average performance of steel ladles in steelworks 2

On average, the slag line bricks in Steelworks 2 are replaced after approximately 60 heats in the ladle. The ladle then continues to operate for another 40 heats. However, at around 100 heats, the bricks in the steel zone become too worn, resulting in the complete demolition of the ladle. In the new campaign life cycle, the implementation of two repairs in the steel zone and two replacements of slag zone bricks extends the ladle's campaign to an average of 185 heats, representing an 85% increase. (Tab.3)

From these values, we can calculate the specific consumption of refractories used for the steel ladle wall per ton of produced steel. (Tab.4a, 4b)

| Capacity of steel ladle | 350 t steel ladle | |
|-------------------------|-------------------|--|
|  | Standard practice | Shotcreting application |
| Quantity of produced steel | 28700 t | 43050 t |
| Tonnage of refractories used | 55,1 t | 77,4 t |
| Refractories used per t of steel | 1,92 kg | 1,80 kg |

Tab.4a. Production of steel and tonnage of refractories per steel ladle in steelworks 1

| Capacity of steel ladle | 160 t | |
|-------------------------|-------|--|
|  | Standard practice | Shotcreting application |
| Quantity of produced steel | 16000 t | 29600 t |
| Tonnage of refractories used | 28,6 t | 40,9 t |
| Refractories used per t of steel | 1,79 kg | 1,38 kg |

Tab.4b: Production of steel and tonnage of refractories per steel ladle in steelworks 2

| Capacity of steel ladle | 160 t | |
|-------------------------|-------|--|
|  | Standard practice | Shotcreting application |
| Number of ladles per year | 219 | 118 |
| Total quantity of refractories | 6256 t | 4836 t |
| Quantity of refractory waste | 1877 t | 1238 t |

Tab. 5: Total number of ladles, tonnage of refractories, and waste per year in Steelworks 2

Knowing the yearly production for Steelworks 2, which is 3,5 million tons of steel, we can calculate the number of required ladles per year, the total amount of refractories needed for the steel ladle wall, and the amount of waste considering that the ladle is demolished when the bricks reach 30% of their original thickness. These numbers reflect significant savings in the cost of refractories, increased availability of steel ladles, and reduced waste generation. (Tab.5)

*Fig. 1: Pictures of steel ladle during complete campaign*
## NEW INSTALLATION METHOD – SHOTGUN

Shotcreting is a versatile monolithic application technique where a castable mix is sprayed onto a surface at high pressure, rapidly setting in place. It offers exceptional flexibility, allowing it to be used in various locations regardless of complex geometries. Crucially, shotcreting achieves refractory linings with comparable technical features to traditional vibrating casting methods, particularly in terms of mechanical parameters. However, shotcreting is typically not used for small repairs due to the higher cost of equipment, longer preparation time, and increased cleaning requirements after installation. These limitations are easily overcome by larger steelworks where the number of steel ladles and the quantity of installed material are high, and top-of-the-line performance is expected. On the other hand, for smaller steel mills, these limitations can be a dealbreaker, hindering them from modernizing their steel ladle management. To assist them in moving into the future, Seven Refractories has developed a new installation technique and material that allows for the utilization of gunning machines to apply similarly performing material as shotcrete.

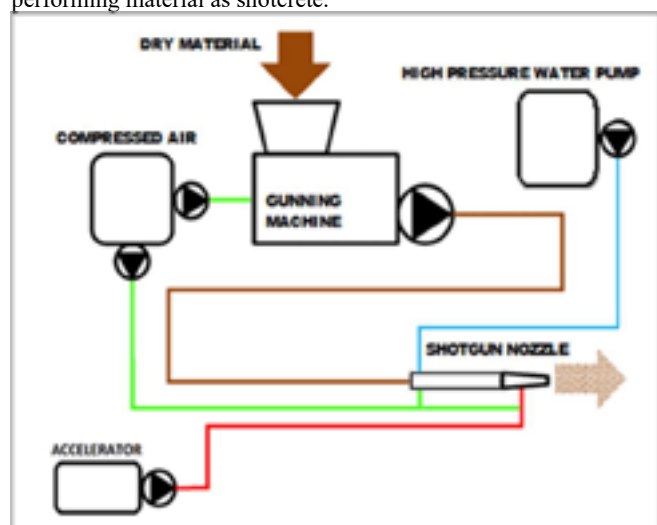

*Fig. 2: ShotGun system*

This led to the development of the SHOTGUN system (*Fig. 2*), which includes a modified gunning machine, high-pressure water pump, compressed air source, accelerator pump, and a special ShotGun nozzle developed by Seven Refractories. (*Fig. 3*) [7]. This system eliminates the need for a planetary mixer and shotcrete pump, which take up a lot of space and are costly, while also significantly reducing setup time and man power. Since water is added at the nozzle, there is no need for cleaning hoses, and there is no wasted material that would normally be left in the mixer, pump, and pipes.

*Fig. 3: New ShotGun nozzle*

The existing Seven Shot material was not fully compatible with the new installation system, requiring a material that is dry pumpable without separation and can be wetted out in a short amount of time. As a result, the particle size distribution and additives were modified, giving rise to a new family of Seven ShotGun products. A comparison of physical properties between the two products shows that both have high CCS (Cold Crushing Strength) values, especially at operating temperatures. The permanent linear change (PLC) is relatively constant and far from the critical value of -1.5%. Although there is a slight reduction in CCS for ShotGun, the values are still sufficiently high, and the less negative PLC reduces the stress experienced by the material.

*Fig. 4a: Comparison of PLC between Shot and ShotGun*

353
*Fig. 4b: Comparison of CCS between Shot and ShotGun*

## RESULTS FROM INDUSTRIAL TRIALS OF SHOTGUN

### Steelworks 3

A bottleneck during the standard campaign was wear in the steel zone of the ladle. The application of the ShotGun solution during the replacement of slag zone bricks extended the campaign until the bottom and slag zones became the limiting factors for the steel ladle's life cycle. This has been confirmed in several steel ladle campaigns. With this solution, all zones reach their end of life at the same time, which is a crucial parameter in economical calculations for all refractory linings and significantly reduces the amount of wasted material.

*Fig.5: Steel ladle repaired with ShotGun*

## CONCLUSIONS

After years of experience, shotcrete repairs for steel ladles have proven to be an effective solution. These repairs extend the service life of ladles, reduce waste, and decrease material consumption per ton of steel. As a result, operating costs are lowered, and the environmental impact is reduced. Furthermore, the repair process helps equalize the life cycles of different zones within the ladles, resulting in reduced refractory waste.

The introduction of the new ShotGun solution has made these benefits more accessible and easier to implement. Laboratory tests have shown only minimal reductions in physical values, ensuring high-quality repairs. Initial feedback from the field has been positive, particularly for smaller steel mills seeking to optimize their steel ladle performance. We are confident that further industrial trials will establish ShotGun as a reliable installation technique, enabling steel producers to transition towards a greener and more efficient future.

Refratechnik Steel GmbH, Research and Development, Düsseldorf, Germany

## ABSTRACT

Among others, the refractory lining material in steel ladles is a potential source for the formation of non-metallic inclusions, which requires in-depth knowledge of the interactions of refractory lining materials with the steel melt and the inclusion population. Within this work, the behavior of different grades of MgO-C refractory materials in contact with liquid steel at 1600°C and 1680°C was studied in detail via immersion tests. The immersed specimens were characterized in terms of their exterior and chemical alteration. Moreover, the inclusion population in the solidified steel samples was investigated particular with regard to the inclusion size distribution using automated feature analysis. Phase analysis of characteristic inclusions were performed using electron back scatter diffraction.

The formation of oxide structures was observed at the specimens' surface, including a coherent MgO layer, spinel containing crystal-like structures and phases from the quaternary $CaO-Al_2O_3-SiO_2-MgO$ system. The amount of accompanying phases correlated with the proportion of such phases in the primary refractory material, i.e. the grade of the used MgO raw materials. These phases further appeared to influence the layer growth and the formation of crystal-like structures. Only at an immersion temperature of 1680 °C the formation of larger bubbles was observed at the specimens' surface irrespective of their MgO grade.

The main inclusions detected in the solidified steel samples were crystalline $Al_2O_3$ inclusions, amorphous Mn-Si-Al-O inclusions and complex inclusions consisting of an amorphous Mn-Si-Al-O matrix with crystalline $Al_2O_3$ and/or $MnTiO_3$ precipitations. Both the MgO grade of the refractories and the steel melt temperature significantly influenced the total number of inclusions detected, the types of inclusions present and particularly their size distributions. Here, a lower MgO grade resulted in the formation of less but larger $Al_2O_3$ inclusions.

## INTRODUCTION

The occurrence of non-metallic inclusions (NMIs) in solidified metals is a research topic of high interest for several decades [1]. Because of their detrimental impact on the metallic properties, there is an ongoing demand for controlling the population of non-metallic inclusions in the steel melt. Here, the goal is to limit their frequency to the lowest possible level by keeping their size distribution, morphology and chemical composition under control.

Several NMI formation mechanisms are already known, such as the deoxidation process [2]. Alternatively, complex NMIs have been reported to form by the mutual collision of pre-existing NMIs, which was previously observed for MgO or MgO-rich spinel NMIs and liquid $CaO-SiO_2-MgO-Al_2O_3$ NMIs [3].

Among others, also the refractory lining material is a potential source for the formation of non-metallic inclusions [4]. Such materials, which are in direct contact with the steel melt, are a potential source of NMI formation by their erosion [5]. Conversely, they also possess the ability to influence pre-existing NMIs through chemical or mechanical interactions [6]. Nowadays, MgO-C refractories are used in BOF or ladle linings based on their superior thermomechanical properties including excellent thermal shock resistance, resistance against hot erosion and corrosion resistance [7].

Recently, MgO-C refractory materials with different MgO grade were investigated in contact with a steel melt via immersion tests carried out in a steel casting simulator [8]. The same materials were utilized for immersion tests at a higher temperature, i.e. 1680°C [9].

This work summarizes and connects these recently published results focusing also on the characterization of the immersed specimens. Although the influence of the immersed MgO-C refractories on the NMI frequency has been intensively discussed, the formation of the characteristic NMIs and their exact phase composition have not yet been investigated. Based on these studies, the previously observed NMIs were in-depth analyzed in this work. Structure and composition analyzes of different NMI species were carried out proposing possible formation and modification mechanisms of NMIs. In addition, the inclusion size distribution of the most observed inclusions, i.e. alumina NMIs were studied in more detail related to the MgO grade of the immersed MgO-C refractories and the immersion temperature.

## EXPERIMENTAL

Bar-shaped specimens of different MgO-C refractories with a carbon content of 10 wt% were subjected to immersion tests carried out in steel casting simulator (Systec, Germany) schematically shown in Fig. 1. The chemical composition of the used MgO-C refractories after coking is shown in Tab. 1, while details regarding the refractory specimen preparation were reported in a previous work [8].

*Tab. 1: Chemical composition of the MgO-C refractories determined by X-ray fluorescence spectroscopy in wt%; carbon excluded*

| Grade | MgO | CaO | $Al_2O_3$ | $SiO_2$ | $Fe_2O_3$ |
|---|---|---|---|---|---|
| G90 | 89.83 | 2.90 | 0.26 | 5.51 | 1.27 |
| G98 | 97.55 | 0.81 | 0.29 | 0.43 | 0.65 |

Approximately 38 kg of 42CrMo4 steel was inductively melted in an alumina/alumina-magnesia spinel crucible. After reaching the target temperature of 1600 °C or 1680 °C, non-metallic inclusions were generated intentionally be oxidizing and deoxidizing the melt using $FeO/Fe_2O_3$ powder (0.5 wt% related to the steel mass) and metallic Al (0.05 wt% based on the steel mass), respectively. The MgO-C specimen was then immersed into the steel melt for 30 minutes. Finally, the steel melt was cooled freely to room temperature after the immersed specimen was removed.

*Fig. 1: Steel casting simulator used for the immersion tests.*

After the melting trials, steel samples ($40 \times 40 \times 12$ mm³) were cut from the solidified steel blocks and analyzed with regards to the non-metallic inclusion population. The immersed specimens were analyzed using optical microscopy, scanning electron microscopy, energy-dispersive X-ray spectroscopy and X-ray diffraction.

Manually selected characteristic NMIs were analyzed by scanning electron microscopy (SEM, AMBER, Tescan, Brno, Czech Republic) with energy dispersive X ray spectroscopy (EDS, Bruker Nano GmbH, Berlin, Germany). In addition, phase analyzes were performed using electron backscatter diffraction (EBSD, Bruker Nano GmbH, Berlin, Germany).

**CONCLUSIONS**

This work investigated the behavior of MgO-C refractories with different MgO grade in contact with an Al-deoxidized steel melt at 1600 °C and 1680 °C and their influence on the population of non-metallic inclusions. Characteristic non-metallic inclusions observed after the immersion tests were intensively studied.

It was shown that the behavior of MgO-C refractories in contact with a steel melt differed depending on their MgO grade and the temperature during the immersion. All specimens were covered by a coherent MgO layer containing accompanying phases from the primary refractory material. The frequency of these phases was dependent on the specimens MgO grade, increasing with decreasing MgO grade. A higher proportion of such phases appeared to densify the newly formed coherent layer hampering layer growth and the formation of crystal-like $MgO/MgAl_2O_4$ structures.

The analysis of the structures and compositions of different inclusion species revealed the presence of various types, including crystalline, amorphous, and complex inclusions that contained both crystalline and amorphous phases. The complex inclusions consisted of an amorphous Mn-Si-Al-O matrix, along with various crystalline phases such as $Al_2O_3$, $MnAl_2O_4$ and/or $MnTiO_3$. The formation of amorphous Mn-Si-Al-O inclusions was attributed to the oxidation of the steel melt, while pure crystalline corundum inclusions resulted from both the oxidation and deoxidation processes. The shapes of the alumina inclusions varied, possibly due to variations in aluminum and oxygen supersaturation in the steel melt during their formation. Complex inclusions were suggested to form through the precipitation on existing inclusions and the mutual collision of pre-existing inclusions, facilitated by the non-wetting behavior of solid alumina inclusions in the steel melt.

The size distribution of the crystalline $Al_2O_3$ inclusions was related to the MgO grade of the previously immersed specimen. Here, a lower MgO grade, i.e. a higher proportion of accompanying phases in contact with the steel melt, resulted in a shift of the inclusion size distribution towards a larger inclusion size.

## ABSTRACT

This paper explores new refractory aggregate compositions and microstructures in the $CaO-MgO-Al_2O_3$ (CMA) system. MagArmour (MagA) is a microporous CMA-aggregate that is designed for application as dopant to MgO-C bricks where amongst other effects it can replace antioxidants like Al and Si metals. But it has also shown positive effects as addition to alumina spinel (A-MA) castables and gunning mixes in terms of thermal shock resistance (TSR). However, the application in castables is limited to relatively small addition rates due to the apparent porosity of the MagA aggregate (25-35 vol. %). It impacts the water requirement so that the full potential of this concept can only be exploited to a small extent in castables. To further build on this positive experience concerning the TSR this study investigates which aspect contributes most to it, the micro porosity of the aggregates or their composition within the CMA-system. It was found within the perimeter of tested materials that some alterations of the aggregate composition have a more significant impact on thermal shock resistance than significant modifications of the porosity of the aggregates. With this it was possible to design new CMA aggregates that are on one hand fully compatible with application requirements in bricks and in castables, in the latter especially with respect to their rheological requirements, and on the other hand provide the resistance to the harsh steel ladle conditions, both in terms of thermal shock and corrosion resistance.

## INTRODUCTION

Alumina-spinel (A-MA) refractories are well known products for steel ladle applications providing excellent refractoriness and corrosion resistance. Although already improved compared to pure alumina refractories due to a small thermal expansion mismatch between alumina and spinel [1], their thermal shock resistance is still significantly inferior to products based on mullite or mullitized andalusite since mullite has a very low coefficient of thermal expansion [2]. However, to minimize interactions with steel, higher amounts of silica containing phases are not desired in direct contact with high quality steel [3]. An improvement of the TSR of A-MA dry-gunning mixes has been reported with the introduction of MagArmour (MagA), a porous aggregate consisting of micro spinel crystallites and hydraulic calcium aluminate phases [4]. However, applied in castables, the water demand increased, and furthermore, without adjusting the matrix composition, shrinkage after firing at 1500 °C may occur. The aim of the present study is to continue the aggregates development in the CMA system by further understanding the underlying mechanism that led to the improved thermal shock resistance of MagA. In this regard the attempt is to investigate which aspect plays a bigger role for the TSR within the CMA system, the micro-porosity of the aggregate or its composition. This then leads to the development of a new generation of CMA-aggregates that combine the positive aspects in terms of thermal shock resistance with a high level of corrosion resistance and enable the universal application in A-MA refractories, including castables, gunning mixes, and bricks.

## TEST MATERIALS

To investigate the effect of the composition of aggregates from the CMA system vs their porosity on the thermal shock resistance of alumina spinel castables, two different aggregate compositions (CMA1 and CMA2) and variants in terms of their apparent porosity (26 and 4 vol.% for CMA1 resp. 6 vol.% for CMA2) have been prepared (Tab. 1). CMA1-26 corresponds to the original MagArmour product of Imerys, France. The composition and apparent porosity of the tabular alumina and the magnesium aluminate (MA) spinel aggregates used in this study are shown as well in Tab. 1.

Tab. 1: Composition and apparent porosity of different refractory aggregates.

| | | MA Spinel | Tab. Alu. | CMA1-26 (MagA) | CMA1-4 | CMA2-6 |
|---|---|---|---|---|---|---|
| $Al_2O_3$ | wt, % | 76 | 99.6 | 69.8 | 69.8 | 77.6 |
| MgO | wt. % | 23 | | 19.0 | 19.0 | 18.9 |
| CaO | wt. % | 0.3 | | 10.4 | 10.4 | 3.0 |
| Ap. Po | vol. % | 3 | 3 | 26 | 4 | 6 |

Aggregates of the fractions 0-1, 1-3 and 3-6 mm have been produced by crushing the synthesized clinkers. SEM backscattered micrographs of the CMA1-26, CMA1-4, and CMA2-6 aggregates can be seen in Fig. 1. The micrograph of CMA1-26 has been taken at a higher magnification due to the smaller crystal size inside the grain structure, mainly consisting of (dark grey) spinel (Sp) and a smaller portion of CA (light grey) and CA2 (grey) phases. Contrary to that, CMA1-4 and CMA2-6 contain larger primary crystals with an assemblage of mainly spinel in both cases, but CA and CA2 as secondary phases in case of CMA1-4 and mainly CA2 in case of CMA2-6. While in case of CMA1-26 the high amount of micro pores are clearly visible (black), the other two aggregates clearly exhibit much less porosity.

*Fig. 1: Microstructures of different aggregates from the CMA system.*

These aggregates have been applied in three different alumina spinel castables. In model formulation type A (Tab. 2) the objective was to keep the total amount of spinel in the recipe close to the 23 % of spinel in the reference formulation (REF-A-SP). Consequently, the amount of added pure MA spinel in the fraction 0-1 mm has been reduced when 20% CMA1-26, CMA1-4 or CMA2-6 have been added. The difference has been compensated with a reduction of tabular alumina.

Tab. 2: Model castable formulation type A with 20 % CMA aggregates and reference model castable formulation REF-A-SP.

| wt. % | | REF-A-SP | CMA1-26A | CMA1-4A | CMA2-6A |
|---|---|---|---|---|---|
| CMA1-26 | 1-6 mm | | 12 | | |
| CMA1-26 | 0-1 mm | | 8 | | |
| CMA1-4 | 1-6 mm | | | 9 | |
| CMA1-4 | 0-1 mm | | | 11 | |
| CMA2-6 | 1-6 mm | | | | 13 |

| Total | | 100.1 | 100.1 | 100.1 | 100.1 |
| Water addition | | 3.25 | 3.75 | 3.25 | 3.25 |

A second set of model formulations (type B) is using 20 % CMA-aggregates only in the fraction >1 mm as replacement for tabular alumina (Tab. 3). Consequently, the total amount of spinel is higher than in REF-A-SP (23 %) and reaches approximately 35 % in

357

CMA1-26B and CMA1-4B, while CMA2-6B reaches a spinel content of 40 %.

Tab. 3: Model castable formulation type B with 20 % CMA aggregates and reference model castable formulation REF-A-SP.

| wt. % | | REF A-SP | CMA1-26B | CMA1-4B | CMA2-6B |
|---|---|---|---|---|---|
| CMA1-26 | 1-6 mm | | 20 | | |
| CMA1-4 | 1-6 mm | | | 20 | |
| CMA2-6 | 1-6 mm | | | | 20 |
| Tab. Alu. | 1-6 mm | 45 | 29 | 29 | 29 |
| Tab. Alu. | 0-1 mm | | 11 | | |
| MA spinel | 0-1 mm | | 23 | | |
| React. Alu. | d50 = 1.5 μm | | 11 | | |
| Secar® 71 | | | 6 | | |
| Peramid® Al 200 | | | 0.1 | | |
| Total | | 100.1 | 100.1 | 100.1 | 100.1 |
| Water addition | | 3.25 | 4.75 | 3.5 | 3.5 |

Finally, a third set of model formulations (type C) has been tested where all the tabular alumina fractions >1 mm have been replaced by the different CMA aggregates (Tab. 4). Here the focus was on the question to which extent a very high spinel content and at the same time a very high total CaO content in the castable, both introduced through the CMA aggregates, would still give interesting thermomechanical properties. These C-type castables are now in fact rather spinel-alumina castables as they contain approximately 55 % spinel (CMA1-26C and CMA1-4B) and 60 % spinel (CMA2-6C), respectively. It also need to be mentioned that the CMA1-26C and CMA1-4C contain a very high lime content, between 6 and 7 % CaO, roughly twice as much as CMA2-6C and about four times more than the reference REF A-SP.

Tab. 4: Model castable formulation type C with 49 % CMA aggregates and reference model castable formulation REF A-SP.

## TEST METHODS

Physical properties (castable bulk density, apparent porosity, permanent linear change, modulus of rupture, crushing strength) have been determined at room temperature on hardened castable prisms (30 x 30 x 120 mm$^3$) after 24 h curing at 20 °C followed by 24 h drying at 110 °C, and after firing in a chamber furnace at different temperatures (800, 1100, 1400, 1600 °C) with a dwell time of 5 h.

Thermal shock tests have been carried out in accordance with NF EN 993-11 on prisms with the following dimension: 230x54x63 mm$^3$ (format B). Prior to the thermal shock tests the prisms have been pre-fired at 1600 °C (6 h), the temperature that is expected during the application in a steel ladle. For the thermal shock test itself the samples are put into a furnace that is pre-heated at 950 °C where they remain during 30 min to ensure an even temperature distribution within the prism. Then they are removed from the electric oven, placed on a steel plate and exposed to a jet of air (20°C). After this first quenching, the procedure is repeated 4 times. Subsequently, after the last quenching, the residual cold modulus of rupture (MOR) is determined and compared with a sample of the same material (and sample size) that has not undergone this quenching procedure. The thermal shock resistance is defined by the percentage of the residual MOR compared to the MOR of the non-quenched specimen.

Static cup corrosion tests have been carried out using castables, pre-fired at 1600 °C for 6 h. The refractory cup (inner diameter 5 cm) has been filled with 376 g of steel (structural carbon steel

AX48, containing 0.5 % C, 0.65 % Mn, <0.4 % Si, and <0.035 % S and P, respectively. A synthetic slag powder (40 g) with composition as shown in Tab. 4 was added. The corrosion test was conducted in a chamber furnace at 1500 °C for 6 h.

|---|---|---|---|---|---|---|---|---|
| 42.6 | 32.7 | 10.1 | 7.0 | 3.1 | 1.2 | 2.1 | 0.5 | 0.6 |

## TEST RESULTS

### Water demand and vibration flow

For all formulations (Tab. 2-4), water addition was adjusted to achieve a similar initial vibration flow value, in the range between 100 – 120%, directly after 4 minutes wet mixing. The lowest water demand was observed with the reference formulation (REF A-SP). This can be attributed to the low apparent porosity of the tabular alumina aggregates. As expected the high porosity in CMA1-26 leads to a higher water demand, especially when the content in the formulation is high (type C). This aspect is significantly improved with CMA1-4 and CMA2-6, both giving low water demands in formulation types A and B and a moderate increase in formulation type C compared to the CMA-free reference.

### Castable bulk density reduction

Since spinel has a lower density than corundum, a reduction of the castable bulk density is one of the desired effects when increasing the total amount of spinel through the addition of CMA aggregates since it will reduce material consumption and potentially as well the heat loss through the refractory lining, thus creating a more sustainable solution during usage in steel ladles. As can be seen in Fig. 2a, the reduction of bulk density is minimal when the total amount of spinel remains constant (type-A formulations). Only the impact of the higher porosity of CMA1-26 leads here to a more significant decrease (4 %) due to the additional grain porosity and the higher water demand. In formulation type-B (replacement of tabular alumina only) the difference is somewhat more pronounced compared to type-A mixes but still remains at low level (2 % density reduction) for the CMA aggregates with low porosity, while it is significantly higher for the CMA1-26 containing formulation that exhibits a 8 % density reduction versus the reference formulation without CMA (Fig. 2b). The biggest effect has been observed with the highest addition rates for all CMA-aggregate types, ranging from 6-8 % density reduction for the low-porous CMA-versions to 18 % for CMA1-26 (Fig. 2c) where the lower spinel density and the high grain porosity create a double effect.

Fig. 2a: Reduction of bulk density of CMA-containing castables (type A) versus REF A-SP.
*Fig. 2b: Reduction of bulk density of CMA-containing castables (type B) versus REF A-SP.*

*Fig. 2c: Reduction of bulk density of CMA-containing castables (type C) versus REF A-SP.*

**Permanent linear change (PLC) after the first castable firing**

One important parameter for an application in a steel ladle is the volume evolution of the refractory material during the first heat-up. The experience has shown, that refractories with a slightly positive PLC, for example alumina-magnesia castables (expansive spinel + CA6 formation at high temperature), bring a potential performance advantage over alumina-spinel castables. The latter typically exhibit only a small expansion related to CA6 formation or even show a slight shrinkage. Almost all tested formulations in this study remained within a very small shrinkage or expansion window between -0.2 and +0.2 % for all firings up to 1600 °C. However, it was noticed that the reference formulation and the formulation types A and B with CMA1-26 tended more to a small shrinkage at 1400 and 1600 °C as shown exemplary for the type A formulations (Fig. 3a) while the formulations with CMA1-4 and CMA2-6 showed small levels of expansion. For formulation type C (Fig. 3b) only CMA1-4 exhibited a somewhat higher expansion (0.4 %) while all others showed small shrinkage at 1400 and 1600 °C, with no significant difference between those formulations.

*Fig. 3a: Permanent linear change of type-A formulations.*

*Fig. 3b: Permanent linear change of type-C formulations.*

**Thermal shock resistance**

The most interesting results in this study are related to the performance in the thermal cycling test. As expected the reference formulation gets significantly affected, mainly already after the first shock and loses almost 90 % of its initial modulus of rupture (MOR) after 5 thermal cycles. As already reported in other publications [4], also these test series confirm that with CMA1-26 (MagArmour) the MOR after firing is lower than the reference, but achieves after five thermal cycles in absolute terms a higher MOR than the reference. It keeps between 18 and 42% of the initial MOR with the higher value for the higher addition rate (formulation type C). So the question was if this is related just to the higher micro porosity in MagArmour, or related to the different aggregate compositions. From these tests one can conclude that mineralogy is playing the dominant effect since also the dense version (CMA1-4) exhibits excellent thermal shock resistance, and even better than CMA1-26, with retention rates between 30 and 50% and again with the higher values for the type-C mixes. Contrary to that the CMA2-6 aggregates with their higher $Al_2O_3$ and lower CaO content but similar low porosity as CMA1-4, perform in a similar way as the reference in terms of relative remaining MOR but with even lower absolute values after the 5 thermal cycles. This was also confirmed by some additional experiments where the CMA2 composition was modified towards higher apparent porosity (up to 30%) which did not result in a higher thermal shock resistance.

359
*Fig. 4b: Modulus of rupture of type-B recipes after firing at 1600 °C, after additional 5 thermal shock cycles, and retention rate.*

*Fig. 4c: Modulus of rupture of type-C recipes after firing at 1600 °C, after additional 5 thermal shock cycles, and retention rate.*

360

*Fig. 5: Cup corrosion tests at 1500 °C, 6 h, with 376 g steel and 40 g slag (C/S=1.3, Fe2O3 = 3.1 %).*

**Corrosion resistance**

For a first quick evaluation some cup tests with steel and slag have been conducted with the type A formulations to evaluate if there would be an obvious difference in corrosion resistance between those mixes, that had constant total spinel content, but somewhat different CaO contents, and differences in grain porosity, especially in case of CMA1-26A. Fig. 5 shows the cross sections of the cups after the test at 1500 °C (6 h). It is obvious that castable CMA1-26A with its higher open porosity (14.5 vol. % after firing at 1600°C vs 12.2 vol. % for REF A-SP) shows a higher slag penetration. But both CMA1-4A and CMA2-6A with porosities close to 13% after firing at 1600°C resist the slag attack in a quite similar good way as the reference REF A-SP. Further tests are ongoing to evaluate the corrosion resistance also with a dynamic corrosion test and for the other formulation types.

## SUMMARY AND CONCLUSION

This study has investigated different alumina spinel model castables containing different versions of aggregates from the calcium magnesium aluminate system in comparison with a classical alumina spinel model castable based on tabular alumina and magnesium aluminate spinel. The study has confirmed that employing the microporous aggregate CMA1-26 (MagArmour) one can achieve superior TSR versus the reference material. However, the water demand and open porosity of the castable is increasing with this concept and thus the corrosion resistance is impacted. The modified CMA aggregates in terms of chemistry and porosity have shown that the impact of chemistry and with that the phase assemblage plays a more important role for the TSR than the micro porosity of the aggregates. A newly designed aggregate (CMA1-4) with a much lower porosity versus CMA1-26, but the same composition, has resulted in the best thermal shock resistance while keeping corrosion resistance at a similar good level as the reference material for the formulation type-A. Another effect of the employment of CMA-aggregates is that they reduce the material requirement for a given furnace design, thus safe material, but potentially also energy and contribute to a more sustainable steel production. Overall, so far the new CMA1-4 version resulted in the best compromise between resistance against thermal shock, corrosion and reduction of density. Further investigations are ongoing and will be reported in the future.

## ABSTRACT

When installing new well blocks, seating blocks for purging plugs, or impact pads in steel ladle bottom, self-flowing mixes are usually used for filling the gap between the bottom bricks and the pre-cast shapes. As the material demand is relatively low for these installations, smaller and less powerful mixers or even simple manual mixing procedures are used instead of high intensity refractory mixers. The mixing behaviour of castables strongly depends on the matrix formulation.

In general, the mixes can show shorter or longer wet-out times and softer or more dilatant consistency. An easy mixing behaviour is particularly important with this type of castable to prevent over-watering the mix on site and therefore jeopardizing the performance in use.

The paper describes suitable matrix formulations for this purpose and also practical experience and results.

## INTRODUCTION

A ladle bottom at ArcelorMittal Dabrowa Gornicza is lined with AluMagCarbon bricks with a pre-cast well block (Fig. 1). After 30 heats, the well block is replaced by a new one in a cold repair and replaced again after 50 to 60 heats. In order to close the joint between the well block and the bricks, a self-flowing castable is used as a better alternative to a ramming mix. The castable enables a faster and more reliable installation because less manual work is required.

*Fig. 1: Trial in ArcelorMittal Dabrowa Gornicza*

A castable with good self-flowing properties completely fills the joint and degasses without need for vibration. A low cement corundum-spinel castable is used to achieve the desired wear resistance in the ladle bottom. Adding spinel to the alumina mix improves properties such as thermal shock resistance, slag penetration and corrosion resistance.

Alumina-spinel castables are characterized by a hot modulus of rupture (HMoR) in the range of 20-30 MPa. The increase in strength is due to the formation of a strong bond between the $CA_6$ phase, hibonite, and alumina or spinel grains during sintering at higher temperatures. At a higher temperature (1400-1700°C) in the CaO-$Al_2O_3$-MgO ternary system, ternary CAM phase is also formed. With increasing temperature, the amount of this phase increases at the expense of alumina grains, spinel and the $CA_6$ phase. CAM has a platy hexagonal shape and grows into alumina grains, strongly connecting the matrix with the aggregates, resulting in high hot strength. [1,2] Alumina-spinel castable is used for precast shapes for example purging plugs, well-blocks and lances or for in-situ monolithic linings of steel ladles. In secondary metallurgy it is used for RH-snorkel and ladle cover and lip-ring. In the steel ladle bottom, it is used to fill the gap between bottom bricks and precast shapes.

Only a small amount of castable is required to line the joint between the bottom bricks and the well block. Therefore only small, less powerful mixers are used. Sometimes even manual mixing must be sufficient. It is important that the castable can cope with such sub-optimal mixing conditions and is designed for fast wet out behaviour, low dilatancy during mixing and handling, and low stickiness of the mix.

Particle size distribution determines the rheology of the castable. The degree of self-flowing is determined by the grain size below 100 μm, and more specifically below 45 μm, because the smallest fraction predominantly determines the flowability [3]. Three types of reactive alumina were used in the study: monomodal, bimodal and spinel-containing bimodal reactive alumina E-SY 2000. The bimodal distribution is composed of a finer and a coarser fraction, which results in a higher density and therefore lower porosity of the mix [4]. The E-SY 2000 has a special particle size distribution designed for easy mixing behaviour, fast wet out and low dilatancy of the mix for easy handling on site.

Due to the fact that this work focuses on rheological properties, it is worth adding that it is mainly reactive alumina that decides and controls the flow and also the type and development of bonds. The works of other authors also focused on flow (approx. 250mm), wet out time tests, where 45s was achieved as the lowest result [5]. E-SY was also used in the research, which allowed comparable spreading results to be achieved with a much lower mixing water content (4 wt.%). It's not easy to find articles that discuss the issues in industrial tests, so the work focuses mainly on the practical properties.

The purpose of this study was to create an alumina-spinel self-flowing castable with a modified matrix which meets the requirements of easy application in industrial conditions. This can be confirmed during tests in the steelworks and in the laboratory by short wet out time and ball drop test. It should have a long setting time, which allows application of the castable between well-blocks without risk of flow decay during transport to the steel ladle. In our research we compare three basic recipes that differ in the content and type of matrix alumina and AR78 spinel, which affect the thermomechanical strength and, in particular, the rheological properties.

## MATERIALS AND METHODS

The following raw materials were used for the research: ALMATIS Tabular Alumina T60/T64 in various fractions (3-6 mm, 1-3 mm, 0.5-1mm, 0-0.3 mm, -45 and -20MY). Each recipe had 5 wt.% of cement with a long setting time. Samples contained alumina rich spinel AR78 in two fractions (0-0.5 mm and -90MY) with a total of 17 wt.% plus 1 wt.% additives.

The most important variable is the use of different grades of reactive alumina. Mix (A) contains 13 wt.% of bi-modal $Al_2O_3$, mix (B) contains 13 wt.% of mono-modal $Al_2O_3$ and mix (C) contains reactive alumina with spinel E-SY 2000 in total 20 wt.%, to compensate for the reduced amount of spinel.

The castables were prepared in the laboratory initially by dry mixing for 1 minute, then, after adding the appropriate amount of water, wet mixing for 4 minutes. The wet out time, flow, ball drop test, and exothermic reaction during cement setting (EXO method) were measured. Industrial trials of the one selected mix were carried out at AM Dabrowa Gornicza for joint filling around the well block in the steel ladle bottom.

For flow testing (PN-EN ISO 1927-4:2013-06) a metal cone with dimensions 80x100 was used and filled with castable. The flow was measured 2 and 20 min after wet mixing.

Wet out time is a test that shows how quickly a material combines with water to form a wet mass. The result is the time measured from adding water to observing the wetting of the material. The shorter the time, the easier the material mixes. This also applies in industrial conditions.

In the ball drop test, a steel ball (110g, 30 mm diameter) falls from a height of 1 m into the castable in the mixing bowl. The result of the test is the time measured from the moment the ball is released until it is completely immersed in the mix [3]. A short immersion time is a quantitative indicator of the softness of the mix, which is important for easy installation on site. The ball drop test is a very simple but important method which shows different behaviour of castables with regard to stiffness caused by dilatancy. High dilatancy is a big negative for the handling of castables on site. This often causes excess water to be added by the operators which, in turn decreases the performance of the lining in use. The challenge is therefore to create a castable with the lowest possible water requirement combined with lowest dilatancy.

Test bars with dimensions of 64x64x240mm were made using each recipe. Firstly, samples were dried at 110°C/24h and then fired at 450°C/5h or 1570°C/5h respectively. Open porosity and bulk density (993-1:2019-01), cold crushing strength (EN 196-1:2005) and cold modulus of rupture (EN 993-5:2019-01), PLC (PN-EN ISO 1927-6:2013-06) were measured. Samples for HMoR had dimensions of 25x25x148 mm (PN-EN 993-7), and were dried at 110°C/24h and pre-fired at 1500°C/5h. The test was carried out at 1450°C.

**Tab. 1:** Compositions of castables

| Castable<br>Components | | A | B | C |
|---|---|---|---|---|
| Tabular Alumina | | 64 | 64 | 66 |
| Cement | | 5 | 5 | 5 |
| Reactive alumina bi-modal | | 13 | - | - |
| Reactive alumina mono-modal | Wt. % | - | 13 | - |
| Reactive alumina E-SY 2000 | | - | - | 20 |
| Spinel AR78 | | 17 | 17 | 9 |

## RESULTS AND DISCUSION

### Rheological properties

After 20 minutes all test castables show good self-flow behaviour without flow decay (Tab. 2). Castables B and C need 0.2% less water to achieve the desired flow value.

Wet out time is similar for all castables. In the ball drop test, castable C clearly obtained the best result.

The EXO results are shown in Table 2 and Figure 3. Start 1 indicates the end of workability and flow. Start 2 shows when hydration of cement and strength development start. Exo Max shows the point when sufficient green strength for demoulding is achieved. Comparison of the results from EXO test shows the longest setting time was achieved with castable C. This allows for a longer time for castable application in industrial conditions.

**Tab. 2:** Wet castable properties.

| Properties | | A | B | C |
|---|---|---|---|---|
| Water [%] | | 5.0 | 4,8 | 4,8 |
| Flow [mm] 2 min | | 237,5 | 238,1 | 236,5 |
| Flow [mm] 20 min | | 232,5 | 240,1 | 242,5 |
| Wet out time [s] | | 35 | 35 | 30 |
| Ball drop test [s] | | 15 | 15 | 6 |
| EXO | Start 1 / min | 348 | 234 | 402 |
| | Start 2 / h | 11,2 | 8,7 | 13,1 |
| | Exo Max / h | 13,2 | 10,6 | 15,3 |

**Fig. 2:** Ball drop test

**Fig. 3:** EXO test for castable samples

### Thermo-mechanical properties

Figure 4 shows bulk density (a) and open porosity (b) for the castable samples at different temperatures. For each sample density decreases and porosity increases with increasing temperature. The typical values for alumina-spinel castables are approximately $3 \text{ g/cm}^3$. Open porosity at 1500°C can reach up to 20% [3].

a)

b)

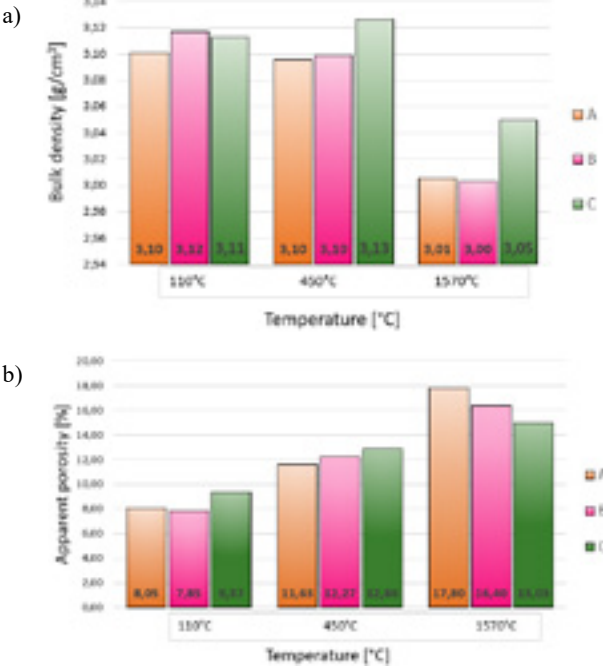

**Fig. 4:** Bulk density (a) and open porosity (b)

Fig. 5 shows permanent linear change at 110, 450 and 1570°C. All samples achieved slight expansion at 1570°C. To sum up alumina-spinel castables are stable and deviations in dimensions are not significant.

**Fig. 5**: *Change linear dimensions for castable samples*

Fig. 6 shows cold modulus of rupture, and Fig. 7 cold crushing strength. All materials show a significant effect of temperature increase on the strength of the material.

**Fig. 6**: *Cold Modulus of Rupture for castable samples*

**Fig. 7**: *Cold Crushing Strength for castable samples*

The castable is used in a highly erosive environment in the steel ladle bottom. Therefore hot modulus of rupture was carried out at a temperature of 1450°C (Fig. 8) as an indicator of erosion resistance at high temperature. High hot strength values were obtained, which prove the high resistance of the material even in difficult conditions. Each of the samples obtained >30MPa. The highest result was observed for sample C. This may be due to the type of reactive alumina. In its composition, E-SY 2000 contains super fine spinel, which is more reactive and enables better sintering. [6]

**Fig. 8**: *HMoR for castable samples*

## PRACTICAL EXPERIENCES

After analysis of the above results, sample C was selected for the industrial trial. Figure 1 shows application of castable around the well-block in the steel ladle bottom in Dabrowa Gornicza. Initially the product was dry mixed and then the specified amount of water was added. The total mixing time was approximately 6 minutes. Because of the short wet out time of max 30s, the operators rely on the castable behaving normally and therefore not add additional water. Long setting time and consistency of the mix (doesn't stick to the blades or to the walls of the mixer) allows for smooth and reliable application.

The desired lining life performance is achieved at ArcelorMittal Dabrowa Gornicza, and the joint lining is never the root cause for early repair of the bottom. However the wear of the well block defines the maintenance pattern.

## CONCLUSIONS

Joint lining between bricks and well block in the bottom is important for the performance of the entire ladle bottom lining. Self-flowing corundum spinel castable with spinel-containing bimodal reactive alumina type E-SY 2000 has shown good performance at AM Dabrowa Gornicza. The developed castable shows low water demand, fast wet out, low dilatancy as tested by the ball drop test, and low stickiness. Mixing and installation in the steelplant works well without problems even in sub-optimal conditions, and has become the standard practice. The desired lining life is achieved by the wear resistant corundum spinel low cement castable.

# APPLICATION OF UNBURNED MAGNESIA BRICKS
# FOR STEEL SECONDARY REFINING PROCESSES

Yuya Tomita, Takahiro Anan, Kiyoshi Goto and Katsumi Morikawa
Krosaki Harima Corporation, Kitakyushu, Japan

## ABSTRACT

In the steel refining processes, magnesia carbon or magnesia chrome bricks have been widely used conventionally as refractories for holding molten steel to be refined due mainly to satisfy the material requirement for high corrosion resistant. However, magnesia carbon bricks and magnesia chrome bricks have heat loss and hexavalent chromium formation problems, respectively. A novel unburned magnesia brick have been developed for use in the steel secondary refining process that contains neither graphite nor chromium, in light of future environmental issues. As a notifying point of the developed brick, the high temperature corrosion resistance against iron oxide, FeO was superior to the conventional magnesia-carbon and -chromite bricks. Thus, newly developed environmentally friendly unburned magnesia brick will be contributing not only in the reduction of $CO_2$ and carbon neutrality but also in the elimination of chromium.

## INTRODUCTION

Magnesia carbon (MgO-C) bricks and magnesia chrome (MgO-$Cr_2O_3$) bricks with high corrosion resistance are used widely in the secondary refining processes of steel. The development of chromium-free material is examined as a countermeasure against the problem that magnesia chrome bricks easily react with alkaline components in the molten steel and produce harmful hexavalent chromium compound [1 - 4].

In future, the challenge for $CO_2$ reduction and carbon neutrality will be required more keenly for industrial world. MgO-$Cr_2O_3$ bricks are fired at temeratures higher than 1700 °C, and a large amount of carbon dioxide is emitted during production. An unburned MgO-$Cr_2O_3$ brick tempered at 200 °C for the secondary refining was examined and reported to have corrosion resistance equivalent to that of fired MgO-$Cr_2O_3$ bricks [5], [6] .

Since the MgO-C bricks contain flake graphite, there are concerns about heat dissipation into the atmosphere due to increased thermal conductivity and carbon leaching into the molten steel. It was reported that applying low graphite MgO-C bricks to the converters, the heat loss could be reduced by 17 % with improved durability of the brick [7].

Considering these situations, we also have examined to develop an unburned magnesia brick for the secondary refining without containing neither chromium nor graphite. In the present study, the characteristics of the developed bricks were investigated, together with the effect of heat loss control when used in an actual furnace.

## EXPERIMENTAL PROCEDURE

### Test Materials

The unburned magnesia (MgO) bricks without containing graphite and MgO-C bricks with the graphite contents of 1, 3, and 5% were named materials A to D, respectively. They were chosen as test materials together with material E of a direct bonded MgO-$Cr_2O_3$ brick for comparison, as shown in **Table 1**. Raw materials powders for the test materials A to D were mixed with both suitable amounts of phenol resin as binder, and some antioxidant agent, molded and formed to 230×100×110mm shape bar using a vacuum hydraulic press, then dried at 250°C for 5h to prepare the test samples.

### Test Method

*Density and Porosity*

Bulk density and porosity were measured based on JIS R 2205. The measurements were carried out for each sample for materials A to D after drying and after firing at 1400°C for 3h under the reducing atmosphere as shown in **Table 2**. As a comparision the direct bonded magnesia chrome brick (E) after fired was also evaluated.

*Thermal Property and Corrosion*

The thermal conductivity was measured at 800 °C using the heat flow method in the specimen after the firing at 1400 °C for 3h.

**Figure 1** shows a schematic of the apparatus and method of high-temperature Fe-oxide corrosion test. The test was carried out by a method in which a specimen, which had been reduced and fired at 1400 °C for 3h in advance, was heated to 1750 °C and held for 30min, oxygen was blown from a steel lance, and the brick was corroded by the Fe-oxide formed with heat generated by oxidation reaction in th the lance tip under a high temperature [8]. The degree of corrosion was evaluated by measuring the amount of errosion in a cut surface of the specimen after the corrosion test and in addition to the microstructure observation in the cross section of the specimen at the vicinity of corroded surface after the high temperature Fe-oxide test. Assessment of the corrosion behavior was performed by two methods; a direct measurement of the amount of corrosion and an analysis of microstructural observation of corroded surface. In the former assessment, measured amount of corrosion for each sample was converted to corrosion index to compare the amount relatively by setting the amount of corrosion for MgO-$Cr_2O_3$ to 100. Microstructural observation as an another assessment, was carried out in the specimen obtained from the cross section of the sample for each material at the vicinity of corroded surface using scanning electron microscope (SEM) including detail analysis using EPMA (Electron probe micro-analyzer).

## EXPERIMENTAL RESULTS AND DISCUSSION

### Bulk Density and Apparent Porosity

**Table 2** shows the physical properties of materials (A-D) after dried and after fired at 1400 °C for 3h and material (E) after firing as a conpmarision. **Figure 2** shows the variations of bulk density (a), apparent porosity (b) with amount of graphite addition for both dried and fired states.

First, the bulk density showed a tendency to increase with the graphite addition for the amount up to 1% then, decrease with exceeding addition to 1% for both dried and fired states. Next, the apparent porosity tended to decrease with increase in the graphite addition for after dried states, and showed almost constant value in the case of the addition exceeding 1%, though it slightly decreased with the graphite addition for after fired states.

Tab. 2: Bulk density and porosity of materials A~ E

| Material<br>Density/Porosity | A<br>MgO | B<br>MgO-C | C | D | E<br>MgO-Cr$_2$O$_3$ |
|---|---|---|---|---|---|
| Bulk density<br>/ × 10$^3$kg·m$^{-3}$ | 3.14<br>(3.15) | 3.14<br>(3.16) | 3.12<br>(3.15) | 3.08<br>(3.10) | 3.27 |
| Apparent porosity<br>/ % | 9.0<br>(5.4) | 8.3<br>(4.3) | 8.2<br>(3.5) | 8.3<br>(3.0) | 15.6 |

(   ) : After drying

Fig. 2: Variations of bulk density (a) and apparent porosity \ (b) with amount of graphite addition for both dried and fired states.

**Thermal Conductivity and High Temperature Corrosion**
The dependences of the graphite addition amount on the thermal conductivity at 800°C and the corrosion index in the high temperature Fe-oxide test are shown in **Figure 3** (a) and (b), respectively. Decreasing the graphite content, the thermal conductivity lowers to the minimal value with 0% addition, resulting in the 50% reduction from the value with 5% graphite. The thermal conductivity value of the material without graphite is almost the same value of the direct bonded MgO-Cr$_2$O$_3$ brick.

Fig. 3: Variation of thermal conductivity (a) and corrosion index obtained by the high temperature Fe-oxide test (b) with amount of graphite addition.

Supposing the corrosion index of the magnesia chromite specimen as 100, the index of MgO-C bricks was much lower than that of the magnesia chromite brick and the index lowered with decreasing the graphite indicating the improvement in the corrosion resistance.
The corrosion resistance of the MgO-C bricks after firing has been reported to be affected by the porosity in the manner in which the corrosion resistance became higher with lowering the porosity [9]. As shown in the **Figure 3** (b), the corrosion resistance against Fe-oxide at high temperature was improved in the bricks without graphite, although the porosity after firing was higher than in the other bricks. To investigate the reason why this occurred, we have carefully observed the microstructure at the vicinity of corroded test surface of the specimen after high temperature Fe-oxide test.

**Microstructure of Corroded Surface of Bricks**
**Figure 4** shows the microstructures at the vicinity of corroded test surface of the cross section after high temperature Fe-oxide test for materials with (a) 5 %, (b) 0 % graphite and (c) the direct bonded MgO-Cr$_2$O$_3$ brick.

Fig. 4: Microstructure of the cross section of the specimen at the vicinity of surface after high temperature Fe-oxide corrosion test for materials A, D and E for (a), (b) and (c), respectively.

365

Although formation of MgO clinker on the corroded test surface is observed, in both materials with graphite of 5 %(a) and 0 %(b) the clinker has poor continuity by intervening the pores. In the case of (a) large pore formed by corrosion with MgO-C reaction. On the other hand, in the case of (b), no large pore in the layer of MgO clinker is observed on the corroded test surface, and there is durable connecting layer was reserved. The formation of the pores due to MgO-C reaction in the specimen inside under the clinker layer was also significantly suppressed in the case of (b) compared with that of (a). Thus, it was apparent that the material without graphite showed higher corrosion resistance than those with graphite by preventing the clinker layer formed in the corroded surface from the penetration of Fe-oxide and the dispersion of Mg with MgO-C reaction, protecting the inside under the layer.

In the case of (c), which had the worst corrosion resistance test results, no large pore was observed on the corroded test surface like as the case of (b). On the other hand, the shape of the aggregate in the material E (c) was observed to be indistinct, unlike both the materials A (b) and D (a).

To investigate the difference in erosion between the materials A (b) and E (c), EPMA was used to analyze the microstructure. **Figure 5** shows the state of the hot surface of for both materials A (a) and E (b) after the Fe-oxide test. Focusing on the elemental distribution of iron, it was observed that in the A (a), the iron remained on the hot surface, while in the E (b), the iron infiltrated into the interior of the structure. Thus, the material A (a) was considered to have improved corrosion resistance where the infiltration of iron was more controlled than in the material E (b) .

*Fig. 5: EPMA analysis of the materials A (a) and the E (b) after the Fe-oxide test.*

## Possible Improvement of Heat Dissipation

The heat conduction in the steady state was calculated on the assumption that four materials shown in the **Table 1** were applied respectively to the vessel wall (wear brick) in the lower vessel of the typical RH degasser. **Figure 6** shows the cross sectional view of the lower vessel of the RH degasser (a) and the part of area surrounded by the broken line was simplified to a model cylinder with (b), showing also layer composition of the vessel wall. 2500 mm height and 1000 mm distance from the center to the surface of the wear brick for the calculation. In addition, **Table 3** shows thickness and thermal conductivity for 4-layer materials composing the wall as a calculation condition. The measured values shown in **Figure 3** (a) were used as the thermal conductivity of 4 materials in the **Table 3** (1).

*Fig.6 : Cross sectional view of the lower vessel of the typical RH\* degasser(a) and the part of area surrounded by the broken line was simplified to a model cylinder(b) with wall composed by 4-layer materials shown in Table 3.   (\*RH: Ruhrstahl Heraeus degassing process)*

Tab. 3: Condition for calculation of heat conduction in vessel wall

| Layer composition of wall | | Thickness /mm | Thermal conductivity, $\lambda$ /W·m$^{-1}$·K$^{-1}$ |
|---|---|---|---|
| (1) | Wear brick(inner) | 450 | 4.0~9.5(MgO-C brick, see Fig.3(a)) |
| (2) | Permanent brick | 50 | 3.0 |
| (3) | Insulating brick | 30 | 0.1 |
| (4) | Steel shell (outer most) | 30 | 40.0 |

Assuming steady heat conduction, heat release from the steel shell of the outermost layer in the vessel wall shown in **Figure 6** (b), is estimated for the case that the inner and outer surface sides are contacting with 1600 ℃ molten steel and 25 ℃ air, respectively, and the emissivity of the steel shell as 0.85.

For 4 materials in the **Table 1**, the estimated both temperature of external steel shell and heat flux are shown in **Figure 7** as a function of graphite amount in the materials. As shown in the **Figure 7**, the temperature of steel shell lowered with the graphite content, and the temperature for the material without graphite was lower than that for the 5%graphite content by about 16℃. Heat flux reduced also with the graphite content as shown in **Figure 7**, and the heat flux for the material without graphite decreased by about 13% compared with that for the 5% graphite content.

In the estimation performed so far, the heat release was calculated with the constant thickness of wear brick as 450mm. In actual operation, however, the wear brick must be thinned with time due to erosion of molten steel. Thus, assuming that the brick is thinned to 100mm at a constant rate, the temperature of both external shell and heat flux are calculated for the 4 materials with taking account of thinning of the wear brick during operation, as shown in **Figure 8**(a) and (b). As apparent in the figure, when the wear brick becomes

100mm thickness, the temperature of external shell and heat flux increased from those for the original thickness of 450mm by about 30% and about 75%, respectively.

*Fig.7 : Variations of temperature of exteranal steel shell, and heat flux with amount of graphite addition.*

*Fig.8 : Variations of temperature of exteranal steel shell (a), and heat flux (b) with thickness of wear brick for 4-kind of MgO-C system materials*

Next, the accumulated heat radiation from the lower vessel of the RH degasser, Heat transfer amount Q was calculated using the equation (1) as shown in **Figure 9**, when the 4 materials are applied to the wear brick of the vessel wall. As the assumption, total life of the lower vessel is considered as 350ch with 30 min each.

$$Q = h_c \cdot S \cdot (T_s - T_a) + \sigma \cdot \varepsilon \cdot S \cdot (T_s^4 - T_a^4) \qquad (1)$$

Where, $h_c$ is convective heat transfer coefficient of external surface: $1.16 \times 10^{-5}$ W/mm$^2$ · K$^{-1}$, S is area of heat transfer, $T_s$ and $T_a$ are temperatures of surface of the wear bricks and outside air, respectively, σ is Stefan Boltzmann constant:$5.67 \times 10^{-14}$ W/mm$^2$ · K$^4$ and ε is emissivity of the steel shell: 0.85.

The accumulated heat radiation decreased with decreasing graphite content, and the heat radiation of the brick without containing the graphite was about 10% lower than that with 5% graphite content as shown in **Figure 9**.

*Fig.9 : Accumulated heat radiation of the lower vessel of RH degasser estimated for the cases of 4 MgO-C materials used as the wear brick of the furnace.*

## SUMMARY

The characteristics of unburned graphite-free magnesia bricks were confirmed to be lower bulk density, higher porosity, and lower thermal conductivity in comparison with the bricks containing graphite. In addition to the expected suppression of the heat loss, due to low thermal conductivity, the unburned graphite-free magnesia brick showed higher corrosion resistance against Fe-oxide at high temperature than the MgO-C (graphite) bricks. Thus, in the practical use of the unburned graphite-free magnesia brick, the steel making process is expected to be improved by increasing durability of refractories for the secondary refining, by decreasing the environmental loading through both CO$_2$ reduction and chromium eliminations from the refractories, and by minimizing the opportunity of the steel to pick-up carbon from the refractories.

**ABSTRACT**

With high-calcium fused magnesite produced by Tibetan microcrystalline magnesite in China and graphite as main raw materials, aluminum powder、 silicon powder and silicon carbide powder as antioxidants, and phenolic resin as binder, a new type of high-calcium magnesia-carbon brick was prepared after mixing, molding and drying. Then its physical and chemical properties were tested. To investigate the influence of the new high-calcium magnesia-carbon brick on molten steel quality in smelting process, a high-temperature vacuum tube furnace was adopted, the smelting temperatures were 1550℃ and 1600℃, and the smelting times were 20min, 40min, 60min, 80min and 100min. The comparison experiment between new high-calcium magnesia-carbon brick and traditional magnesia-carbon brick was conducted for the second smelting of 45 steel. By comparing the change characteristics of molten steel composition and inclusions before and after smelting, the purification of S and P elements and the removal of inclusions by the new high-calcium magnesia-carbon brick were explored. The results show that: 1) The new high-calcium magnesia-carbon brick produced with high-calcium fused magnesia has a CaO content of about 5wt%, and its physical properties are equivalent to those of traditional magnesia-carbon brick; 2) The purification of S and P elements in steel by the new high-calcium magnesia-carbon brick is obviously higher than traditional magnesia-carbon brick, and the removal rate of S and P can separately reach 14.58% and 19.41% under the melting condition of 1600℃×40min. 3) The new high-calcium magnesia-carbon brick has obvious removal effect on the number and size of inclusions in steel.

## INTRODUCTION

Magnesia-carbon brick is a common material of ladle. The main raw materials are magnesia, graphite, resin and antioxidant. Traditional magnesia-carbon brick has the advantages of high temperature resistance, good slag corrosion resistance and thermal shock resistance.

Magnesium-calcium refractories not only have good chemical stability to molten steel and good slag corrosion resistance, but also can purify molten steel[1-2].

The crystal structures of MgO and CaO are NaCl-type structures, belonging to face-centered cubic lattice, cubic crystal system and Fm-3m space group [3].

The lattice constant of MgO is 0.4211nm, the theoretical density is about 3.58g/cm3, and the melting point is 2800℃. MgO has good corrosion resistance, but its thermal stability is poor. So, it is easy to be infiltrated and eroded by slag. The lattice constant of CaO is 0.4810nm, the theoretical density is about 3.582g/cm3, the melting point is 2572℃. CaO has a small thermal expansion coefficient at high temperature and low saturated steam pressure. And the structural spalling resistance and slag resistance are excellent.

At the same time, CaO easily reacts with $SiO_2$ in molten slag to generate $C_2S$ and $C_3S$. These products have high melting point and high viscosity, which can improve the viscosity of slag. Thus it becomes easy for slag to hang on the surface of working layer to form a covering layer, which can block pores and effectively slow down the penetration of slag into bricks, and then protect refractories from being corroded by molten slag. Finally, the slag resistance of the material is improved. At the same time, the covering layer makes the furnace lining not directly contact with air. This reduces carbon oxidation. Moreover, CaO has high chemical activity and can effectively absorb [Al], [S], [P] and other impurities in molten steel. In addition, the existence of free CaO makes magnesia-calcium-carbon brick have good slag corrosion resistance to high alkalinity, and the slag alkalinity is low in the initial stage of refining. Free CaO can improve the slag alkalinity on the surface of working lining brick and then reduce the chemical corrosion of slag.

Based on the above theory, this paper firstly prepares a new type of high calcium magnesium carbon brick with high calcium magnesia compared from Tibetan microcrystalline magnesite (Western CHINA ) as raw material, in order to improve the purification effect of ladle brick on molten steel; Then, to investigate the influence of new high-calcium magnesia-carbon brick on the quality of molten steel in the smelting process, a high-temperature vacuum tube furnace was used to select different smelting process conditions, and a comparative experiment was carried out between new high-calcium magnesia-carbon brick and traditional magnesia-carbon brick, and 45 steel was used for secondary smelting, and the characteristics of molten steel composition before and after were compared. The interaction mechanism between new high calcium magnesium carbon brick and molten steel is analyzed, and the purification law of molten steel is explored.

## 1. EXPERIMENTAL PROCEDURE

### 1.1 Raw materials

The main raw materials are ordinary magnesia and Tibetan high calcium magnesia, and their chemical compositions are shown in Table 1.

Tab.1: chemical compositions of magnesia

| Magnesia | ω/% | | | |
|---|---|---|---|---|
| | SiO₂ | Fe₂O₃ | CaO | MgO |
| Ordinarymagnesia A | 0.58 | 0.61 | 1.76 | 97.05 |
| Tibetan high-calcium magnesite B | 0.51 | 0.42 | 6.03 | 92.85 |

### 1.2 Sample preparation

Traditional magnesia-carbon bricks and new magnesia-carbon bricks with high calcium content were made from three kinds of magnesia and graphite in Table 1, aluminum powder, silicon powder and silicon carbide powder as antioxidants and phenolic resin as binder, respectively, after mixing, molding and drying, and their physical and chemical properties were tested. The results are shown in Table 2.

Tab.2: Properties of two kinds of magnesia-carbon bricks

| Brick | chemical composition ω/% | | | | | physical properties | |
|---|---|---|---|---|---|---|---|
| | CaO | MgO | C | SiO₂ | Al₂O₃ | B.D. | CCS |
| A | 1.88 | 86.37 | 8.01 | 2.02 | 2.03 | 2.99 | 35.9 |
| B | 5.01 | 83.43 | 8.01 | 2.01 | 2.02 | 3.01 | 35.7 |

### 1.3 Experimental process

A high-temperature vacuum tube furnace (model CQL16-60, as shown in Figure 1) was adopted in order to investigate the influence of new high-calcium magnesia-carbon brick on the quality of molten steel during smelting.

While the smelting temperature was set to 1,550℃ and 1,600℃, and the smelting time was set to 20min, 40min, 60min, 80min and 100min.

The secondary smelting experiment was conducted on 45 steel with new high-calcium magnesia-carbon brick and traditional magnesia-carbon brick.

By comparing the change characteristics of molten steel composition and inclusions before and after smelting, the purification effect of new high calcium magnesium carbon brick on [S] and [P] elements in steel and the removal of inclusions were explored.

*Fig.1: high-temperature vacuum tube furnace*

## 2. RESULTS & DISCUSSION

### 2.1 Effect of high calcium magnesium carbon brick on sulfur in steel

The effect of magnesia-carbon brick on sulfur in steel under different smelting conditions was shown in Figure 2.

It can be seen that，

1) Under the melting condition of 1550℃, the highest desulfurization rate is only 2.17% when using traditional magnesia-carbon brick A, while that is 5.38% when using high calcium magnesia-carbon brick B.

2) Under the condition of melting at 1600℃, the highest desulfurization rate is only 7.29% when using traditional magnesia-carbon brick A, while that is 14.58% when using high calcium magnesia-carbon brick B.

3) Compared with traditional magnesia-carbon brick, high calcium magnesia-carbon brick has obvious desulfurization effect.

It is considered that, there is some free CaO in the new high calcium magnesium carbon brick compared with traditional magnesia-carbon brick. when melting, the free CaO component in the new high calcium magnesium carbon brick will react with [S] in molten steel as follows:

$$[S]+(CaO)\rightarrow(CaS)+[O] \tag{1}$$

CaS will adhere to the surface of refractories, forming a dense sulfide layer. Moreover, the concentration of CaS gradually increases with the extension of reaction time, and a dense reaction layer is formed. Part of the reaction layer falls off due to the stirring of molten steel, and CaS will enter the steel to form inclusions or gradually enter the slag for removal.

（a）1550℃ （b）1600℃
*Fig.2: Effect of magnesia-carbon brick on sulfur in steel under different melting conditions*

### 2.2 Effect of high calcium magnesium carbon brick on phosphorus in steel

The effect of magnesia-carbon brick on phosphorus in steel under different smelting conditions was shown in Figure 3. It can be seen that，

1) Under the melting condition of 1550℃, the highest dephosphorization rate is only 9.7% when using traditional magnesia-carbon brick A, while that is 14.5% when using high calcium magnesia-carbon brick B.

2) Under the melting condition of 1600℃, the highest dephosphorization rate is 16.1% when using traditional magnesia-carbon brick A, while that is 19.4% when using high calcium magnesia-carbon brick B.

3) Compared with traditional magnesia-carbon brick, high calcium magnesia-carbon brick has obvious dephosphorization effect.

It is considered that, when the new high calcium magnesium carbon brick is used for smelting, the free CaO component in the brick will react with [P] in molten steel as follows:

$$2[P]+5[O]=(P_2O_5) \tag{2}$$

$$(P_2O_5)+4(CaO)=(4CaO \cdot P_2O_5) \tag{3}$$

Therefore, the new high calcium magnesium carbon brick has good dephosphorization effect when melting.

（a）1550℃ （b）1600℃
*Fig.3: Effect of magnesia-carbon brick on sulfur in steel under different melting conditions phosphorus*

### 2.3 Effect of high calcium magnesium carbon brick on the change of inclusion quantity in steel

The effect of magnesia-carbon brick on Quantity and area ratio of inclusions in steel under different smelting conditions was shown in Figure 4. It can be seen that,

1) Under the melting condition of 1550℃, the reduction ratio of the Inclusion quantity in steel is 28.3% when melting with traditional magnesia-carbon brick A, while that is 29.7% when melting with high calcium magnesia-carbon brick B.

2) Under the melting condition of 1600℃, the reduction ratio of the Inclusion area in steel is 25.1% when melting with traditional magnesia-carbon brick A, while that is 29.1% when melting with high calcium magnesia-carbon brick B.

369

（a）1550℃       （b）1600℃
*Fig.4: Effect of magnesium carbon brick on the inclusion quantity in steel under different melting conditions*

Figure 5 shows the distribution of inclusions in the original steel sample. The selected 45 steel is with low cleanliness and high inclusion content. So many banded inclusions can be observed, and the distribution is relatively dense as a whole.

Figure 6 shows the distribution of inclusions in steel samples after melting with new magnesia-carbon brick B. It can be seen that the number of inclusions in steel is obviously reduced and the inclusion distribution transformed into sporadic point distribution after melting.

*Fig. 5: Banded distribution of typical inclusions in original steel samples*

*Fig.6: Distribution of Inclusions in Steel Samples after Melting*

*（1600℃×40min）*

Above all, compared with the traditional magnesia-carbon brick, the high calcium magnesia-carbon brick significantly improves the reduction ratio of the number of inclusions and the area of inclusions in steel. That is, the effect of removing inclusions in steel is stronger.

## 2.4 Effect of high calcium magnesium carbon brick on size distribution of inclusions in steel

Figure 7 shows the influence of magnesia-carbon brick on the size distribution of inclusions in steel under different melting conditions (small particle inclusions with a diameter of 1-3 μ m; Large particle inclusions, diameter > 3 μ m), it can be seen that,

1) Under the melting condition of 1550℃, compared with the traditional magnesia-carbon brick A, the reduction ratio of small particle inclusions in steel is basically the same, but the reduction ratio of large particle inclusions in steel is significantly improved.

2) Under the melting condition of 1600℃, compared with the traditional magnesia-carbon brick A, the reduction ratio of small particle inclusions and large particle inclusions in steel is basically the same.

In summary, compared with the traditional magnesia-carbon brick, when high calcium magnesium carbon brick is used for smelting, the size of inclusions in steel is obviously reduced; while the reduction ratio of small particle inclusions in steel is basically

the same, but the reduction ratio of large particle inclusions is obvious.

（a）1550℃       （b）1600℃
*Fig.7: Effect of magnesium carbon brick on the inclusions size under different melting conditions*

## CONCLUSIONS

1) The new high-calcium magnesia-carbon brick produced with high-calcium fused magnesia has a CaO content of about 5wt%, and its physical properties are equivalent to those of traditional magnesia-carbon brick;

2) The purification of S and P elements in steel by the new high-calcium magnesia-carbon brick is obviously higher than traditional magnesia-carbon brick, and the removal rate of S and P can separately reach 14.58% and 19.41% under the melting condition of 1600℃×40min.

3) The new high-calcium magnesia-carbon brick has obvious removal effect on the number and size of inclusions in steel.

# STEEL LADLE: CAPACITY INCREASE, LINING CONCEPTS AND RECYCLING EXPERIENCE OVER 25 YEARS

Reinhard Exenberger, Georg Grimm
voestalpine Stahl Gmbh, Linz, Austria

## ABSTRACT

The annual production in Linz has grown from 3.6 mt/a in 1998 to almost 5.3 mt/a in 2023. To provide these figures, an increase of the heat weight from 151,2 t/heat to 178t/heat had been necessary. When we had been changing the LD vessels to bigger sizes in 2001 and 2009, we also had to purchase new ladle vessels to handle the bigger heat size. To relax the pressure in the daily converter production, we procured bigger steel shells in 2022 again.

Whilst changing the steel ladle vessels, we realized modifications to the lining concepts, for an increase of ladle capacity. We gained experience with brick lined and monolithic ladles.

Regarding refractory breakout material we relied on our decades of experience in recycling. Magnesia breakout has been recycled to Magnesia Carbon bricks in the inhouse brick plant, whereas fine grains from the bag filters have been charged into the LD vessel as Magnesia carrier. Alumina breakout has been recycled into slag formers for the secondary metallurgy.

## STEEL PRODUCTION AT VOESTALPINE LINZ

voestalpine is a globally active group and represented by 500 companies that produce, process, and further develop high-quality steel products in 50 countries on all 5 continents. The headquarter is in Linz/Austria. There is the group's biggest steel plant as part of an integrated mill for flat steel production. The production facilities of the melting shop and the caster area are three hot metal desulfurization stands, one hot metal mixer with a capacity of 2000 t, three LD vessels with a capacity of 180 t/heat, four ladle furnaces, four RH degassers, one double strand slab caster and four single strand slab casters (figure 1). It is worth mentioning, that there is a brick plant for Magnesiacarbon bricks located in Linz.

Fig. 1: Production facilities

The annual production increased over several ups and downs from 3.6 mt/a in BY 1998 to 5.3 mt/a in BY 2023, where the daily production increased from 65,7 heats per day to 83,4 heats per day (figure 2).

Fig. 2: Annual production and heats per day.

To increase the heat size from 151,2 t to 178 t over the years, we exchanged the LD vessels in 2002 and 2009. The ladle vessels were exchanged in 2002, 2009 and 2022 (figure 3) and the lining concepts were adjusted again and again.

Fig. 3: Heat size

## STEEL SHELLS AND REFRACTORIES

The lining has developed in refractory quality and dimensions.

Starting in 2001, the steel ladle was lined with a high alumina vibration castable in the bottom and the wall and Magnesiacarbon bricks in the slag line. It was usual, to reline the wall every second slag line and bottom campaign. The thickness of the bottom sloped down from 300 mm to 250mm towards the teeming hole. The thickness of the wall was chosen increasing from 167 mm below the slag line to 204 mm above the bottom. The slag line was a balanced mix of 3P, 4P and 5P shapes (figure 4). The average heat size was appx. 151 t/heat with a bottom lifetime of 119 heats on average between 1998 and 2001.

Fig. 4: Steel ladle until 2001

All steel shells were so deformed that we decided to purchase a new ladle fleet in 2001. Since a bigger heat size provided a higher daily production, we used the opportunity to increase the diameter of the shell by 80 mm and the height by 40 mm. The dimensions of the lining were almost the same as in the ladle before. The thickness of the bottom sloped down from 350 mm to 250 mm towards the teeming hole. The wall thickness was increasing from 171 mm below the slag line to 193 mm above the bottom and the slag line was a balanced mix of 3P, 4P and 5P shapes again. The wall was relined every second bottom and slag line campaign. This resulted in a capacity increase of about 5 tons per heat, the average heat size was about 156 tons at lifetime of 117 heats (figure 5).

371
*Fig. 5: Steel ladle from 2002 to 2009*

Because of the startup of a third RH-Degasser in 2007, freeboard became more and more significant. To increase it by 150mm, we reduced the thickness of the wall from 171 mm in 2002 to 106 mm in 2007. Then we had to reline the wall every bottom- and slag line campaign. Spinel forming castables in the wall and Spinel containing, self-flowing castables in the bottom were established in 2005. In the bottom impact we changed from spinel containing castables to AMC bricks in in 2007. To compensate the weak point in the wall just above the bottom and the bucket deformation of the steel shell, we had to adapt the mould of the wall to balance the lining. The average lifetime was close to 125 heats (figure 6).

*Fig. 6: Steel ladle, adjustment to +150mm freeboard*

A further decision to increase the heat size again, leaded into the change of LD-Vessels and bigger ladles in 2010. The diameter of the steel shell was increased further 90 mm. Concerning the lining, we went on with the good experience of the ladle fleet before. The wall thickness was chosen by 110 mm below the slag line and 136 mm above the bottom without reinforcement, while the impact AMC bricks measured 300mm and the bottom 250 mm. The slag line was balanced again with 3P, 4P and 5P shapes. From 2010 to 2012 the average heat size was166 t, the ladle lifetime 116 heats.

When the oldest continuous caster which was limited to 155 tons per heat was shut down in 2013, a capacity close to 173 tons per heat was ensured. The lining lifetime was 104 heats from 2013 to 2022 (figure7).

*Fig. 7: Steel ladle from 2010 to 2022*

In 2010 we also made trials with brick lined walls. We choose our inhouse Magnesia Carbon bricks based 100% recycled Magnesia, and cut 5P bricks in half, what ended in a wall thickness of appx. 107 mm (figure 8).

*Fig. 8: Brick lined ladle 2010*

The lifetime of the lining was comparable to the monolithic wall. We compared metallurgical parameters from ULC heats. The Carbon Content showed an insignificant increase (figure 9a) and the Total Oxygen Content as indicator for steel cleanliness was equal (figure 9b).

*Fig. 9: Carbon and total oxygen in ULC Steel*

Because the thermal conductivity of MgO-C is higher, we made some simple steady state calculations to estimate the increase of the temperature on the steel shell. By changing the wear lining from high alumina to MgO-C the calculation showed a temperature increase from 377°C to 415°C with the usual 40mm bauxite safety lining and 13 mm vermiculate insulation layer (figure 10a, figure 10b). Since we wanted an equal temperature, we had to add a lightweight brick layer of 20 mm. The calculation showed 367°C (figure 10c).

*Fig. 10: Steady state heat transfer*

The electric power consumption was interesting, too. We compared one steel grade, that required intensive treatment in secondary metallurgy. In case of MgO-C bricked walls we had a consumption of 38,3±8,0 kWh/t$_{Crude\ steel}$ while high alumina lined ladles needed 33,7±7,0 kWh/t$_{Crude\ steel}$ (figure 11).

*Fig. 11: Electric power at LF for HIC Steel Grade*

It must also be added that we lost filling weight due to the additional insulating layer. This meant a capacity loss of two tons. The wear lining bricks had to be backfilled. When breaking out the ladle, we found sticky backfill material on the safety lining, which became more and more after each campaign. This resulted in the need to reline the safety lining every 3 to 4 campaigns. This is about 4 times as much as a monolithic wall.

In 2022 we had to produce 98 heats per day in full production, to reach our production goals. That was very difficult to achieve. With more ladle capacity we could have relaxed the situation. We decided to purchase bigger ladles again. This had become possible, because we had to exchange the crane runway girders before and increased their carrying capacity.

The limiting factors for the ladle steel shell were the trunnion spacing and the total height of the lade. To gain more capacity, we reduced the taper of the steel shell and shortened the legs. This resulted in an increase of 50 mm in height and 80 mm in the lower diameter.

What about refractories? Wall thickness was chosen uniform by 150 mm. Bottom impact AMC bricks measured 350mm and the bottom 270 mm. The slag line was balanced again with 3P and 4P shapes. Since the lipring of the new steel shell must support the static load of the ladle, we have been protecting it with a self-flowing steel needle enforced concrete based on high alumina.

The average heat size is 178 t, the average lifetime 104 heats (figure 12). Daily production has eased somewhat. The new target figure at full production is 94 instead of 98 heats now.

*Fig. 12: Steel ladle from 2023*

## REFRACTORY BALANCE

To present a representative material balance, I refer to the lining concept of the monolithic ladle that was in use from 2013 to 2022. The figures reflect the average for approx. 3000 linings. A similar balance can be expected for the current ladle.

A new lining requires 0.7 t of impact bricks, 6.1 t of floor concrete, 8.7 t of wall concrete and 6.8 t of slag zone bricks.

For relining, 100% of the impact and slag zone bricks are replaced. In the bottom, 3.7 t of concrete and in the wall 6.2 t of concrete are re-casted. The amounts of wear and breakout for high alumina are roughly estimated from the laser scan (figure 13a), the amounts of MgO-C are obtained from weighing reports. High alumina breakout can be quantified at appx 6,5 t/ladle, MgO-C at 2,9 t/ladle (figure 13b). The specific consumption in the impact is 0.04 kg/t, in the bottom 0.21kg/t, in the wall 0.24 kg/t and in the slag zone 0.38 kg/t (figure 13c).

*Fig. 13: Refractory balance*

## RECYCLING

Recycling has a long tradition in our plant. Concerning the steel ladle, we separate MgO-C and Alumina breakout at our breakout stand (picture 1).

*Pic. 1: Ladle breakout stand*

*Magnesia Carbon*
In the slag line, we install about 2030 t/a of Magnesia Carbon bricks. The breakout can be estimated at 850 t/a, which is 42% of the original quantity. Of this, 560 t/a are used as recycled material for brick production, which is 28% of the original quantity. The remaining 14% is used as MgO carrier in the LD vessel (figure 14).

*Fig. 14: Recycling balance MgO-C*

*High alumina*
Our annual demand for high alumina materials for new linings and relinings amounts to 3350 t/a. Of this, 1930 or 57% is breakout, of which 1640t/a, or 48% is processed as slag former for the secondary metallurgy in the inhouse recycling department. The remaining 9% is passed on to the cement industry (figure 15).

*Fig. 15: Recycling balance high alumina*

## CONCLUSIONS

To accompany the capacity increases, it was necessary to purchase LD-vessels and new ladles. The ladle lining has been adjusted several times. The monolithic lining has proven itself in the wall.

MgO-C breakout has been used for production of recycled bricks in the in-house brick factory and as MgO carrier in the LD crucible. Alumina excavated material has been processed into slag formers in the in-house recycling center and a small portion has been passed on to the cement industry.

## ABSTRACT

ECO-TAB® is a new alumina refractory aggregate with lower density when compared to the globally produced Tabular Alumina T60/T64 (3.3 vs. 3.55 g/cm³). The business case for the development of this new aggregate is based on its application in a steel ladle wear lining. Two factors are relevant here. The heat capacity and the thermal conductivity of the wear lining material are important for reducing the thermal losses of steel into the refractory lining during the thermal cycling of the ladle whilst in use. With lower heat capacity and thermal conductivity of the lining, the heat losses while the ladle is empty can be reduced and accordingly the heat losses from the steel to the refractory lining later. In addition, a lower density and weight of the refractory lining enables lower materials demand and higher tapping weight of steel into the ladle when the maximum crane weight in the steel works becomes the limiting factor during the ladle campaign. Firstly, the volume is the limiting factor but with increasing refractory wear, the crane weight then becomes the new limiting factor. ECO-TAB® contributes to energy saving, capacity improvement, and reduced material consumption through lower weight of the refractory lining.
The paper discusses the material properties and application testing of the new aggregate including induction furnace slag testing and thermal conductivity.

## INTRODUCTION

Tabular Alumina is known for its exceptional thermal and mechanical properties. It has high refractoriness, which means it can withstand very high temperatures without undergoing significant deformation or melting. This makes it suitable for various high-temperature applications and is therefore a very common synthetic aggregate used in a number of applications for steel making refractories such as steel ladle linings, impact pads, sliding gates, nozzles and purging plugs.
One key physical parameter for Tabular Alumina is it's density, also called BSG (bulk specific gravity). It is common knowledge in the refractory industry that the higher the density of the aggregates, the better the quality. However, for the steel ladle where a thermal cycling process is applied during emptying and refilling, the density of aggregate used in the steel ladle lining influences two key factors, the thermal and weight factors.

### Thermal factor

Fig. 1 shows the temperature change in the refractory lining of a steel ladle from empty to full as discussed by Ogata et al. [1].
After emptying the ladle, the hot surface of the working lining has cooled down to 800°C, as indicated in the graph. During filling and teeming, the refractory working lining temperature increases up to 1550-1600°C, resulting in energy transfer from the liquid steel to the cooler refractory lining leading to a reduction in steel temperature.
The main reasons of heat loss in the refractory lining during standard operation of a steel ladle are heat radiation and heat storage. The radiation at the steel shell can effectively be reduced by installation of insulating refractories or optimisation of the thermal conductivity of the applied refractories.

The dashed area in Fig. 1 corresponds to the heat storage ($\Delta Q$) as defined in equation (1).

$$\Delta Q = W C_p \Delta T = \rho V C_p \Delta T \qquad (1)$$

Considering the equation above, we can conclude that a reduction of heat losses by heat storage can be achieved either by reduced density ($\rho$) of the working lining or by decreasing it's volume ($V$). $W$ represents the weight and $C_p$ the constant specific heat capacity.

Fig. 1: Schematic drawing of the temperature change in the refractory lining of a steel ladle during operation. Drawing after [1]

Volume reduction of the working lining is often limited. A balance needs to be achieved between optimising thermal and mechanical stability whilst at the same time maximising the number of heats per ladle. The density of the refractory lining is defined by the raw materials used and the processes applied to manufacture the lining. High density raw materials are commonly used to reduce wear during application.
The costs for the loss of 1K steel temperature is considered to be in the range of 0.05 – 0.1 € per ton of steel [2]. In times of energy crisis these costs can be easily doubled.
As confirmed by Tata Steel IJmuiden [3] the costs of 1K loss per ton of steel has been €0.05. However, the current costs are expected to be in the range of €0.14 /mt steel, considering the increased energy and $CO_2$ prices.

### Weight factor

In addition, a lower weight of refractory lining enables a higher tapping weight of steel into the ladle when the maximum crane weight in the steel works becomes the limiting factor during the ladle campaign. Initially, the volume is the limiting factor but with increasing refractory wear, the crane weight becomes the new limit instead.

### ECO-TAB®

ECO-TAB® is a new alumina refractory aggregate with lower density when compared to the conventional Tabular Alumina aggregate T60/T64. The thermomechanical stability of refractory formulations is maintained at reduced bulk heat capacity leading to energy saving opportunities.

The typical physical parameters for a regular T60/T64 Tabular Alumina and ECO-TAB® are listed in Tab. 1.

Tab. 1: Typical physical parameters of T60/64 Tabular and ECO-TAB®.

|  |  | T60/T64 | ECO-TAB® |
|---|---|---|---|
| Typical density (BSG) | g/cm³ | 3.55 | 3.3 |
| Typical apparent porosity | % | 2 | 11 |
| Typical water absorption | % | 0.5 | 3.5 |
| Al₂O₃ content | % | 99.5 | 99.5 |

It is worthwhile mentioning that the lower density is not achieved by a change in chemistry but by proprietary modifications during the production process to achieve the designed microstructure. ECO-TAB® is as volume stable as Tabular T60/T64 at steelmaking temperatures.

**EXPERIMENTAL**
Refractory castables based on regular Tabular T60/T64 and ECO-TAB® were produced and investigated with regard to physical properties and wear resistance. Tab. 2 shows the mixture of the vibratable spinel containing castables and Tab. 3 of the vibratable spinel forming castables. In the latter, 0.5% silica fume was added to compensate for the expansion due to in-situ spinel formation.
The water demand was adjusted to achieve similar flow properties and curing of the test bars was performed at 20°C for 24h.

Tab. 2: Composition of spinel containing test castables.

The refractoriness under load, thermal conductivity and induction furnace corrosion tests were performed at the German refractory institute in Höhr-Grenzhausen.

**RESULTS**
**Microstructure investigations of ECO-TAB®**
The typical microstructure of ECO-TAB® is shown on the right side of Fig. 2. The pore structure is more pronounced and finely distributed when compared to regular T60/T64 Tabular. Also, the grain size is smaller than for Tabular.
A pore size analysis was performed using the image processing software ImageJ [4] for 32 SEM images to ensure statistical value. The average pore size of 2.6 $\mu m^2$ is smaller than that of Tabular. The major difference is shown in the area of the images covered by pores. For ECO-TAB® an average of 7.2% is covered by pores, whereas for Tabular it is only 2.5%.
This optical and two-dimensional method to investigate the porosity shows a lower porosity for ECO-TAB® when compared to the bulk density (BSG) test using the normal water absorption method.

However, the primary focus here was to investigate the pore size within the material.

Fig. 2: Image based pore size analysis of ECO-TAB® in comparison to Tabular T60/T64. 1000x magnification.

**Physical properties of refractory castables**
The cold crushing strength (CCS) and cold modulus of rupture (CMoR) for the spinel containing castables is shown in Fig. 3. In the cured state (20°C / 24h) the strength for regular T60/T64 Tabular and ECO-TAB® is very similar. For the other temperatures ECO-TAB® is slightly lower in strength but still clearly exceeding the minimum level of 30 MPa CCS for steel ladle applications. Both castables show the typical drop in strength at 1000°C due to the dehydration of calcium aluminate hydrates.
Strength data for the spinel forming castables is shown in Fig. 4. Here, T60/T64 Tabular and ECO-TAB® show very similar results for all temperatures tested.
It is reported that an increase in water demand of only 1% can already reduce the strength properties by 50% [5]. Although, the water demand for the ECO-TAB® containing castables had to be increased by 1.5% and 1.2% respectively, the strength properties are not negatively affected. This can be explained by the fact that the additional water is absorbed by the higher porosity in ECO-TAB® whilst not weakening the matrix bond.

Fig. 3: Cold crushing strength (CCS) and cold modulus of rupture (CMoR) of spinel containing test castables.

375
Fig. 4: Cold crushing strength (CCS) and cold modulus of rupture (CMoR) of spinel forming test castables.

The dashed bars in Fig. 5 and Fig. 6 represent the density evaluation of the dried and sintered test castables. The castables based on ECO-TAB® exhibit on average approximately 5% less bulk density (0.15 g/cm³ lower) than Tabular based castables. Fired at high temperature the difference decreases and the ECO-TAB® castables remain at ~0.1 g/cm³ lower density.

The permanent linear change as shown in the solid lines is lower for the ECO-TAB® castables, especially when fired at 1650°C or 1550°C respectively. The increased shrinkage of ~0.5% during firing is assumed to be due to the slightly increased sinter reactivity of ECO-TAB® when compared to the dense aggregate T60/T64.

Fig. 5: Density and shrinkage of spinel containing refractory castables.

The spinel forming castables exhibit higher total positive permanent linear shrinkage due to the expansion by spinel formation during heat treatment. In addition, the castable based on ECO-TAB® shows lower expansion than the castable based on T60/T64.

Fig. 6: Density and shrinkage of spinel forming refractory castables.

The thermal conductivity for the spinel containing test castables measured by the hot wire method is shown in Fig. 7. The castable based on ECO-TAB® exhibits approximately 10% lower thermal conductivity for the full range of tested temperatures.

Fig. 7: Thermal conductivity for the test castables measured by hot wire method; samples pre-fired at 1000 °C / 5 h.

**Refractoriness under load of spinel containing refractory castables**

For the measurement of the refractoriness under load (RUL) the spinel containing refractory castable test bar was pre-fired at 1000°C with a holding time of 5h. The results for a constant pressure of 0.2 MPa and heating rate of 5 K/min are shown in Fig. 8.

Fig. 8: Refractoriness under load of the spinel containing test castables.

The expansion curves of T60/T64 Tabular and ECO-TAB® show very similar results. The point of maximum expansion ($D_{max}$) is at a higher temperature (1283°C) with ECO-TAB®.

**Induction furnace corrosion tests of refractory castables**

In order to judge the feasibility in application, a corrosion test was conducted in an induction furnace. The test setup has the advantage of being as close as possible to real life conditions in the steel ladle. The test segments were cured at 20°C for 24h and pre-fired to 1000°C with a 5h holding time. The position of the segments in the induction furnace is shown in Fig. 9.

Segment 1 & 1a: VIB-SC-TAB

Segment 2 & 2a: VIB-SC-ECO

Segment 3 & 3a: VIB-SF-TAB

Segment 4 & 4a: VIB-SF-ECO
Fig. 9: Schematic drawing of segmentation for the induction furnace corrosion test.

The test was performed at 1600°C for 2h with 14 kg of ST52 steel and 750 g of a synthetic slag typical for Al-killed steel (Wt%: CaO 41.5; Al$_2$O$_3$ 38.5; SiO$_2$ 5.0; MgO 5.0; FeO 6.0; MnO 4.0). The slag was exchanged after 1 hour.

The post-mortem segments are shown in Fig. 10 and the corresponding depth of corrosion in Tab. 4. It can be seen that the depth of corrosion at the Marangoni convection zone [6] is very similar for all type of tested castables.

Fig. 10: Images of castable test segments after corrosion test.

Tab. 4: Depth of corrosion of tested castable segments.

|  | VIB-SC-TAB | VIB-SC-ECO | VIB-SF-TAB | VIB-SF-ECO |
|---|---|---|---|---|
| Corrosion depth [mm] | 7.15 | 7.25 | 5.80 | 6.65 |

The slag infiltrated area is very visible in the polished sections as shown in Fig. 11. The dark area on the left side of each segment is remaining slag. The infiltrated area can be separated into two zones. Zone I is characterised by a brownish colour. During infiltration, the Fe and Mn content in the slag decreases leading to loss of the brownish discoloration of the refractory material (zone II). The depth of infiltrated area is very similar in the castables based on ECO-TAB® and Tabular T60/T64.

It can be concluded, that despite the significantly higher porosity of ECO-TAB®, the slag resistance of the refractory castables is very comparable.

Back scattered electron (BSE) images were taken to further investigate the reaction of the aggregate grains with the infiltrated slag. The BSE image of the area highlighted in the polished section in Fig. 11 depicts the cooled slag on the left side and infiltrated refractory castable on the right side (Fig. 12).

The solidified slag shows zonation with higher Fe contents at the hot side (white area) which remained at the surface during cooling after completion of the test.

Fig. 11: Polished segments of VIB-SC-TAB (1) and VIB-SC-ECO (2) used for SEM investigations.

Fig. 12: BSE images of segments (1) and (2) close at the slag zone.

The fine matrix is completely infiltrated by the slag, whereas coarse alumina grains remain (dark grey phase). The Tabular Alumina T60/T64 grains in the left image show some conversion to Hibonite (CaO·6Al$_2$O$_3$) at the surface of the grains in contact with the infiltrated matrix (lighter grey phase). This reaction is the result of calcia availability provided by the infiltrated slag. The ECO-TAB® grains as shown on the right image show more pronounced formation of Hibonite, hence higher reactivity. However, the depth of infiltration and the resistance of the castables against corrosion is not affected.

## CONCLUSIONS

This paper introduces ECO-TAB®, a new alumina aggregate with reduced density of ~3.3 g/cm$^3$ compared to ~3.55 g/cm$^3$ for regular Tabular Alumina T60/T64. Advantages in steel ladle linings are reduced energy losses by lowered heat capacity and thermal conductivity. In addition, the lower weight of the refractory lining enables lower material demands and higher tapping weight of steel into the ladle when the maximum crane weight in the steel works is the limiting factor.

Despite the lower aggregate density of ECO-TAB®, application tests with relevant castables show no difference in strength or refractoriness compared to the reference castable based on Tabular T60/T64. Corrosion tests reveal slightly higher reactivity of the ECO-TAB® grains in contact with slag infiltrated matrix but without any negative effect on corrosion or infiltration depth.

ECO-TAB® contributes to energy saving, capacity improvement, and reduced material consumption through lower weight of the steel ladle refractory working lining while maintaining end application performance.

## ABSTRACT
In this study, the influence of different contents of recycled magnesia-carbon (MgO-C) material in MgO-C refractories on the non-metallic inclusions in steel was investigated. Recyclate-containing MgO-C samples and a recyclate-free reference material were tested in contact with a 16MnCr5 steel melt and a slag on the top of the melt. By means of a subsequent automated feature analysis of the solidified steel, MnS and $Al_2O_3$-MnS inclusions were found to be the predominant ones. No negative influence of the recyclate, neither with regard to the number nor the size of the inclusions, was detected.

## INTRODUCTION
MgO-C refractories are widely used in the steel industry, mainly as wear lining material in converters, electric arc furnaces, and steel treatment ladles. This is due to beneficial properties such as high thermal shock resistance and low slag infiltration depths [1, 2]. However, the production of the raw materials sintered and fused magnesia from magnesite as their main source is energy-intensive and associated with high $CO_2$ emissions [3]. The partial replacement of virgin raw materials with MgO-C recyclates is therefore of great interest and provides economic advantages as well. The possibility of producing MgO-C materials that have suitable physical, mechanical, and thermomechanical properties using recyclates has been demonstrated (for example in Ref. [4]), but little is known about the influence of the recyclates on the non-metallic inclusions in steel. This issue is very important because such non-metallic inclusions, depending on their properties (such as size, hardness, and morphology) can significantly impair the steel properties [5].
In the present work, MgO-C refractory samples having different recyclate contents, with two different recyclates being used, were subjected to a steel melt in a steel casting simulator. Slag was added onto the melt. After the experiment, the non-metallic inclusions in the solidified steel were analyzed.

## MATERIALS AND METHODS
Following raw materials were used for preparing MgO-C refractory samples:
- MgO-C recyclate R94A1 (3–6, 1–3, and 0–1 mm) or R92A4.5 (3–5, 1–3, and 0–1 mm),
- Chinese fused magnesia FM97 (3–5, 1–3, and 0–1 mm),
- fine-grained Chinese fused magnesia FM96DIN,

with the recyclates and fused magnesia being provided by Horn & Co. Minerals Recovery GmbH & Co. KG, Germany, and
- graphite NFL90/92 (Quingdao Kropfmuehl Graphite, China).

Starting from a recyclate-free reference mixture, the weight ratio between the recyclate and the fused magnesia FM97 was increased in three steps—from 0:100 to 50:50, 80:20, and finally 100:0. The carbon content as sum of graphite NFL90/92 and carbon introduced by the recyclate was adjusted to approximately 10 wt% in each case. The corresponding recyclate contents of the MgO-C materials were 0, 40, 65, and 82 or 83 wt% (in the case of the samples containing recyclate R94A1 and R92A4.5, respectively).
After preparing the raw material mixtures, which also contained a combination of carbonaceous binders, test bars with dimensions of 150 mm x 25 mm x 25 mm were produced by uniaxial pressing,

cured at 180 °C, and coked at 1000 °C with 5 h holding time under reducing conditions (for more information see [6]).
Using ground samples after burning out the carbon, the chemical composition of the refractory materials was analyzed by X-ray fluorescence analysis (XRF) in an XRF spectrometer S8 Tiger II (Bruker).
Tests in a steel casting simulator (Systec, Germany) were performed. One MgO-C sample per test was fixed in an $Al_2O_3/MgAl_2O_4$ crucible, 16MnCr5 steel was filled into the crucible and melted by increasing the temperature to 1650 °C. Thirty minutes after reaching this temperature, a crushed slag, whose main components were CaO (54 wt%), $Al_2O_3$ (24 wt%), $SiO_2$ (8 wt%), and MgO (6.5 wt%), was added. Steel and slag were provided by Deutsche Edelstahlwerke Specialty Steel GmbH & Co. KG, Germany. After a time of 60 min at 1650 °C, the heating was switched off. All experiments took place under argon atmosphere.
Samples of the solidified steel were taken and examined by an automated feature analysis using a scanning electron microscope equipped with energy dispersive X-ray spectroscopy (ASPEX PSEM eXpress, FEI, USA) to determine the non-metallic inclusions contained. The inclusions were classified by chemical composition and by size, the latter using the maximum inclusion diameter ($D_{I,max}$) and the square root of the inclusion area ($\sqrt{A_I}$). Population density functions were calculated according to Equation 1.

$$PDF = \frac{n_I(h_{ab})}{h_b - h_a} \qquad (1) [7]$$

$n_I(h_{ab})$     inclusion number per unit of area in a given bin
$h_b - h_a$     bin width

## RESULTS
Figure 1 shows the non-metallic inclusions classified by their chemical composition. The steel samples investigated were designated according to the MgO-C material used in the test, with "RI" representing the R94A1 recyclate, "RII" the R92A4.5 recyclate, and "FM" the FM97 fused magnesia. The designation "0R-100FM" stands for the reference test with the recyclate-free MgO-C material.

*Fig. 1: Inclusions in the solidified steel from the experiments with MgO-C samples containing recyclate RI (a) or RII (b) in comparison with the test using the recyclate-free MgO-C.*

The majority of the detected inclusions were assigned to the MnS and $Al_2O_3$-MnS classes. MnS inclusions are formed during solidification of the steel [8]. They may even be beneficial to some extent because they improve the steel's machinability [9]. By

contrast, hard and brittle oxide inclusions such as $Al_2O_3$ are the most detrimental, especially for fatigue strength [5]. The steel samples contained only a few pure $Al_2O_3$ inclusions. Instead, existing $Al_2O_3$ inclusions apparently served as nuclei for the precipitation of MnS according to a mechanism known from the literature [10], resulting in complex $Al_2O_3$-MnS inclusions.

Both recyclates did not lead to an increase in the number of inclusions compared with the experiment using the recyclate-free reference material (see Fig. 1).

The size distribution of the inclusions was similar in all steel samples. However, a trend to a lower number of larger inclusions in the steel samples from the experiments with recyclate-containing MgO-C was observed for the sum of the $Al_2O_3$ and $Al_2O_3$-MnS classes, especially in the case of the tests with MgO-C containing the recyclate RII (see Fig. 2). This trend, which had to be verified by further tests, might be explained by the decreasing content of the impurities $SiO_2$, CaO, and $Fe_2O_3$ in the MgO-C material with increasing proportion of recyclate (Table 1). It is consistent with similar results obtained in recent studies using industrially produced MgO-C refractories with varying degrees of MgO purity [11, 12]. There it was assumed that the impurity phases from the MgO-C material interact with the molten steel and promote the agglomeration and sintering of $Al_2O_3$ inclusions.

The size of the MnS inclusions was less effected by the recyclate content of the refractory material.

*Fig. 2: Population density function of $Al_2O_3$ + $Al_2O_3$-MnS inclusions vs. the maximum inclusion diameter (a) and the square root of the inclusion area (b) in the solidified steel from the experiments with MgO-C samples containing the recyclate RII in comparison with the test using the recyclate-free MgO-C.*

Table 1: Content of magnesia and the main impurities in the refractory materials containing the recyclate RII compared with the recyclate-free reference material (analyzed after burning out the carbon).

| MgO-C material | MgO | $Al_2O_3$ | $SiO_2$ | CaO | $Fe_2O_3$ |
|---|---|---|---|---|---|
| | (wt%) | | | | |
| 0R-100FM [6] | 95.6 | 0.46 | 1.16 | 1.75 | 0.80 |
| 50RII-50FM | 94.6 | 1.93 | 1.08 | 1.41 | 0.70 |
| 80RII-20FM | 94.3 | 2.55 | 0.93 | 1.32 | 0.69 |
| 100RII-0FM | 94.1 | 3.12 | 0.80 | 1.16 | 0.62 |

## CONCLUSIONS

The investigation of recyclate-containing MgO-C samples in contact with molten 16MnCr5 steel and a slag did not indicate any negative influence of the recyclate on the steel cleanliness in terms of non-metallic inclusions. Especially in the case of one of the two recyclates used, there was rather a trend towards a smaller number of larger inclusions for the classes $Al_2O_3$ + $Al_2O_3$-MnS.

These results refer to the first use of the refractory material. The influence of the recyclate in the case of repeated contact between the refractory and the molten steel is to be investigated in further studies.

## ABSTRACT

It is evident that the demand for lower carbon-footprint materials in the steelmaking industry tends to increase due to environmental concerns and operational demands, such as the need for lower shell temperatures resulting in energy savings and lesser thermal stresses in the equipment's structure. In addition, the ever-increasing quality control in special steels production demands processes that minimizes the carbon pick-up effect. Therefore, among the relevant strategies to meet such needs, Ultra-Low Carbon (ULC) bricks, used as an alternative to traditional MgO-C brick products (with such high carbon content) and MgCr bricks, are being developed. The ULC brick technology (retained carbon $\leq$ 1.8 %wt) has been validated and is currently being applied in steel production processes, presenting similar or even better performance, if compared to the originally used refractories. Despite its considerably low carbon content, the product can fulfill the thermomechanical behavior and corrosion resistance needed for steel processing. This performance is made possible through the usage of special carbon sources. This paper aims to show how these different carbon sources affect ULC bricks properties.

## INTRODUCTION

MgO-C refractory bricks are extensively used in various iron and steelmaking equipment, including mainly LD converters, electric-arc furnaces and steel ladles. Its satisfactory performance for such applications can be attributed to the association of the basic ceramic material's capacity of maintaining its physical and chemical stability under high-temperature conditions with the carbon addition providing excellent thermomechanical properties and low wettability by slags. Therefore, this class of refractory has outstanding slag infiltration and thermal shock resistances, which contributes to lower wear rates.

Although this kind of product has been successful thus far, conceptual changes need to be made to align it with market tendencies. It is evident that demands of different natures push the refractory industry to lower the amount of carbon used. Among them, cleaner steel productions require less carbon, lesser $CO_2$ emissions and higher energy savings, which in turn incentivizes the use of refractories that both have lower carbon footprint and that are less thermally conductive to reduce shell temperatures. Additionally, special high purity steel productions for specialized applications require carbon content in the final product as low as less than 0.005 %wt [1] and, as such, carbon pick-up effects caused by high-temperature diffusion between the lining and molten steel during processing must be minimized.

One of the strategies often implemented to avoid carbon related issues is the use of fired refractories such as MgCr and doloma bricks in steel ladles and RH Degassers. However, these products are more susceptible to slag infiltration, which in turn causes structural spalling due to the difference in coefficient of thermal expansion between infiltrated and non-infiltrated brick regions, leading to uneven and higher lining wear rates. Moreover, the absence of carbon results in stiffer bricks, which have considerably worse thermomechanical properties and lower resistance to crack formation, and thus requires much lower preheating and cooling rates for operation. Besides, the production of fired bricks incurs higher energy costs compared to unfired ones, making the final product more expensive for the steel industry.

Aiming to take advantage of what MgO-C technology offers while meeting the industry's decarbonization expectations, several studies in the last years have consolidated the ULC technology. It is important to notice that simply reducing the amount of carbon added to traditional bricks does not yield adequate results [2].

By using special carbon sources associated with specific binder systems and additives, it was possible to create new ULC bricks with less than 1.8 %wt fixed carbon content while maintaining satisfactory thermomechanical properties, avoiding spalling, and presenting good performance when compared to the originally used linings that can have up to 12 %wt carbon content. This product line, ensuring minimal carbon pick-up, is currently used in steel ladles for secondary treatment of special steels requiring less than 25 ppm of carbon content [1].

Given the technological success of ULC bricks and the steel industry's requirements for continuous improvement, it is important to keep developing this technology and look for ways of reducing the carbon content even further. Such advancements are likely to result in longer lining lifetime, as well as in partial replacement of less environmentally friendly bricks, such as MgCr ones.

As such, this paper aims to explore how different carbon sources affect ULC bricks properties. More specifically, four different kinds of carbon sources with varying morphologies, surface areas, and ashes content were tested in current ULC formulations. The main interest properties include the physical properties after curing and coking, thermal shock resistance and relaxation tests.

## EXPERIMENTAL PROCEDURE

### Carbon sources characterization

In order to characterize the different carbon sources used, all four of them were submitted to surface area analysis through Brunauer-Emmett-Teller (BET) tests, morphology analysis by scanning electron microscopy (SEM), oxidation behavior evaluation by thermogravimetric tests using a LECO TGA 701 thermogravimetry analyzer (10 °C/min heating rate, under oxidizing atmosphere, until 1000 °C). The loss on ignition (LOI), moisture, fixed carbon, volatiles and ash content were also measured using LECO TGA 701.

### Brick specimens' production and heat treatments

Tested formulations can be seen in Table 1. Most of the compositions use commercially available carbon sources, except C4 and C6 that contains an experimental material (CS4). These carbon sources are added in an amount of < 1.0 %wt. All formulations have the same phenolic resin type resole as binder and use the same type of MgO (a fused magnesia FM98 from China). Compositions C5 and C6 are equivalents to C2 and C4 with the use of antioxidant additives to evaluate their interaction with the different carbon sources.

Tab. 1: Compositions adopted for the experimental procedure.

|  | C1 | C2 | C3 | C4 | C5 | C6 |
|---|---|---|---|---|---|---|
| FM 98 | X | X | X | X | X | X |
| Carbon Source | CS1 | CS2 | CS3 | CS4 | CS2 | CS4 |
| Additive 1 | + | + | + | + | + | + |
| Additive 2 | - | - | - | - | + | + |
| Resin | + | + | + | + | + | + |

It is essential to ensure that all mixing and pressing equipment are thoroughly cleaned before the bricks production, in order to avoid carbon contamination from previous batches. Then, the raw materials with adequate particle size distribution are mixed with the

phenolic resin in a determined mixing sequence. The mixing has been adjusted to obtain good dispersion and homogenization of the components, especially of the carbon sources, contributing to better overall properties. Afterwards, the material is hydraulically pressed with a maximum pressure of 170 MPa.

Once conformed, the samples are cured at 200 ºC for 6 hours. Additionally, some of the samples were coked at 1400 ºC for 5 hours and others at 1100 ºC for 8 hours to simulate the temperature conditions of refractory use while avoiding oxidation.

## MgO-C bricks tests

The samples cured and coked at 1400 ºC were submitted to bulk density (BD), apparent porosity (AP), modulus of rupture (MOR), cold crushing strength (CCS), dynamic modulus of elasticity (MOE) tests. Other additional experiments made with the cured samples were carbon content and relaxation tests while thermal shock resistance (TSR) and hot compression strain (HCS) tests were conducted with specimens coked at 1100 ºC and 1400 ºC respectively. The bricks' carbon content was obtained using a LECO CS 200 equipment.

BD and AP tests are based on NBR-6220 using the Archimedes principle. MOR was obtained using a 3-point bending test in a Kratos device (KE 3000 MP) with a loading speed of $(60 \pm 10)$ N/s and spacing between the supports of 100 mm. The CCS was measured according to NBR 6224 using 50 mm diameter and 50 mm height cylinders with rectified faces. The specimens were compressed with an increasing vertical load rate of $(200 \pm 0.1)$ kgf/s until crack formation.

The dynamic modulus of elasticity was obtained according to NBR-11222 by propagating an ultrasonic wave through the biggest dimension of the sample and measuring the time taken by the wave to cross the material. Therefore, MOE values can be used to evaluate the refractory's internal microstructure, as the presence of microcracks, and different phase formations, since overall components distribution affects the wave propagation.

The relaxation test measures the stress developed by the sample itself (cylinder with 35 mm diameter and 50 mm height) in the first heating cycle of a steel ladle lining. The cured samples were placed in a Material Testing System (MTS) 810 equipment and subjected to a heating rate of 5 °C/min in inert atmosphere keeping the bars fixed after touching the sample. Then, the force generated by the sample's tendency to expand while heated is measured by the equipment's sensor until the sample failure or until a maximum standard tension of 40 kN is reached.

The hot compression strain (HCS) test is conducted in the same MTS equipment used for the relaxation test but using cylindric samples of 25 mm of diameter and 50 mm height with rectified faces. The samples are previously coked at 1400 ºC for 5 h. During the test, a heating rate of 5 ºC/min under inert atmosphere is applied until reaching a stable temperature of 1400 ºC for at least 15 minutes. Once the temperature is stabilized, a force is applied at the rate of 0.2 mm/min and their deformation is measured by sensors located perpendicularly to the specimen until critical failure.

The specimens coked at 1100 ºC were used in a thermal shock resistance (TSR) test. The different coking temperature was chosen as a way of simulating the preheating process in steel ladles for this test. During the test, (160 x 40 x 40) mm³ bricks are wrapped in a nickel foil and heated to 1200 ºC with a dwell time of 30 minutes and cooled to room temperature on top of a steel plate refrigerated with water. This process is repeated 20 times and the MOE is measured at the beginning of the test as well as at the end of the 1st, 3rd, 5th, 10th, 15th and 20th cycles. Analyzing the evolution of the residual modulus of elasticity, which is the comparison between the current MOE value and the one from before the cycles, it is possible to observe structural changes caused by the thermal stresses.

## RESULTS AND DISCUSSION
### Carbon sources characterization

The LOI, moisture, fixed carbon, volatiles, ash content and specific surface area (SSA) of each carbon source are described in Table 2. The main differences are the LOI (comparing the first 3 sources to the last one) and the SSA, playing an important role in the material's distribution in the brick's matrix.

Tab. 2: Carbon sources characterization results.

| Carbon source | CS1 | CS2 | CS3 | CS4 |
|---|---|---|---|---|
| LOI (%) | 97.8 | 99.9 | 99.8 | 45.8 |
| Fixed carbon (%) | 96.1 | 98.5 | 97.6 | 42.1 |
| Volatiles (%) | 1.70 | 1.43 | 2.19 | 3.63 |
| Ash (%) | 2.25 | 0.06 | 0.10 | 54.20 |
| SSA (m²/g) | 1.86 | 9.32 | 18.31 | 37.24 |
| XRD | Graphite | Graphite | Graphite | MgO Graphite |

CS4 has the highest ash content among the carbon sources because this material is constituted by nano carbon tubes (nCT) deposited on a MgO substrate. The materials' oxidation behavior can be observed in Figure 1, and it is possible to associate the oxidation resistance to each material's SSA. CS4 starts to oxidize at a lower temperature (~ 500 ºC) due to its higher SSA, while CS1 presents the opposite behavior, starting the oxidation process at ~ 700 ºC. Such a lower oxidation resistance for the CS4 means that the Al and/or Si powder would not be effective to protect this carbon source against oxidation, since it oxidizes at lower temperatures than the metallic powders themselves [2].

*Fig. 1: Relative weight loss profile comparison.*

The morphology of the carbon sources can be observed in Figure 2. The SEM images show a flake structure for CS1, which justifies its small SSA and higher oxidation resistance. CS2 and CS3 present leaf-like morphology, and the CS4 presents nanotubes morphology - what confirms the higher SSA reported. The average diameter of the nCT is in the range of 20-40 nm.

*Fig. 2: Carbon sources SEM images.*

### Brick's Characterization After Curing and Coking.

Table 3 shows the results of the cured samples using the different carbon sources (C1-C4). It is possible to say that the investigated physical properties are mainly affected by the SSA of the carbon source. As the SSA of the carbon source increases, it is observed a

tendency to decrease the BD, MOE, MOR and CCS, and increase the AP. The total carbon content and the fixed carbon are according to the expected range. The composition C4 presented the lowest fixed carbon, which could be explained by the higher volatile content of this carbon source.

Tab. 3: Results after curing at 200 °C/6h.

|  | C1 | | C2 | | C3 | | C4 | |
|---|---|---|---|---|---|---|---|---|
|  | Avg | SD | Avg | SD | Avg | SD | Avg | SD |
| BD (g/cm³) | 3.18 | 0.01 | 3.17 | 0.01 | 3.09 | 0.01 | 3.08 | < 0.01 |
| AP (%) | 5.94 | 0.33 | 5.73 | 0.5 | 9.17 | 0.54 | 9.62 | 0.14 |
| MOR (Mpa) | - | - | 26.2 | 1.7 | 19.6 | 3.7 | 10.7 | 2.0 |
| CCS (Mpa) | 88.4 | 9.1 | 83.4 | 8.7 | 73.9 | 7.1 | 71.2 | 12.8 |
| MOE (GPa) | 113.0 | 5.1 | 119.5 | 4.0 | 86.9 | 2.2 | 53.0 | 1.6 |
| Fixed C (%) | 1.76 | - | 1.62 | - | 1.5 | - | 1.46 | - |
| Total C (%) | 2.88 | - | 2.86 | - | 2.59 | - | 2.64 | - |

The results after coking are shown in Table 4. The trend observed for the variables was similar to the samples after curing. The MOE of the sample using the carbon source with the lowest SSA (C1) was 61 GPa, while for the sample using the carbon source with the highest SSA (C4) the MOE was 14 GPa. Taking the lower MOE after coking, it was expected that composition C4 could have the better thermal shock resistance among all the evaluated compositions. On the other hand, a higher SSA, as shown before, means a lower oxidation resistance, which could impair other important properties for this type of material.

Tab. 4: Results after coking at 1400 °C/5h

|  | C1 | | C2 | | C3 | | C4 | |
|---|---|---|---|---|---|---|---|---|
|  | Avg | SD | Avg | SD | Avg | SD | Avg | SD |
| LV (%) | -0.16 | 0.02 | -0.14 | 0.01 | -0.2 | 0.02 | -0.24 | 0.01 |
| VV (%) | -0.74 | 0.02 | -0.65 | 0.04 | -0.88 | 0.06 | -1.16 | 0.02 |
| BD (g/cm³) | 3.12 | 0.01 | 3.11 | 0.02 | 3.07 | 0.04 | 3.06 | 0.02 |
| AP (%) | 10.81 | 0.27 | 11.20 | 0.56 | 12.09 | 1.08 | 12.49 | 0.55 |
| MOR (Mpa) | - | - | 5.7 | 0.1 | 2.4 | 0.1 | 1.3 | 0.2 |
| CCS (Mpa) | - | - | 29.5 | 2.7 | 26.8 | 5.1 | 21.4 | 3.2 |
| MOE (GPa) | 61.1 | 2.7 | 55.6 | 3.1 | 36.2 | 5.2 | 14.0 | 2.3 |

Therefore, to control the oxidation rate (and improve the thermal shock resistance) of the ULC bricks, an additive was tested in compositions C5 and C6; the results are shown in Tab 5. The additive does not seem to affect the properties after curing but they do have an effect after coking. The compositions with the additive show a higher MOR, CCS, MOE and a lower coked porosity if compared to their versions without additives. For the similar compositions without additive (C2 and C4), the coking process causes a decrease of the MOR, CCS and MOE. While the same pattern can be seen for the mentioned properties in composition C5, composition C6 presents an increase of MOE with the coking process (from 74 GPa to 110 GPa). Therefore, the effect of the additive is in the way to increase the MOR, CCS and MOE and to reduce the coked porosity compared to the coked values in its absence, which helps to increase the brick's corrosion resistance. However, the final word in terms of the effect of the different carbon sources and the use of the additive will come from analyzing the thermomechanical properties discussed in the next topics.

**Thermomechanical and oxidation test results**
The relaxation test results for the compositions with each carbon source (C1 to C4) is shown in Figure 3. It is possible to identify an overall tendency of higher force produced by the heated sample with lower carbon SSA. Additionally, the samples with lower bulk density and higher apparent porosity after curing (C3 and C4) are also the ones that better performed in this test.
This result is consistent with the expected behavior, since more empty spaces and surface area of malleable material within the brick's internal structure allow for better tension accommodation.

Tab. 5: Test results of C5 and C6 (compositions with additive).

|  | After Curing | | | | After coking (1400 °C/5h) | | | |
|---|---|---|---|---|---|---|---|---|
|  | C5 | | C6 | | C5 | | C6 | |
|  | Avg | SD | Avg | SD | Avg | SD | Avg | SD |
| BD (g/cm³) | 3.18 | 0.01 | 3.04 | 0.01 | 3.13 | 0.01 | 3.08 | 0.01 |
| AP (%) | 5.73 | 0.21 | 9.53 | 0.42 | 10.00 | 0.30 | 11.20 | 0.17 |
| MOR (Mpa) | 27.4 | 2.0 | 12.8 | 0.7 | 11.6 | 0.4 | 8.7 | 0.2 |
| CCS (Mpa) | 88.8 | 9.3 | 128.0 | 6.9 | 58.0 | 1.8 | 92.7 | 19.0 |
| MOE (GPa) | 126.4 | 3.0 | 74.2 | 4.2 | 114.4 | 4.4 | 110.6 | 1.3 |
| Fixed C (%) | 1.84 | - | 1.60 | - |  |  |  |  |
| Total C (%) | 3.03 | - | 3.00 | - |  |  |  |  |

Particular attention is drawn to composition C4, which yielded an excellent result considering the low amount of carbon used. As such, it could be expected that refractories made with carbon source CS4 would present very little or absent spalling during the equipment's pre-heating step.

*Fig. 3: Relaxation test results for each carbon source composition.*

Another interesting observation is that, although the carbon sources from compositions C2 and C3 have a 2-fold difference in SSA, their force generation when heated is relatively similar in intermediate temperatures. One hypothesis to explain such behavior is that the carbon source morphology has a significant impact on tension accommodation that is not necessarily dependent on the surface area it generates, as both compositions have a leaf-like morphology. However, by introducing the additive, compositions C5 and C6, the force increased compared to the similar ones without additive (C2 and C4). This behavior is not well understood so far, but it was replicated in prior testing.
The stress-strain curve obtained at 1400 ºC can be seen in Figure 4. As the driving stress factor in steel ladles is related to strain caused by thermal expansion, instead of load-bearing [3], it is necessary to analyze the presented data accordingly by observing the maximum stress related to the strains that would be caused by thermal expansion in an operational situation.
The results show a clear pattern of higher maximum stress values for compositions with carbons of lower SSA and higher strain in the point of maximum stress for compositions with higher SSA carbon sources. This could indicate, for example, that sample C1 has worse thermomechanical behavior, as it develops higher tensions in its internal structure when submitted to relatively low strains. By associating these results with the relaxation test, it seems that carbon source CS1 is not efficient enough in the matter of tension dissipation to be used in such low amounts, while the other three are viable options, being carbon source CS4 the more promising of them.
Regarding the thermal shock resistance test, which can be seen in Figure 5, initially only compositions without additives (C1 to C4) were tested. Curiously, the results obtained were the exact opposite of the hypothesized based on information gained from the relaxation and hot compression strain data, being composition C1 the one which kept most of its structural integrity throughout the thermal shock cycles and C4 being the worst one.
*Fig. 4: Stress-strain curves at 1400 ºC for each composition.*

*Fig. 6: Cross section of the samples without and with additives after 20 thermal shock cycles.*

*Fig. 5: Thermal shock resistance results for each carbon source composition and two compositions with additives.*

Upon visual inspection of the samples' longitudinal cross sections, it become evident that the nickel foil method was not sufficient to prevent oxidation, Figure 6. Analyzing the observed discoloration, it was clear that the specimens suffered oxidation with proportional intensity of their carbon source oxidation rate previously defined. Therefore, compositions using carbon sources with high SSA (C4) have shown the worst results. As such, it is understood that this thermal shock resistance test reflects more the structural changes, caused by the oxidation process and further internal damage (developed due to the lack of carbon) than the real thermomechanical behavior of the brick during operation in a reducing condition of being submerged in slag or molten steel.

In order to further verify this observation and to try to analyze thermal shock resistance, two of the compositions that underperformed (C2 and C4) were altered to include antioxidant additives in the same amount (becoming C5 and C6 respectively). The results showed an excellent performance, indicating that the evaluated carbon sources, when present in low amounts, were able to satisfactorily distribute compression and tensile forces caused by fast and repeated thermal expansion and contraction. However, it was evident that a certain level of oxidation was still present and more intense for composition C6 (higher SSA carbon source.), as seen in Figure 6. Therefore, it is interesting to note that even if the mass of carbon used in the samples was the same, carbon source 4 seems to require higher amounts of antioxidants to reach its full thermomechanical potential expected for this test.

Once again, it is important to emphasize that, during operation in steel ladles, the MgO-C placed on the metal and slag lines have limited contact with oxygen gas, being the preheating step the most critical one in this regard, which happens in lower temperatures than during steel treatment. Therefore, it is not expected that MgO-C bricks after being used present the level of oxidation seen after the thermal shock test, which purposefully reproduces extremely harsh conditions for the material.
## CONCLUSIONS

The different carbon sources characterization successfully showed several key distinctions between them. Among the most important, there is a significant SSA variation, up to a 20-fold difference between the lower and higher obtained values, and three kinds of morphology (flake, leaf-like and carbon nanotubes) were identified. These properties, in turn, lead to the observed varied behavior for the ULC bricks. Carbon source 1 showed a high MOE after coking at 1400 ºC for 5 hours, high stresses developed in both relaxation and HCS tests and low strain at the point of maximum stress in the latter. These are strong indicators that CS1 is not efficient enough in the matter of tension dissipation to be used in such low amounts, even if it seems to be the most oxidation resistant composition without additives. The use of special carbon sources 2, 3 and 4 presented satisfactory physical properties and thermomechanical behavior. Carbon source 4 shows exceptional results in most tests, indicating that even lower amounts of it could be used in further testing. Although carbon source 4 is very promising in the path of refractory decarbonization, thermal shock tests associated with visual inspection revealed that higher amounts of antioxidants are necessary to prevent the brick's oxidation if compared to other sources with lower SSA and oxidation rates. Therefore, carbon sources 2 and 3 show themselves as good compromises between performance and oxidation resistance for situations in which oxidation may be a significant factor (such as operations with high intermittency and long preheating time periods) and in which the excessive use of antioxidants is undesired due to possible cost disadvantages.

# UNFIRED ZERO C BRICK FOR ENERGY SAVINGS AND PERFORMANCE INCREASING OF METAL LINE FOR STEEL LADLE

Carlos Pagliosa, Marcelo Borges, Leandro Martins, Bruno Laidens, Haylander Avila, RHI MAGNESITA, Contagem, Brazil

## ABSTRACT

As the requirements for steel quality have become increasingly strict with strong demand for high strength and high toughness steel plates, increased number of customers are concerned about carbon pick up. A new generation of unfired zero carbon refractories was developed to replace firing and carbon bonded bricks, reducing $CO_2$ footprint with performance increasing. Steel ladle lining plays an important role on the energy consumption during the production and the refractory lining design contributes to minimize thermal bath loss and shell temperature. This work presents the development of the unburned Alumina-Magnesia technology with a unique microstructure for better heat scattering with energy savings and customers' performance compared to resin bonded bricks.

## INTRODUCTION

The iron and steel industry are one of the most energy-intensive worldwide and accounts for around 21% of global industrial energy use and about 24% of industrial $CO_2$ emissions. Global steel production has more than doubled between 2000 and 2018. The energy use and greenhouse gas (GHG) emissions of the steel industry is likely to continue increasing because of the higher demand for steel, particularly in developing countries, due to infrastructure constructions and the higher output for cleaner steels [1].

Clean steel encompasses a multitude of concepts that are based on fulfilling customer requirements and can be produced in many ways depending on the existing equipment. A common feature of all clean steel production is a tight process control along with continuous monitoring. The major remaining issues to be addressed are disturbances that occur in industrial reality. This requires continuous improvements in processes and equipment on one hand and further development of quality assurance systems for full size control of any possible detrimental effects on the other hand [2].

To meet an increasing demand for cold-rolled (CR) steel sheets of improved mechanical properties, and to cope with the change of the annealing process from a batch-type to a continuous process, it is necessary to establish a technique for making ultralow carbon (ULC) steel. Particularly, for an economical manufacture of extra deep drawing or high tensile strength CR steel sheet with superior deep drawing properties, it is essential to obtain ULC molten steel with a C-concentration lower than 20 ppm for the steelmaking process. ULC steel is widely used for the automotive industry [2,3].

The composition, quantity, and size distribution of non-metallic inclusions (NMI) in steel, determine the quality and performance in application. Over the past decade, ULC steel, also referred to as interstitial free (IF) steel, has been used in automobile parts because of the excellent formability. However, the high quantity of inclusions, especially larger ones, can cause a deterioration of surface properties. In addition to the low C (< 30 ppm) and the low N (< 30 ppm) requirements for obtaining an extraordinary formability and providing a non-aging property, a constraint over the maximum inclusion size (< 100 μm) is also required for ULC steels [4].

The ULC molten steel is produced by two decarburization steps: 1) in the BOF for reducing the C concentration to approximately 300 ppm, and 2) in the ladle, where vacuum decarburization in the RH, under reduced partial pressure of CO (carbon monoxide) gas is obtained. Passing the initial quick decarburization period, when C

and O (oxygen) are abundantly available, the decarburization rate becomes stagnant after a few minutes in the RH degasser. To further bring the C down, O must be injected into the liquid steel to speed up the decarburization reaction. Such O injection contributes to the higher concentration of dissolved O in liquid steel after degassing. Consequently, aluminium addition is necessary for complete deoxidation of the ULC steel. This results in the generation of a large number of indigenous $Al_2O_3$ (alumina) inclusions after the deoxidation step in the ladle. However, inclusion agglomeration due to Brownian motion, Stokes collision and liquid steel bath turbulence followed by flotation lead to the inclusion removal [4,5].

The last decarburization process takes time to reach the desired C-content, which results in a drop in the steel temperature, which is offset by increasing the BOF tapping temperature, leading to higher steel cost, and placing higher demands on the refractory material, mainly in the secondary metallurgy [5].

The secondary metallurgy is a high energy-intensive step in steelmaking process as it requires an accurate match of the composition and temperature of the molten metal during the ladle refining. So, the steel ladle lining plays an important role on the energy consumption of the process, as the refractory thermal properties are strictly related to the ladle ability to keep constant the bath temperature. Aiming to improve the energy efficiency, reducing costs and the environmental impacts, a different approach in working lining material is necessary [6].

The iron and steel industry that carry out high temperature processes, require advanced energy solutions for efficiently heat management during their processing. Steel makers have been looking for new strategies and solutions to decrease the energy consumption, due to the growing demands for steel products and the reduction in the environment impacts. Most of the green solutions will depend on the proper design of the refractory linings in all furnaces and machinery, suppressing the molten metal heat losses and reducing the specific refractory consumption per ton of steel. Also, controlling and monitoring the thermal state of the process is essential to ensure the final product quality and to guarantee the steel mill operational flow [2,3].

A major challenge in modern industry is to guarantee the competitiveness with observance of environmental requirements. Steel ladle lining plays an important role on the energy consumption during the steel production and the refractory lining design contributes to minimize thermal bath loss and shell temperature. A new generation of unfired zero carbon refractories was developed with two specific approaches: 1) replacement of firing bricks reducing $CO_2$ footprint and 2) replacement of carbon containing bricks with performance increasing. Bricks can be used in working linings with a unique microstructure with better heat scattering and similar thermomechanical properties. This work presents customers' performance compared to traditional products highlighting energy savings.

## ZERO CARBON BRICK TECHNOLOGY

Ladle lining configurations are most based on the customer's operational cycle and the type of the steel shop. Anyway, is possible to distinguish common refractory specifications for barrel or metal line. For integrated steel shops tempered bricks ($Al_2O_3.MgO.C$ – AMC or $MgO.Al_2O_3.C$ – MAC) are most used.

This aim of this paper is to present original solutions for energy savings products replacing the conventional approach used as working lining, to maximize shell temperature reduction.

Zero carbon unfired brick technology is based on the development of a new binder system with a surface treatment on fines of the composition, enabling that the raw materials develop a binder effect. No resin or pitch is added enabling zero C-pickup on the production of ULC steel. This novel binder can be applied for most of refractories, as basic and alumina bricks. Basic bricks cover products with dead burned magnesia (DMB), fused magnesia (FM) and magnesia-crome (MgO-Cr). Alumina bricks cover all range of the products from 45% to 95% alumina content, making this binder very flexible to plant production. All bricks are delivered to the customer just after tempering, that can range from 170 to 250°C, the same as carbon binder bricks [7].

Replacement of carbon containing products, mainly for the barrels of steel ladles has some advantages summarized as follow:
1. No pollutant binder.
2. No oxidation of the bricks during pre-heating or during the ladle campaign.
3. In situ spinel formation for joint closing for the safety and working brick linings.
4. No carbon pick-up for ULC steel production.
5. Energy saving: reduction of shell temperature and bath temperature loss due lower thermal conductivity compared to conventional carbon bonded bricks.
6. Easy for recycling as no carbon or antioxidants are in the composition.
7. Performance increase in most of the cases when carbon bricks were replaced by this technology.

To meet the requirements for the ULC steel quality with strong demand for high-strength and high-toughness plates, some customers demand a zero C brick for metal line. Steel ladles are subjected to high temperature effects, aggressive slags, long-lasting metal holding time, and many refining factors that require high-quality refractory products. Usually, the current refractory solution is a fired brick based on alumina-magnesia compositions and fired over 1500 °C prior to delivery, forming magnesia-alumina (MA) spinel ($MgO.Al_2O_3$). This new phase presents unique properties as follow: 2135 °C melting point, high mechanical resistance at high temperatures, better corrosion resistance against basic slags than alumina aggregates, low thermal expansion value, similar thermal shock resistance as alumina, high stability under vacuum and environmentally friendly, with no risks of chrome-bearing products Few customers also consent on standard products such as AMC and MAC bricks, although, natural graphite and the C from the binder system have been identified as potential sources for C-pickup [8-10].

Unfired alumina-magnesia bricks were developed as a technological alternative for the barrel of the ladles for any C-steel grade but with an additional benefit for ULC steel for avoiding C pickup. Although, all customers can take benefit of the reduction of the shell temperature due to the low thermal conductivity of the brick. Spinel $MgO.Al_2O_3$ formation still occurs during ladle operation with an expansive reaction for joints closing, that can prevent metal and slag infiltration, better corrosion resistance and operational safety. Thermodynamic simulation performed in this work was based on the minimization of the free energy of the system to find out the nature of the solid, liquid, and gaseous phases, as well as its chemical composition and reaction rate at the thermodynamic equilibrium [11]. Simulation was carried out using FactSage (version 8.1) and it is presented in figure 1. Phase development shows a preformed spinel to counter act corrosion resistance since the beginning of ladle operation and spinel forming as the vessel has been soaked by molten steel. This expansion reaction will promote joint closing to avoid liquid infiltration and

guarantee safety operational conditions and performance increasing.

*Fig. 1. Phase evolution predicted by the thermodynamic simulations for the zero carbon unfired brick.*

Table 1 shows the chemical, physical and mechanical properties of the conventional barrel design brick (referred as MAC) and the zero carbon unfired brick (referred as AM-K).

Tab 1. Chemical physical and mechanical properties of the conventional barrel design brick (MAC) and the zero carbon unburned brick (AM-K).

| | MAC | AM-K |
|---|---|---|
| $Al_2O_3$ (%) | 22.8 | 94.7 |
| MgO (%) | 74.8 | 4.7 |
| C (%) | 6.7 | Zero |
| Binder | Resin | New binder |
| Antioxidant | Yes | Zero |
| **After Tempering 180 °C** | | |
| Bulk Density (g/cm³) | 2.94 | 3.33 |
| Apparent Porosity (%) | 10.0 | 8.4 |
| Cold Crushing Strength (MPa) | 65 | 57 |
| Elastic Modulus (GPa) | 63 | 52 |
| **After coked 1000 °C** | | |
| Bulk Density (g/cm³) | 2.88 | 3.27 |
| Apparent Porosity (%) | 14.8 | 15.8 |
| Permanent Volumetric Expansion (%) | -0.54 | 0.15 |
| Cold Crushing Strength (MPa) | 50 | 43 |
| Elastic Modulus (GPa) | 24 | 25 |
| Slag corrosion[1] (%) | 82 | 21 |
| **After coked 1400 °C** | | |
| Bulk Density (g/cm³) | 2.79 | 3.16 |
| Apparent Porosity (%) | 17.1 | 17.2 |
| Permanent Volumetric Expansion (%) | 4.16 | 2.19 |
| Cold Crushing Strength (MPa) | 41 | 48 |
| Elastic Modulus (GPa) | 19 | 71 |

Bulk density of AM-K product was higher than MAC brick at all temperatures due to a higher proportion of raw materials with fewer defects and impurities. The apparent porosity of the AM-K product had a similar behaviour to MAC, mainly after firing at 1400 °C. The main reasons for increasing porosity in MAC were the burning of volatiles and formation of the spinel phase. For the zero C product (AM-K) the predominant factor was only the formation of the expansive spinel phase. Due to differences in the binder system, AM-K brick showed higher cold crushing strength (CCS) after

firing at 1400 °C, while the MAC product had slightly higher CCS after tempering and at 1000 °C.

Regarding the elastic modulus, the AM-K product showed improved behaviour after being exposed over 1400 °C due to the higher sintering capability compared to the MAC brick and resulting in smaller number of internal defects. This fast sintering also has consequences for much better result for corrosion index due to a physical barrier that is formed at hot face and for the spinel formation.

AM-K brick presented a positive volumetric expansion at 1000 °C and 1400 °C. Brick-joint closure started earlier than MAC product during the ladle operation, preventing the penetration of liquid metal. Also, at 1400 °C, the expansion value of the AM-K is lower when compared to the MAC product, then less stress is generated in the barrel bricks.

**Example 1 – Customer A – Ladle 350t**

Figure 2 shows the results of average performance after the roll-out of this novel zero carbon concept in the operational cycle of melt shop. Steel ladles with AM-K lining showed 23% better average performance when compared to MAC lining. A significant remaining thickness was also noticed during tear-out. Over the years, MAC brand presented an average ladle life of approximately 96 heats and a remaining safety thickness of 40 mm. AM-K bricks are achieving 130 heats with a remaining thickness of 70 mm.

*Fig. 2. Average performance comparison between MAC and AM-K lining with the zero carbon technology concept.*

One of the most significant benefits accomplished by the AM-K lining was the lower bath temperature loss. More than 220 steel temperature samples were taken just prior to the ladle leaving the first secondary metallurgy station and just after it arrived in the second station. A comparison between both linings was made and the results are shown in figure 3. A decrease of 8% was achieved in bath temperature loss, which lead to a lower consumption of raw materials by the customer for maintaining the desired temperature, also creating a significant impact in energy savings.

*Fig. 3. Comparison of bath temperature loss for MAC and AM-K linings with the zero carbon technology concept.*

Figure 4 shows an example of the visual inspection of AM-K linings at the end of the ladle campaign. No drawbacks were noticed during the whole cycle.

*Fig. 4. Examples of the visual inspection of two ladles at the end of the campaign of AM-K linings with the zero carbon technology concept.*

**Example 2 – Customer B – Ladle 320t**

Evaluation was conducted with a direct comparison of MAC and AM-K linings at the same steel ladle in order to guarantee the same operational conditions in both products during the whole campaign. Figure 5 shows the barrel assembling. Zero carbon brick lining is easily identified. Figure 6 shows both products after 180 heats, with a better coating and insolation protection for the AM-K.

Shelf temperature was monitored using infrared camera during the campaign to measure the benefits of this technology, as shown in figure 7. Total measurements were 49 shots that presented an impressive average shelf temperature reduction of 28°C (82.4 °F), also a direct benefit for energy savings. Figure 8 presents the laser scan on the ladle at 180 heats. Lowest remaining thickness for the both products were as follow: 47mm for MAC against 87mm for AM-K bricks.

*Fig. 5: Ladle barrel assembling for customer trial with MAC and AM-K lining with the zero carbon technology concept.*

*Fig. 6: Ladle barrel after 180 heats, with a better coating and insolation protection for the AM-K lining with the zero carbon technology concept.*
*Fig. 7: Shell temperature measurement by infrared camera after the first heat - point 1: MAC brick and point 3: AM-K brick*

## SUMMARY AND CONCLUSIONS

A new generation of unfired zero carbon refractories was developed for replacement of firing bricks and carbon containing ones, with lower $CO_2$ footprint during fabrication, easy recyclability and a fast sintering process development on customer's site.

This novel binder can be applied for most of basic and alumina refractories products, making this technology very flexible to plant production and attending wide spread of customer's demand.

Customer's trials showed better performance for the working line with expressive shell temperature reduction due to the better heat scattering related to porous distribution, highlighting the potential of the this zero carbon technology for saving energy at real application's on the steel shops.

## ABSTRACT

The influence of calcium magnesium aluminate (CMA) aggregate on the slag corrosion resistance of MgO–C refractories was investigated by the induction furnace tests and the sessile drop test. The results showed that $CaAl_2O_4$ in CMA converted into low melting phases when facing slag, while spinel diffused into the refractory-slag interface. The Al-containing liquid phase melted from $CaAl_2O_4$ increased the Al content of slag, increasing the proportion of indirect dissolution, forming more spinel and decreasing the corrosion rate. Furthermore, the spinel and liquid slag formed solid-liquid mixture at the interface, increasing the viscosity and promoting the formation of protective slag layer, which avoided direct contact between slag and refractory. The combined use of CMA aggregate and silicon carbide showed better corrosion resistance because silicon carbide increased the oxidation resistance and inhibited the decarburized layer, while the FeSi alloy and higher viscosity also enhanced the slag corrosion resistance of refractory.

## INTRODUCTION

Since 1970s, MgO–C refractories had been widely used as lining material for ladle slag line because the low wettability of graphite with slag gave such refractories excellent slag corrosion resistance [1].

With the development of metallurgy technology, the high scrap ratio metallurgy was regarded as important method to reduce $CO_2$ emission and consume fast-growing scrap output [2-3]. However, with the large-scale applicant of high scrap ratio, the service life of refractory lining reduced. Increasing the scrap ratio makes slag contain more impurities, changing the chemical compositions and reducing the viscosity of slag. To adapt high scrap ratio metallurgy, it is necessary to develop new kind of MgO–C refractories with better slag corrosion resistance.

Previous research showed that calcium magnesium aluminate (CMA) aggregate, a newly-developed porous aggregate, had positive effect on the slag corrosion resistance of various refractories. Preisker *et al.* [4] investigated the formation of protective slag layer through finger test and static cup tests, finding that the brownmillerite-rich phase promoted the formation of protective slag layer in MgO–CMA–C refractories. However, the formation of such layer may be influenced by the testing condition and the compositions of the slag. The static cup test used in previous works did not well simulate the violent turbulent motion of slag/steel in the ladle, and the slag with different chemical composition may change the phases in protective slag layer, causing different corrosion behavior of refractories.

In present work, influence of CMA aggregate on the MgO–C refractories was comprehensively studied by induction furnace slag tests. The suitable addition of CMA was also obtained by combined use of CMA and silicon carbide. The sessile drop test was used to further investigate the corrosion behavior of CMA aggregate. Thermodynamic calculation was applied to the corrosion behavior analysis to further explain the slag corrosion process. Based on Einstein-Roscoe equation and thermodynamic calculation, the viscosity of protective slag layer as well as the formation mechanism of such layer were explained in details.

## EXPERIMENTAL

The raw material of CMA cylinder samples was CMA powder (200 mesh). To prepare the CMA cylinder samples (φ50 mm × 10 mm), 50g CMA powder with 5g binder (30 wt% phenolic resin) were pressed under 150 MPa. Then the CMA cylinder samples were cooked at 1600°C for 3 h to sinter. As for MgO-C refractories specimens, raw materials were CMA aggregates (3-1 mm and 1-0 mm), fused magnesia (5-3 mm, 3-1 mm, 1-0 mm and 180 mesh), silicon carbide (1-0 mm and 200 mesh), flake graphite (100 mesh), carbon black (100-700 nm), pitch powder (Carbores P, 85 wt% carbon), $B_4C$ powder (325 mesh), aluminum powder (180 mesh) and liquid phenolic resin (36 wt% carbon yield). The formulations of MgO-C refractories are shown in Tab. 1.

Tab. 1: Formulations of MgO–C specimens

| Raw materials | R | C | S | CS |
|---|---|---|---|---|
| Fused magnesia | 96.7 | 91.7 | 91.7 | 86.7 |
| CMA aggregates | / | 5 | / | 5 |
| Silicon carbide | / | / | 5 | 5 |
| Antioxidants | 0.8 | 0.8 | 0.8 | 0.8 |
| Carbon | 2.5 | 2.5 | 2.5 | 2.5 |
| Phenolic resin | +4 | +4 | +4 | +4 |

Apparent porosity (AP) and bulk density (BD) were obtained by Archimedes principle. CMOR and HOMR were measured by three points bending tests. For CMOR, the tests carried out at room temperature; for HMOR, samples were cooked at 1400 °C for 30 min in reducing atmosphere. The specimens were tempered at 1600 °C for 3h

to test oxidation resistance. The oxidation index (OI) was the ratio of oxidized area to total area of the section. The sessile drop method was used for the corrosion behavior of CMA cylinder. 5 g slag and the cylinder sample were tempered at 1600 °C for 10 min. Then, corroded specimens were cut along the central line. To evaluate the slag corrosion resistance of the MgO–C refractories with CMA aggregates and silicon carbide, induction furnace slag tests was used. The rectangular samples were embedded into the castable crucible. The crucible was fixed in the induction furnace, and cylindrical No. 45 low-carbon steel (φ90 mm × 130 mm) melted at 1600 °C. After complete melting of the steel, 75 g slag was poured into the crucible and the corrosion time was 30 min. The automobile plate slag (Angang Steel Group Limited, Anshan, China) was used in this work, and its chemical compositions are shown in Tab. 2.

## RESULTS AND DISCUSSION

### Properties of MgO–C refractories

Tab. 3 represents the apparent porosity (AP), bulk density (BD), hot modulus of rupture (HMOR) and oxidation index (OI) of MgO–C refractories. With the addition of CMA aggregates, the bulk densities of specimens with CMA aggregates decreased while the apparent porosity slightly increased. A slight decrease in HMOR of specimens with CMA aggregates could be observed due to the formation of liquid phase in CMA aggregate at high temperature. The specimens without silicon carbide had poor oxidation resistance (Fig. 1). The OI of specimens with CMA aggregates was slightly lower than those without them, which was related to the higher apparent porosity.

Tab. 3: Properties of MgO–C refractories

| | AP (%) | BD (g/cm³) | HMOR (MPa) | OI (%) |
|------|------|------|------|------|
| R | 5.2±0.3 | 3.14±0.02 | 14.2±0.2 | 85.73 |
| C | 5.9±0.8 | 3.11±0.02 | 13.2±0.8 | 89.98 |

*Fig. 1: Oxidzied specimens: (a)R, (b)C, (c)S, (d)CS*

### Visual inspection of corroded refractories

Fig. 2 shows the images of corroded specimens after induction slag tests. As shown in Fig. 3, the corrosion area of specimen R was the largest (78.84 mm²), and the corrosion area of specimen C and S were 62.10 mm² and 54.14 mm² respectively. As shown in Fig. 4, protective slag layer could be observed at the corroded area, and it was porous with thickness of 2 mm for specimen CS.

*Fig. 2: Images of corroded specimens*

*Fig. 3: Corrosion area of different specimens*

*Fig. 4: Images of protectvie slag layer of specimen CS*

### Microstructure of corroded refractories

The microstructure of corroded specimens was presented at Fig. 5. Decarburized layer could be found at specimen R and C due their poor oxidation resistance. For specimen S and CS, no obvious infiltration layer or decarburized layer existed, and a slightly corroded CMA aggregate was observed at the slag-refractory interface of specimen CS. The SEM images of protective slag layer were shown in Fig. 6. Main compositions of protective slag layer were low-melting phase and spinel. Tab. 4 shows the EDS results of metal. Obviously, for specimen C without silicon carbide, Fe and MnO were the main compositions of the metal, while the FeSi could be found for specimen CS with silicon carbide, indicating that silicon carbide powder converted FeO into FeSi. Obviously, the slag layer was solid-liquid mixture instead of pure liquid.
*Fig. 5: Microstructure of corroded specimens: (a)R, (b)C, (c)S, (d)CS*

*Fig. 6: Microstructure of slag layer: (a)C, (b)CS*

Tab. 4: EDS area analysis results

| Specimen | Area | Possible phases |
|----------|------|-----------------|
| C | 1-2 | Fe, FeO, MnO |
| CS | 3-5 | FeSi, Fe, FeO, MnO |

**Corrosion behavior of CMA cylinder**

To comprehensively demonstrate the corrosion behavior of CMA aggregate, the sessile drop test was used in this work. Fig. 7 shows the images of corroded CMA cylinder specimen. The slag was melted and spread on cylinder, and it tended to flow along the side. The slag coating was porous, and the brown corroded area could be observed at the contact surface of cylinder.

*Fig. 7: Corroded CMA cylinder specimen*

Fig. 8 presents the microstructure of corroded CMA cylinder. Obviously, the slag-CMA interface was seriously corroded, and porous slag could be observed above the CMA cylinder. Since both CMA and slag contain Mg, Ca, and Al elements, Fe and Si were selected to analysis the ending of the penetration. Fig. 8b shows the microstructure

of corroded interface. The slag-CMA interface was not smooth due to the corrosion of slag, and CMA at the edge was disintegrated. Fine particles remained at interface, which were mainly spinel (Points 1-5) according to Tab. 5. Few amount of Fe was dissolved in spinel, meaning that $Mg(Al, Fe)_2O_4$ was formed. At the outer side of slag (Points 6-8), low melting phases including gehlenite could be observed, which were compositions of the slag after cooling. Fig. 8c shows the corroded area of CMA cylinder. The $CaAl_4O_7$ (Points 11, 12) and spinel (Points 13, 14) could be detected due to their higher stability against slag. Ca-containing phases (Points 9, 10) including Gehlenite and FeO could be observed inside the CMA, which were corroded low melting phases after the infiltration of the slag. The $CaAl_2O_4$ phase could not be detected because it converted into low melting phases and melting into liquid phase.

*Fig. 8: Microstructure of corroded CMA cylinder (a), CMA-slag interface (b) and penetrated area (c)*

Tab. 5: EDS point analysis results

| Area | Point | Possible phases |
|------|-------|-----------------|
| Interface | 1-5 | $Mg(Al, Fe)_2O_4$ |
| Slag | 6-8 | Gehlenite, FeO, $Ca_2SiO_4$ |
| CMA | 9-10 | Gehlenite, FeO |
| | 11-14 | $CaAl_4O_7$, $Mg(Al, Fe)_2O$ |

When facing the slag, the $CaAl_2O_4$ in CMA was firstly converted into corroded phases like gehlenite. Those phases were mainly low melting phases, making the structure of CMA unstable at high temperature, thus the CMA at the interface was disintegrated. After the disintegration of CMA, the spinel particles diffused into the slag, which could remain stable at the slag-CMA interface.

**Thermodynamic calculation**

The thermodynamic calculation results of MgO–C refractories were shown in Fig. 9 and Tab. 6. The specimen with CMA aggregates (C and CS) had more spinel compared with the specimens without CMA aggregates (R and S). A part of spinel was from the CMA aggregates, and a part was formed as the product of the indirect dissolution of periclase. The MgO in refractories reacted with the $Al_2O_3$

in the slag, formed intermediate solid phase instead of directly diffused into slag following Fick's first law. As a result, the direct dissolution was inhibited and the proportion of indirect dissolution was increased. The specimens with silicon carbide (S and CS) could found solid FeSi alloy. FeSi was formed through the reaction between silicon carbide and FeO. The infiltrability of FeSi was lower compared with $Fe^{2+}$ in the slag due to its poor wettability with the refractory. The addition of silicon carbide also increased the oxidation resistance of the specimens, thus no decarburized layer was observed in S and CS.

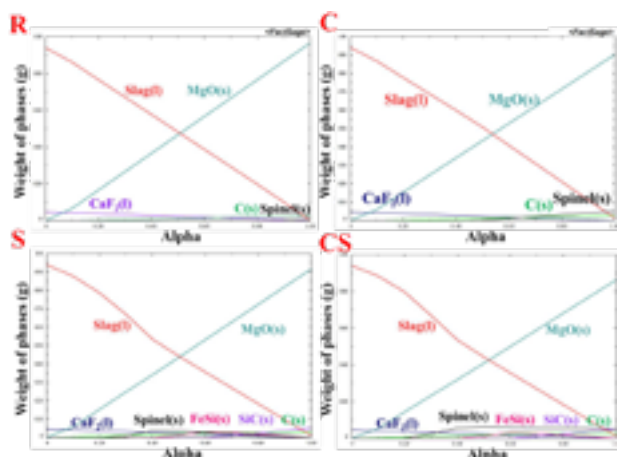

Fig. 9: Calculation results of MgO–C refractories

Tab. 6: Maximum spinel and FeSi amounts of different specimens (g)

| Specimen | Maximum Spinel Amount | Maximum FeSi Amount |
|----------|----------------------|---------------------|
| R | 0.62 | / |
| C | 4.96 | / |
| S | 3.57 | 3.09 |
| CS | 6.04 | 3.09 |

The protective slag layer was solid-liquid mixture instead of pure liquid phase. Therefore, in present work, Einstein-Roscoe equation was used to calculate the viscosity of liquid-solid mixture (Fig. 10).

Fig. 10: Viscosity of liquid-solid mixture

For specimens with silicon carbide (S and CS), the viscosity gradually rose at the *Alpha* range of 0.10-0.40 because the formation of

FeSi alloy decreased the contents of $Fe^{2+}$ in the slag. For specimens with CMA aggregates (C, CS), the viscosity dramatically increased at the *Alpha* range of 0.60 to 0.90, which was nearly same as the range of spinel formation, indicating that the spinel significantly contributed to the increase in the viscosity of liquid-solid mixture.

Therefore, at the refractory-slag interface, liquid slag mixed with spinel and FeSi and formed a highly viscous solid-liquid mixture. The high viscosity of such mixture decreased the infiltrability of the slag, thus no infiltration layer was observed in corroded specimens. The viscous solid-liquid mixture also promoted the formation of protective slag layer, which avoided the direct contact between slag and refractories and increased the slag corrosion resistance of refractory.

**CONCLUSIONS**

(1) When facing the slag, the $CaAl_2O_4$ in the CMA aggregate were converted into Al-containing liquid phases, which increased the Al content of the slag, promoted the formation of spinel and enhanced the indirect dissolution of MgO–C refractories. After the disintegration of the CMA, the original spinel component in CMA aggregate diffused into the slag-refractories interface.

(2) The spinel and liquid slag formed high viscous solid-liquid mixture at the slag-refractory interface. The high viscosity of solid-liquid mixture decreased the penetration ability of the slag, while the mass transport from the refractories to slag was also inhibited by it. Furthermore, the protective slag layer avoided direct contact between liquid slag and refractories.

(3) Combined use of CMA aggregate and silicon carbide for MgO–C refractories had better slag corrosion resistance. The silicon carbide further increased the viscosity of liquid-solid mixture. The enhanced oxidation resistance inhibited the formation of porous decarburized layer, lessening the channels for slag penetration.

## ABSTRACT

The present work experimentally studied the corrosion behavior of MgO-C ladle refractory exposed to molten slag during steel refining. The corrosion of ladle refractories, especially at the slag line, causes issues that require maintenance and repair and can even lead to melt outages.

## INTRODATION

Carbon bonded ceramics are in high demand in iron and steelmaking industries as the refractory material [1,2]. The addition of carbon into the oxides is considered as the beneficial approach to enhance its thermal properties such as thermal shock resistance, thermal conductivity, minimize the corrosion, and erosion process of the liquid slags, i.e. due to the low wettability of graphite to the liquid slags [3–5].

Magnesia-carbon refractory materials (MgO-C) is the most widespread carbon bonded ceramic for steelmaking industry. They are applied as a lining material in steel ladles, basic oxygen furnaces (BOF), electric arc (EAF) furnaces, and casting furnaces [6–8]. The service life of refractory material can vary from type steelmaking. This is strongly correlated the factors such as: temperature, pressure, atmosphere, and chemical reactivity of the melt. Changing these production conditions could enhance the carbon oxidation, the increasing of open porosity, and the dissolution of MgO grains into slag [9–11]. All of this phenomena lead to a decrease of life time of the refractory [12].

Normally, when the steel ladle is preheated above 500 °C, carbon from the MgO-C refractory material reacts with oxygen in the pores and form $CO_2$-gas on the surface of the refractory [13].

Subsequently, as the $CO_2$ temperature rises, the $CO_2$ gas reacts further with carbon to form CO gas. This type of reaction is called direct carbon oxidation.

However, above 1400 °C an indirect carbon oxidation takes place in the MgO-C refractory. This reaction involves the reaction between MgO and carbon, found in resin and graphite, resulting in the formation of Mg and CO gases [14–17].

The oxidation process not only increases the weight loss of the refractory material, but also enhances the open porosity. Open porosity represents the effective volume of pores within the refractory that can be penetrated by melt. An increase in the open porosity of the refractory has a negative effect on the corrosion resistance of the refractory in contact with molten slags and metals.

Corrosion in MgO-C can be divided into three stages [14]:

1 – The penetration of the melt into the hot surface of the refractory material. If the temperature of the refractory falls below the solidus temperature of the melt, the melt freezes and penetration stops.

2 - If the melt does not freeze, it penetrates the capillaries of the refractory. The melt penetrates the refractory material through the capillary infiltration, which affects the refractory matrix. Infiltration usually occurs when there are large temperature gradients from the hot surface to the cold surface of the refractory material.

3 - Refractory material is impregnated with melt to such an extent that the core is held together by the melt as the matrix corrodes.

According to the increased requirements, a change in the chemical composition of the steel or process leads to a change in the chemical composition of the slag. These changes directly affect the ability of the slag to dissolve the refractory, and the thermophysical properties of the slag. The penetration and infiltration of refractory material by the melt is influenced by the open porosity, wetting angle of the refractory, viscosity, surface tension, and contact time, **Equation 1**[18–21].

$$l^2 = \frac{r \cdot \sigma \cdot \cos\theta}{2\eta} \cdot t \qquad \text{Equation 1}$$

where r (m) is the open pore radius of refractory, σ (N/m) is the surface tension of the slag, θ is the contact angle between the slag and refractory, η (Pa·s) is the slag viscosity, t (s) is the contact time and l (m) is the infiltration depth.

Hence, a combination of high viscosity, low surface tension, open porosity, and appropriate contact angle serves to minimize the infiltration of slag into the refractory and subsequent dissolution [18]. Besides, temperature also has a great influence on MgO-C refractory wear, with increasing temperature, the viscosity values decrease and the maximum dissolution of MgO in the slag increases. This allows the slag to penetrate deeper into the refractory and actively dissolve its grains, weakening the entire structure.

Borges et al. studied the addition of sodium to desulphurisation slags and showed the sodium addition to calcium-aluminium silicates increases the dissolution of MgO grains and reduces the life of the steel ladle [22]. Guo et al. investigated the effect of VOD (Vacuum Oxygen Decarburization) slag with 15 wt% $Al_2O_3$ content on the refractory material MgO-C at 1650 °C and low oxygen partial pressure [23,24]. Later on, a porous MgO layer was formed on the sample surface instead of a dense MgO layer. This indicates that under these experimental conditions, Mg gas oxidation from molten oxides is not complete. Such porous MgO layer in industrial and turbulent conditions is not effective for slowing down the slag infiltration into the refractory material. The authors also argued that at temperatures above 1650 °C, the oxidation of MgO-C by atmospheric oxygen or metal oxides in the slag is limited and the main reaction of decarburization of refractory is indirect carbon oxidation in MgO + C. Liu et al. observed direct and indirect dissolution of MgO particles in a low basicity $CaO-Al_2O_3-SiO_2$ slag. He demonstrated that the dissolution rate of MgO increases with increasing slag temperature and decreases strongly with increasing MgO concentration in the slag [25]. Wang et al. investigated the dissolution rate of MgO solids in synthetic ladle slag. According to their experimental results, the increase of $Al_2O_3$ and MgO in slag decreases the dissolution rate of MgO due to the formation of magnesia spinel layer at the interface, and the increase of $CaO/SiO_2$ basicity also increases the dissolution rate of solid MgO in slag [26]. Several studies have demonstrated that when slags containing $Al_2O_3$ come into contact with MgO-C refractories, the surface of the refractory forms a protective layer of magnesian spinel. This magnesian spinel layer acts as a barrier, inhibiting the infiltration of slag [27–29].

The present study is a logical continuation of two previous studies, where the effect of $SiO_2$ addition on changes of thermo-physical properties of slag and the interaction between refining slag with $CaO/Al_2O_3$ ratio 1:1 on refractory MgO-C material [7,30]. In this study, the focus was on evaluation of corrosion of MgO-C material with altered $CaO/Al_2O_3$ (C/A) ratio in the slag. This study helps to better understand the effect of C/A and $SiO_2$ in secondary metallurgy slag on refractory corrosion in magnesia-carbon refractory material.

## MATERIALS AND METHODS

The MgO-C samples with 13 wt% of residual carbon based on phenolic resin with adding of Carbores P and 2 wt% of metallic aluminium as an antioxidant, see Table 1. Before the corrosion test, the MgO-C samples catted off from industrial refractory brick with the size 30x30x100 mm. In the upper part of each sample drilled a

25 mm deep hole for installation of $Al_2O_3$ holder. After cementing of the $Al_2O_3$ holder into sample body, the MgO-C samples were dried 12 hours at 120 °C.

Table 1. The constituent of MgO-C refractory (wt%).

| MgO | SiO₂ | CaO | Fe₂O₃ | Al₂O₃ | C | Al |
|-----|------|-----|-------|-------|---|-----|
| **97.5** | 0.6 | 1.2 | 0.6 | 0.1 | 13 | 2 |

The target slags were mixed from industrial slag formers: lime and alumina carrier. The partial size of the slag formers was under 100 μm. All the slags were dried in a desiccator for 24 hours at 120 °C before and after mixing.

According to the $CaO/Al_2O_3$ (C/A) ratio the slags can be divided into: High-$Al_2O_3$, Cleanness, and Desulfurization slag, Table 2. C/A ratio is the parameter, determinate the task of the secondary metallurgical slag. Slag compositions with C/A-ratio < 1 appear after deep deoxidised steel and steels with high aluminium content. In the case of C/A= 1, the slag has a refining function to agglomerate non-metallic inclusions out of the steel. Slag with C/A> 1 and up to 2 has desulphuration function in steel production processing. The increased MgO content in the High-$Al_2O_3$ slag is related to its content in the alumina carrier. Also the Table 2 contains the viscosity values of these three slags at 1650 °C from the previous publication [30].

Table 2. Chemical composition of ladle slags (wt%) and viscosity values (mPa*s) at 1650 °C.

|  | **High-Al₂O₃** | **Cleanness** | **Desulfurization** |
|---|---|---|---|
| CaO | 30.09 | 43.33 | 59.77 |
| Al₂O₃ | 53.86 | 43.33 | 30.06 |
| SiO₂ | 1.05 | 1.08 | 0.98 |
| MgO | 13.91 | 11.00 | 8.12 |

| Viscosity (mPa*s) | 1777.24 | 100.29 | 70.32 |

The MgO-C corrosion test carried out according to the Finger Testing method, a schematic description of setup is shown in Fig. 1. A pre-dried slag of about 1000 g. melted in a graphite crucible (130 mm height x 80 mm inner diameter) in an induction furnace. After reaching the target temperature, the melt is held for at least 30 minutes at the constant temperature for the homogenization.

At the other hand, the MgO-C sample was carbonised in a metal box under graphite powder for 60 minutes at 1000 °C. Right after carbonisation, the MgO-C samples were immersed into the molten slag for 60 minutes.

5- induction coil,
6- MgO–C sample,
7- molten slag,
8- graphite crucible
9- argon supply

At the end of holding time, the MgO-C samples were removed from the slag and cooled in the air, see Fig. 2. The slag solidified on the sample immediately when the sample left the molten slag,

and forming a dense layer on the MgO-C surface. Afterward, the samples were embedded epoxy resin and cut crosswise to a thickness of 10 millimetres for optical and SEM- analyse.

## RESULTS AND DISCUSSION
### Surface analyses of MgO-C

Fig. 3 represents photos of the MgO-C refractory samples immersed in the molten slag at 1650 °C for 60 minutes. After the finger testing experiments, the slag layer was observed to adhere on the surface of the refractories. The thickness of the refractory surface adhered slags was related to wettability of the refractory to the slags, hence, the factors such as the temperature, the roughness, and the porosity of the refractory, and the thermophysical properties of the slags, i.e. surface tension and viscosity of the slag could play an influential role. The present investigation focused on the utilization of a singular type of refractory material as the immersion sample. Consequently, the primary roughness and porosity were assumed to be identical among the specimens. As a result, the depth of corrosion emerged as the determining factor influencing the thickness of the adhered slags. The subsequent analysis considered the influence of viscosity and surface tension on the corrosion process, with specific attention given to the anticipated viscosity value.

The upper part of the refractory material above the slag was oxidised. Compared to the primary MgO-C refractory, the areas that were not in contact with the slag turned from dark to grey. The protective gas employed in the experiments, namely Argon 5.0, contained a minor concentration of oxygen (2-3 ppm oxygen). The oxygen content within the gas initially interacted with the carbon residing on the surface of both the refractory material and the graphite crucible, fostering a reducing atmosphere characterized by the presence of CO gas. Subsequently, the CO gas further reacted with carbon, ultimately yielding $CO_2$ gas.

Furthermore, a part of the slag was found to be pulled up to the non-immersed part of the refractory to the decarbonised layer. The height of the pulled up liquid slag (h) can be expressed by Jurin's law [31] as depicted in Equation 2. Clearly, the factors such as surface tension, contact angle, and density of the liquid slag could directly affect the h, consequently they also affect the contact area between liquid slags and refractory, namely the corrosion area. The degraded MgO from the side of refractory to the side of liquid slags could change the factors (surface tension, density, and also the contact angle).

$$h = \frac{2\gamma \cos\theta}{\rho g r_0}$$

Equation 2

where h is the height of the top of the layer to the liquid surface (m); θ is the contact angle of the liquid on the crucible wall; γ is the surface tension of the liquid (mN·m-1); ρ is the density of the liquid (kg·m-3); g is the gravitational acceleration and $r_0$ is the crucible radius (m).
**Fig. 3** Photographs immersed MgO-C refractory in the slag melts: a) High-Al$_2$O$_3$ b) Cleanness, and c) Desulfurization

**Microstructure analyse**

Fig. 4 shows the MgO-C sample after contact with the molten High-Al$_2$O$_3$ slag. This slag has a high viscosity of 1777 mPa*s at 1650 °C. Because of this high slag viscosity, no visible slag infiltration can be seen. Cracks and ducts in the refractory remain free of slag since the high viscosity of the slag prevents the infiltration of slag into the refractory. Nevertheless, the residual slag build-up on the refractory is up to 2.3 mm.
**Fig. 4.** Cross section of MgO-C after 60 minutes contact with High-Al$_2$O$_3$ slag at 1650 °C.

This is a partially dissolved surface layer of the refractory as well as a cured slag layer on the surface. The slag layer is very dense, which during cooling caused numerous pores and slag cracking. The slag contains high amounts of magnesia spinel, which also increases the risk of slag infiltration into the refractory. The large amount of Al$_2$O$_3$ in the slag can break up the MgO grains to form more spinel, which makes the infiltration into the refractory even worse. The SEM-EDX analysis found a large amount of magnesia spinel in the slag and on the refractory surface.

**Fig. 5.** Cross section of MgO-C after 60 minutes contact with cleanness slag at 1650 °C.

Fig. 5 shows the refractory material in a cleanness slag. Its viscosity at 1650 °C is seventeen times less (100 mPa*s) than the previous High-Al$_2$O$_3$ slag. These values are sufficient to infiltrate the slag into the refractory material, through the capillaries, and to crack the grains. The total slag layer on the refractory surface was 1.7 mm. Also a massive of the solid particles of MgO in the slag were found. This suggests that the slag in this composition cannot dissolve MgO grains due to its saturation in the slag. Such solid dendrites can be released when the slag is cooled on a hot refractory, when the MgO solubility in the slag decreases as the temperature decreases.

**Fig. 6.** Cross section of MgO-C after 60 minutes contact with desulfurization slag at 1650 °C.

Fig. 6 shows MgO-C after contacting with the desulphurising slag. The depth of the slag layer is 1.57 mm due to the low viscosity 70mPa*s of the slag. In picture b), a spherical reduced iron with a diameter of 0.91 micrometre is observed. Although this slag does not contain more than one percent FeO, it is reduced to pure iron and agglomerated into a single sphere on contact with the refractory carbon. Due to the low viscosity this slag is infiltrated deep into the refractory. Infiltration is more active in areas where there is no carbon. These are often splits in the MgO grains, where the slag is infiltrated by the droplet effect. As the slag contains a large amount of CaO, its maximum allowable solubility in the slag drops and it is isolated separately as CaO solid.

## CONCLUSIONS

In present work, the effect of different slags on the MgO-C refractory was investigated. The different C/A-ratio in the slag affected the capability of the slag to dissolve the MgO-grain, and prevented slag infiltration into the refractory:

1. Slag infiltration into the MgO-C refractory was not detected at a viscosity of more than 100 mPa*s.

2. Although high-$Al_2O_3$ was reacted with the refractory, it could dissolve the MgO grains to form $MgAl_2O_4$.

3. Cleanness slag has low viscosity values, which lead them infiltrate deeper into the MgO-C refractory. At the same time, dissolution of MgO grains was not possible due to their saturation in the slag.

4. The desulphurized slag has the lowest viscosity index, because of its infiltration into the refractory the deepest. Solid CaO is released from the solidified slag as it is saturated with it.

## ABSTRACT
A new material was developed for the LT lance to endure in the high temperature corrosive environment with high spalling resistance, by suppressing expansion of spinel with reduced magnesia content and densifying with reduced water content using a novel dispersant. The material exhibited both low apparent porosity and residual expansion with keeping an appropriate strength at temperatures higher than 1200°C, together with high thermal spalling resistance. Thus, a parameter, crack index determined by the thermal spalling test was closely correlated with the thermal shock damage resistance and the fracture energy. The developed lance was successfully applied actually to the secondary refining process of stainless steel with increased durability both in the average life and cumulative immersion time in the molten steel.

## INTRODUCTION
Secondary refining of steel in the ladle has been implemented widely with the LT lance which is inserted and blows argon or nitrogen gas into the molten steel to maintain its uniformity in composition and temperature [1]. Major factors affecting on the life of the lance are considered to be corrosion at the slag line as well as crack extension and peeling-off the tip part of the refractories, so the lance must be required to endure in the condition of high temperature corrosive environment with high spalling resistance [2]. In order to decrease the peeling of the refractories covering the steel tube during immersion, we aimed to reduce the thermal expansion of the refractories at higher temperature corresponding to that of the molten steel. In addition, by densifying and strengthening the refractories covering the tubes, we have also aimed to improve the total rigidity of the lance. The LT lance was installed to the ladle with vertical configuration as shown in **Fig.1**, where the one end of the lance was fixed to a beam of the upper structure of the ladle and the other end was immersed to blow gas into the molten steel with three ports perforated in the side wall of the lance slightly upper position from the tip end. Three ports for discharging gas give rise to a rotational moment during blowing the gas. (Although the moment does not generate when the gas blow rate from the three ports is always constant, the gas blow rate varies in the port by port with difference in the state of damaging the refractories around the port.) In the configuration described in the figure, the rotational moment exerted at free end generates a torsional stress in the lance. If the rigidity of the lance (the strength of the refractories) is lower than the torsional stress, the longitudinal cracking of the refractories covering the steel tube will be induced.

In the present study, in order to improve the durability of the LT lance, we aimed to develop the material having both low apparent porosity and residual expansion with keeping an appropriate strength at high temperatures over 1200°C, together with high thermal spalling properties.

## EXPERIMENTAL PROCEDURE
### Test Materials
**Table 1** shows raw material particle size, composition and required water content for the castable refractories sample of the materials A, B and C, respectively. The A is a conventional material, and the B and C are newly developed materials. For the B and C, the dispersant type was changed from that for the A. By changing the type of dispersant, the required water content for mixing castables of the B and C (for Y) could be reduced from the A (for X) with 5.8% to 4.5%. The amount of magnesia in the C decreased by 0.5a% from that in the A, and increased the same amount of alumina with same particle size. The permanent linear change, modulus of rupture, compressive strength and apparent porosity of each sample were measured after drying at 110°C or firing at 1000, 1200 and 1500°C for 3h.

### Thermal Shock Test
We evaluated the material A (conventional) and material C (developed). The A was evaluated by adding f % of stainless steel fiber. In order to investigate the effect of the amount of stainless steel fiber on the heat-resistant spalling properties, the C was evaluated by adding 0 to f % of the fibers as shown in **Table 2**.

**Figure 2** shows a schematic image of the equipment for thermal shock test [3]. In the test, one side (heating surface) of the sample with prismatic shape was quickly heated by a propane-oxygen gas burner. The thermal insulation brick with longer side of the heating side of the sample was arranged on the front of the heating side to prevent the burner flame from going around to the other sides. In one of the side surface other than the front heating surface, there is a temperature gradient from high in the front heating surface to low in back side surface, originating thermal stress to give strain to the sample. The photographs were taken in such side surface with certain interval. The side surface is covered by the heat insulating material which is removed just at the timing of the photographing to prevent

the sample cooled from unfavorable direction. Then, amount of strain was calculated from the displacement before and after deformation due to thermal stress and the initial length by processing the image data of the sample using the digital image correlation method [4]. It is possible to evaluate crack width and length quantitatively in the method, since increase in the calculated strain is reflected in initiation and propagation of the crack.

The sample was 230 × 114 × 65mm prismatic shape, with heat treatments of drying at 110°C for 24h, and then firing at 1000°C for 3h. The heating front surface of the thermal spalling test was 230 × 65mm, and the side surface photographed by a digital camera was 230 × 114mm. An example of the temperature change given to the sample is shown in **Fig. 3** where the temperature was raised to 1600°C at the heating rate of 200 °C/min, kept for 10min, and then cooled for 10min. The thermal cycle was repeated three times in the test. The strain distribution kept count at the timings of 201s and 402s after the start of heating, 871s after the first holding at 1600°C for 10min, 2479s after the second holding at 1600°C for 10min, and 4079s after the third holding at 1600°C for 10min, respectively, with the photographing interval of 67s.

**Corrosion Resistance Test**
Corrosion resistance was evaluated using a rotary drum erosion test apparatus. Slag with C/S (CaO/SiO$_2$) = 3 was charged into the furnace held at 1600°C, heated for 30 min, and then the slag was discharged. After repeating the treatment 10 times, the center of the specimen was cut and the amount of corrosion was measured. We evaluated the material A (conventional) and material C (developed) adding f % of stainless steel fiber.

**RESULTS AND DISCUSSIONS**
**Physical property**
**Figure 4** shows the results of measurement in the linear expansion **(a)**, apparent porosity **(b)**, modulus of rupture **(c)**, and compressive strength **(d)** for all the samples with each heat treatment condition. As seen in the figure, the reduction in the spinel formation due to decreasing addition of magnesia succeeded in suppressing permanent linear change of the C fired both at 1200 and 1500°C. The strengths of developed materials fired in each temperature were higher than those of the A. Especially, the strength increase was remarkable in the materials fired at both 1000 and 1200°C. The developed materials with fired at each temperature had low apparent porosity due to their lowered water content in the green state. Especially, in the C densification was achieved by not only reduction in water content but suppression in permanent linear change by reducing the formation of spinel at firing temperatures higher than 1200°C. As the results, the higher strength was also achieved in the C, finally. Then, we try to check the ability of the developed materials to suppress cracking in the actual use through the thermal shock test.

**Thermal Spalling Resistance**
**Figure 5** shows the strain distributions counted at each timing shown also in **Fig.3** for all the samples tested. The crack index, as one of the measures of the thermal spalling resistance, was determined as the ratio between the total sum of strains higher than 2% in whole detecting positions and whole number of the detecting positions by calculating the amount of strain in all directions (both x and y) in the strain distribution shown in **Fig.5**.
**Figure 6** shows the calculated crack index at the output timing shown in the **Fig.3** for all the samples tested. Comparing the A (conventional) and the C (developed) both with f % stainless steel fiber, the C had smaller crack index at all the timings detected, showing apparently superior thermal spalling resistance to the A.

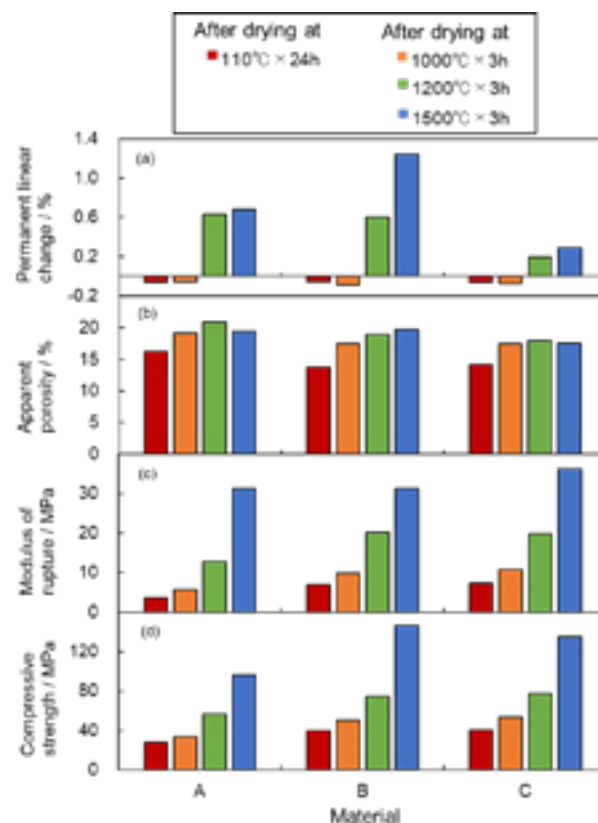

*Fig. 4 Measured properties of (a) permanent linear change, (b) apparent porosity, (c) modulus of rupture and (d) compressive strength for materials A, B and C with various heat treatment conditions showing above the figure.*

**Figure 7** shows the relationship between the crack index at 4079s (after the third holding at 1600℃ for 10min) and the amount of stainless steel fiber added. Since there was a strong correlation between the crack index and the amount of the stainless steel fiber for the C, the usefulness of the stainless steel fiber addition to the refractories for the lance was able to be confirmed.

We investigated the correlations between the calculated crack index determined by the thermal spalling test and various indices representing thermal shock resistance [5]: thermal shock fracture resistance $R$, thermal shock damage resistance $R''''$ and Crack stability index $R_{st}$, as well as, fracture energy $\gamma$.

The equations expressing them are shown below;

$$R = \frac{S(1-\nu)}{E\alpha} \qquad (1)$$

$$R'''' = \frac{E\gamma}{S^2(1-\nu)} \qquad (2)$$

$$R_{st} = \left(\frac{\gamma(1-\nu^2)}{E\alpha^2}\right)^{\frac{1}{2}} \qquad (3)$$

where, $S$:modulus of rupture, $E$:modulus of elasticity, $\gamma$:fracture energy (measured by three-point bending test of notched specimen), $\nu$:poisson's ratio, $\alpha$:thermal expansion coefficient. (Values for $S$, $E$ and $\gamma$ were measured in sample fired at 1000 °C for 3 h).

**Figure 8 (a)~(d)** shows the relationships of the calculated crack index at 4079s to the fracture energy and the three indices representing thermal shock resistance. Although there was no strong correlation of the $R$ with the crack index **(a)**, the other two indices for thermal shock resistance $R''''$ and $R_{st}$ correlated strongly with the crack index **(b, c)**. The fracture energy $\gamma$ has also strong correlation with the crack index **(d)**. The strong correlations of the $R''''$ and the $R_{st}$ with the crack index depended on the fracture energy $\gamma$ which constitutes both equations for the $R''''$ and the $R_{st}$. Therefore, controlling of the fracture energy $\gamma$ is important for suppressing the crack. It was also proven in the C that the increase in amount of the stainless steel fiber was quite effective to improve the $R''''$, $R_{st}$ and $\gamma$.

*Fig. 6 Comparison of calculated crack index at the timings shown in the figure for all the samples tested.*

*Fig. 8 Correlation of the crack index at 4079s with various parameters of (a) R, (b) R'''', (c) Rst and (d) fracture energy.*

**Corrosion Resistance**

**Figure 9** shows the results of erosion investigation using a rotating drum type erosion test apparatus. When base material A is set to 100 for the index, the index for the material C is shown in the figure together with the appearances of the cut surface after the test. Although there was concern that the corrosion resistance of the C would decline because of its lower magnesia content compared to the A, a slight improvement in corrosion resistance was achieved by the densification in the green state due to decreased water content.

**TEST IN ACTUAL OPERATION**

The material C with f % stainless steel fibers, exhibited a high performance in the laboratory thermal shock test with the lower crack index and high corrosion resistance, was used in actual operation.

The developed LT lance was used in first actual operation, and marked an improved performance in both service life and cumulative immersion time of 16ch and 120min (conventionally 11.1ch and 88min), respectively. **Figure 10** shows some views of the LT lance after use. Deep and large longitudinal and ring cracks occurred frequently in the conventional lance were not observed in the developed one. The reason for determining the exchange of the lance changed from cracking to the corrosion of the slag line. **Figure 11**

compares the durability of the developed lance in the actual operation at n = 26 with that of conventional one. It has an improved durability with the average life from 11.1 to 18.0ch, and the average cumulative immersion time from 88 to 121min compared to the conventional one. Since the developed LT lance had excellent durability, it became to be used steadily in the actual operation.

*Fig. 11 Comparison of cumulative immersion time and life for the developed LT lance with the conventional one.*

| Material | A | C |
|---|---|---|
| Corrosion index | 100 | 93 |
| Cross sectional view | | |

*Fig. 9 Cross sectional view of the sample after corrosion resistance test.*

*Fig. 10 Views of conventional and developed LT lances after use in actual operation.*

**CONCLUSIONS**

The developed ladle treatment (LT) lance became to be used steadily in the actual operation as the result of efforts to reduce cracking at the vicinity of the tip, with achieving the following improvements in the material from the conventional one.

(1) Both lower permanent expansion change and apparent porosity, with higher strength at the temperatures higher than 1200°C, were achieved by suppressing the spinel expansion due to decrease in the magnesia content.

(2) Superior thermal spalling properties were also achieved by processing mentioned above with making the crack index determined by the thermal shock test correlates strongly with the thermal shock damage resistance $R''''$ and the fracture energy $\gamma$.

(3) An equivalent or rather better corrosion resistance was achieved by lowering the apparent porosity with decreasing the water content in the green state.

(4) The durability of the LT lance in the actual operation increased the average life and cumulative immersion time significantly by as much as about 60% and 40%, respectively.

(5) The decreased cracking at the vicinity of the tip in the lance resulted in alteration of the reason for exchange the LT lance from the cracking of tip to the corrosion of slag line.

# GRAPHENE ADDED CARBON MGO-C FOR SLAG ZONE IN STEEL LADLE

Goutam Ghosh, Navneet Sinha, Sujat Ali Khan, Prasanta Panigrahi, Brijender Singh

Tata Steel Ltd, Jamshedpur, India

## ABSTRACT

Magnesia carbon (MgO-C) refractories are widely used in iron and steel industries due to its excellent corrosion resistance to basic slag. There are limitations in quantity of Carbon, (mainly by using natural flaky graphite), beyond a threshold limit, as it adversely impacts coked properties, thermal conductivity and Carbon pick-up by steel. To mitigate this adversity, in recent past, there have been several approaches to use of Nano-particle carbon, as it has been reported to have improved the thermos-mechanical properties of MgO-C, by suitably modifying the binding structure. In Tata Steel, Graphene (TSG), as a form of nano-carbon particle was used to develop improved quality MgO-C for the slag zone in the steel ladle. The objective was to get improved oxidation resistance, corrosion resistance, and hot bending strength of MgO-C. The developed bricks were tried in the steel-making shop ladles slag zone. Aluminum killed steel ladle slag showed the lowest corrosion when Graphene added MgO-C brick was used in slag zone. The new class of graphene added magnesia carbon brick has a lower wear rate compared to regular quality of magnesia carbon bricks.

Keywords: Magnesia carbon, corrosion, oxidation, performance

## INTRODUCTION

In modern steel making process, magnesia carbon refractory plays a significant role in the most critical areas like secondary steel making steel ladle and BOF Convertor. Development of high-performance magnesia carbon bricks has been the focus of the steel plant for improved production efficiency and lower cost of steelmaking. Carbon in form of graphite is key element for slag resistance and high temperature strength.

Fig. 1: Steel ladle pictorial view

To enhance the role of carbon a study was initiated to use Graphene as a partial substituted material for formation of nano bonding system in magnesia carbon material. Literature shows that the addition of nano carbon in the magnesia carbon quality forms additional carbides bonds in the matrix. There are various sources such as graphene, carbon nano tube, carbon black of the nano carbon for the magnesia carbon bricks. Addition of graphene provides additional advantage due to structural similarity with the graphite material. This paper illustrates the developmental work of Graphene added magnesia carbon brick for ladle slag zone. The study tries to explore the influence of graphene on thermomechanical properties and corrosion behabour of Mag-C through laboratory experimental setup and field trials in ladle. In Fig 1 schematic picture of steel ladle is shown.

## EXPERIMENTAL PROCEDURE

Magnesia Carbon bricks were manufactured using high purity fused magnesia, 97% Fixed Carbon graphite, Al and Si metal powder as antioxidant and graphene as a source of nano carbon. For laboratory evaluation bricks are produced in 100 Kg Eirich mixture machine and 600 Ton electric screw press. These bricks properties are evaluated in laboratory. The manufacturing process used the same industrial production resource, as for production of regular MgO-C bricks.

Physical and chemical characterisation of bricks were done by several techniques. Chemical analysis of the samples was done using Inductively coupled plasma mass spectrometry (ICP-MS) method. Bulk density (BD) and apparent porosity (AP) were determined by both DIN EN 993-1(DIN 51056) standard and Tata Steel standard. Hot modulus of rupture (HMOR) was determined in HMOR machine (Make: Netzsch) according to ISO 5013: 1985 standard. Thermal expansion measurement was done in dilatometer (TA Instrument) up to $1400^0C$ temperature according to ISO/FDIS 16835. Slag corrosion conducted in dynamic condition in induction furnace (make: Inductotherm) with steel ladle slag for 60 minutes dipping time at 1650 degree C temperature as per Tata Steel standard.

## RESULTS AND ANALYSIS

### Graphene properties

Table 1: Properties of the Tata Steel, Graphene (TSG)

| Parameter | Tata Steel, Graphene (TSG) |
|---|---|
| Appearance | Flakes |
| Number of layers | $\leq 15$ |
| Bulk Density (g/cm3) | 0.04 – 0.06 |
| Thermal Stability | 590 °C (in air), 870 °C (in inert) |
| Elemental Analysis (%) | C (91-95), O (3-5), S (0.1- 0.4) and H (0-1.5) |

The appearance of the Tata Steel graphene is flake like appearance with less than 15 layers of carbon. The bulk density of the graphene is 0.04 to 0.06 gm/cc. The

graphene is oxidized in 590$^0$C in air and 870$^0$C in inert atmosphere. The graphene contains C (91-95), O (3-5), S (0.1- 0.4) and H (0-1.5).

**Chemical and physical properties**
Chemical and physical properties of the materials are analyzed to understand the change behabour of the materials as shown in table 2 and table-3 respectively. The as such and coked porosity of the existing and graphene added magnesia carbon material is similar. Bulk density in as such and coked condition in both the sample is similar in value.

Tab. 2: Chemical analysis of existing and graphene added magnesia carbon bricks

| Test element (Weight %) | Existing magnesia carbon | Graphene added magnesia carbon |
|---|---|---|
| Al$_2$O$_3$ | 3.70 | 3.65 |
| MgO | 91.64 | 91.05 |
| CaO | 1.46 | 1.20 |
| Fe$_2$O$_3$ | 1.01 | 2.09 |
| SiO$_2$ | 1.51 | 1.25 |

Tab. 3: Physical properties of existing and graphene added magnesia carbon bricks

| Sample | Existing magnesia carbon | Graphene added magnesia carbon |
|---|---|---|
| AP as received (%) | 3.12 | 2.26 |
| AP after coking at 1000C/2hrs (%) | 8.18 | 17.35 |
| BULK DENSITY (gm/cc) | 3.03 | 3.04 |
| BD after coking at 1000°C/2 hrs (gm/cc) | 2.97 | 3.00 |
| CCS As received (kg/cm2) | 433 | 456 |
| CCS after coking 1000°C/2 hrs (kg/cm2) | 345 | 364 |

**Hot bending strength**
As shown in the Fig. 2, HMOR value of the graphene added bricks have improved over the existing bricks. Graphene is having the plate like structural similarity of

with the graphite material. The plate like structure of the graphene helps in formation of the reactive phases.

Fig. 2: HMOR of magnesia carbon bricks

**Corrosion resistance**
This slag corrosion test had been done with steel ladle slag at 1600°C with magnesia carbon bricks with a soaking time of 0.5 hours. The induction furnace dip test was done with sample size of 40x40x180mm. This arrangement provides slag to flow over the materials at high temperature. From the pictures in Table 4 we can visualize that the MgO-C brick is getting oxidized from the outer surface. Details measurement of corrosion is given in table 4. Corrosion resistance of the graphene added magnesia carbon is better than the existing magnesia carbon bricks.

Tab. 4: Corrosion of existing and graphene added magnesia carbon bricks

| Sample details | Existing magnesia carbon | Graphene added magnesia carbon |
|---|---|---|
| Pictures of the samples after corrosion test | | |
| Corrosion (%) | 5.9 | 3.9 |
| Visual Observation | Medium groove formation | Low groove formation |
| Ranks | 1 | 2 |

Table 4 shows the photographs of corroded sample after slag corrosion test where a neck formation corresponds to the penetration depth. Slag penetration was found to be minimum for graphene added magnesia carbon bricks. The corrosion index of the two samples is given in table 4. Corrosion index shows graphene added magnesia carbon bricks have better corrosion properties than other sample

of same quality. The relative improvement of corrosion behabour is more for graphene added magnesia carbon bricks sample compared to existing magnesia carbon sample.

**Thermal expansion value**

The thermal expansion is an essential data point for design of refractory structure, and it is important parameter which plays a role in thermal shock resistance. Reversible thermal expansion curve was obtained with the help of push rod dilatometer from room temp to 1400˚C. The heating rate was 5℃/min. Fig 3 shows that there is not much difference in the thermal expansion values of existing and improved quality magnesia carbon bricks.

Fig 3: Thermal expansion curve of existing and graphene added magnesia carbon bricks

**APPLICATION IN STEEL LADLE**

Magnesia carbon bricks with graphene addition is manufactured in the plant and installed in the slag zone of 8 ladles in the Al- killed steel making shop. The relining of graphene added magnesia carbon bricks picture given in Fig. 4.

Fig 4: Steel ladle relining

The scan report of the steel ladle after the campaign is given in Fig. 5 which shows erosion of the trunnion zone of steel ladle slag zone. The condition of ladle during the operation was observed normal as shown in the picture 6. During relining of the ladle, the used graphene added magnesia carbon bricks was observed to have less oxidation during use as shown in Fig. 7. The trial performance is shown in the Table 5 which shows a trend of around 10-20% performance improvement of the graphene added magnesia carbon bricks over existing magnesia carbon bricks.

Tab. 5: Performance of graphene added magnesia carbon

| Area | Erosion rate (mm/ heat) | left over thickness (mm) | Erosion rate (mm/heat) |
|---|---|---|---|
| Steel ladle slag zone (average erosion) | 1.10 | 67.90 | 1.46 |
| Steel ladle slag zone (maximum erosion) | 1.61 | 35.00 | 2.05 |

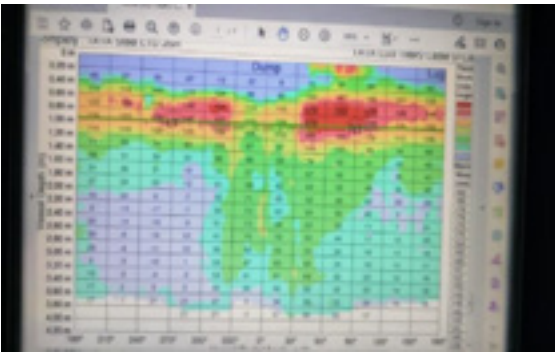

Fig. 5: Scan report after campaign

Fig. 6: Condition of ladle during operation

Fig. 7: Ladle condition during dismantling

**CONCLUSION**

The conclusions of the work are:

1. Addition of graphene in magnesia carbon bricks have the potential for improving the key performance determining properties like hot strength, elasticity and corrosion resistance.

2. Optimization of quantity of graphene addition plays a significant role in magnesia carbon properties. Further development in this regard to be continued with respect to quantity and types of graphene.

3. Details analysis reveals that formation of the carbides in presence of reactive graphene.

4. Plant trial of the graphene added magnesia carbon bricks in steel ladle slag zone shows slight improvement in the performance. More trials with various recipes of graphene in steel ladle to be done to further improvement in the performance.

# EFFECTS OF CALCIUM MAGNESIUM ALUMINATE BINDER ON PROPERTIES OF ALUMINA–MAGNESIA CASTABLES FOR STEEL LADLE

Kun Ming Chen*, Chia Hung Kuo, Tung Hsin Su

New Materials Research & Development Dept., China Steel Corporation, Taiwan, Republic of China

## Abstract

The starting material of the alumina-magnesia castables contains $Al_2O_3$ and $MgO$, which formed the alumina-magnesia spinel phase during high temperature service. This phase formation consequently resulted excessive expansion and cracking that lead to poor performing castables. The main purpose of this study is to observe the improvements in the properties of alumina-magnesia castables by adding Calcium-Magnesium-Aluminate (CMA) binder and reducing MgO powder addition. Corrosion resistance was defined by the deepest penetration depth of molten steel. The experiment results revealed that steel corrosion resistance was enhanced as CMA binder increased when comparing to original alumina-magnesia castables. However, addition of CMA binder had no significant improvement on thermal shock resistance. Furthermore, corrosion behavior was observed in 0% and 2% CMA binder samples through microstructural analysis. Corrosion was firstly occurred in the matrix region and then the aggregate area could have been exposed during high temperature service which resulted in spalling and reduced performance. It was also found that 2% CMA binder added sample had a distinct interface layer. Further analysis by SEM/EDS showed that the refractory interface layer was mainly alumina-magnesia spinel phase. This spinel phase could block the continuous penetration of molten steel. In this study, refractory matrix area was enhanced by the addition of CMA binder into the castables, thereby improved the ladle lifespan.

## Introduction

The production technology of clean steel has been developed rapidly [1], which made secondary refining of steel ladles extremely important in recent years. In addition, the steel types also tend to be diversified and the tapping temperature is correspondingly increased, resulting a more stringent conditions for ladles. Therefore, the refractory material "Alumina-Magnesia Castables" used on the ladle working lining has to satisfy the essential requirements: (1) Excellent peeling resistance, (2) High resistance to iron oxide corrosion, (3) Good resistance to steel penetration, (4) Well thermal shock resistance, (5) High strength. The alumina-magnesia castables are mainly composed of aggregates and powders. The main materials for the aggregates are fused white corundum, brown corundum, and sintered tabular corundum. The fine powder includes alumina powder, magnesia powder, calcium aluminate cement, silica powder, and various additives, etc [2-5]. The most critical property of alumina-magnesia castables is the corrosion resistance of molten steel. Poor corrosion resistance may reduce ladle lifespan and increase the cost of steelmaking. In severe cases, it could even cause safety accidents such as steel leakage. The starting material of the alumina-magnesia castables contains $Al_2O_3$ and $MgO$, which would form the alumina-magnesia spinel phase during high temperature service. This phase formation consequently resulted excessive expansion and cracking that lead to poor performing castables [6]. Recently, a new type of cement "Calcium Magnesium Aluminate (CMA) Binder" was developed by Kerneos, which contains both calcium aluminate and alumina-magnesia spinel phases. Q. Chen et al. introduced CMA binder into magnesia carbon ladle bricks and obtained significant improvements on thermal shock and corrosion resistance [7]. Therefore, the main purpose of this study is to add CMA binder into alumina-magnesia castables and simultaneously reduce the amount of MgO powder to inhibit excessive expansion, thereby improve the performance of alumina-magnesia castables.

## Experimental Procedure

The composition of alumina-magnesia castables in this study is divided into two particle size categories, aggregates (size>200mesh) and fine powder (size≤200mesh). Aggregate uses white corundum with purity≥99%, and its particle size includes 5~8mm, 3~5mm, 1~3mm and 0.075mm~1mm. The fine powder uses α-$Al_2O_3$ micropowder (purity≥99%, D50≤5um), MgO powder (purity≥90%, particle size≤200mesh), micro-silica (purity≥97%, particle size≤1um), calcium aluminate cement ($Al_2O_3$≥70%, CaO≤30%) and dispersant. In addition to the above mentioned raw materials, this study added a new type of cement "Calcium Magnesium Aluminate (CMA) Binder" developed by Kerneos. It contains both calcium aluminate and alumina-magnesia spinel phases, and its chemical composition is $Al_2O_3$ (69~72%), CaO (7.5~10.5%), and MgO (19~22%). The experiment adds CMA binder while reducing the amount of MgO powder to keep the chemical total amount of MgO in the castables at 6%. In this study, the addition of CMA binder were 0%, 0.5%, 1%, 1.5%, and 2%, as shown in Table 1.

In terms of sample preparation, the raw materials are first proportionally prepared per design for aggregates, powders and additives. The raw materials are loaded into a blender (Hongda, JD-402) with appropriate amount of water added and stired for 3 minutes. The mixture was poured into the mold and held for 24 hours. After demoulding, the samples were dried in an oven at 110°C for 24hrs and then heat-treated at 1500°C/3hrs to set for analysis. Analysis process include (1). Measuring the fluidity of castable materials by jumping table method with reference to ASTM C1446-19; (2). Measuring the bulk density (BD) and the apparent porosity (AP) with a density tester (Precondar, XQK-04); (3). Using a universal testing machine (Hung-Ta, HT-2402) to measure the modulus of rupture (MOR) at room temperature with reference to ASTM C583-15; (4). Using a crushing strength tester to measure the cold crushing strength (CCS) at room temperature with reference to ASTM C133-97; (5). Referring to ASTM C1171-05 to define the thermal shock resistance. The experimental conditions increase the temperature to 1000°C/15min, then take the samples out to room temperature for 15min as a cycle, a total of 5 cycles. MOR is measured before and after the thermal shock test and then convert the recession rate; (6). Referring to JIS R2214 to carry out the steel penetration resistance. In this study, medium carbon steel block was selected and the test condition was 1600°C/3hr; (7). Using polarizing optical microscope and scanning electron microscope (SEM/EDS) for microstructure analysis and erosion mechanism. In addition, the sample with better steel penetration resistance was selected to investigate the influence of steelmaking conditions. The operating conditions were 1600°C±50°C and maintained for 4±1 hours.

*Tab. 1: Formula table of alumina-magnesia castables with different additions of CMA binder*

| Sample | CMA-(0) | CMA-(1) | CMA-(2) | CMA-(3) | CMA-(4) |
|---|---|---|---|---|---|
| Aggregates | 70% | 70% | 70% | 70% | 70% |
| CMA | 0% | 0.5% | 1% | 1.5% | 2% |
| MgO | 6% | 5.9% | 5.8% | 5.7% | 5.6% |
| Other Powders | 24% | 23.6% | 23.2% | 22.8% | 22.4% |

## Results and Discussion

(1) Fluidity and physical properties

The Fluidity becomes extremely important for alumina-magnesia castables since the main construction method is to pour into the working lining at the bottom and wall of the ladle. Poor

fluidity tend to create holes or gaps after pouring. These defects increase the risk of steel leakage during the ladle carries molten steel. Fig. 1 shows the effect of adding CMA binder on the fluidity of alumina-magnesia castables. The results revealed that the fluidity of castables increased with the addition of CMA binder, which is beneficial to ladle construction. The effect of adding CMA binder on the physical properties of aluminum-magnesium castables is shown in Tab. 2, including permanent line change rate (PLC), modulus of rapture (MOR), cold crushing strength (CCS), apparent porosity (AP) and bulk density (BD). It was found that the addition of CMA binder had no significant effect on MOR, CCS, AP and BD, but PLC decreased with the increase of CMA binder addition. The reason could be due to the replacement of MgO powder by CMA binder in this study while maintaining the total chemical composition of MgO at 6wt%. It reduced the expansion caused by the process of forming spinel phase ($MgAl_2O_4$) from MgO and $Al_2O_3$ after the temperature of heat treatment reached over 1200°C. This help improving the excessive expansion and cracking of the working lining of ladle.

*Fig. 1: Effect of adding CMA binder on fluidity of castables*

*Tab. 2: Effect of adding CMA binder on the physical properties*

| Sample | Physical properties (@1500°C/3hr) | | | | |
|---|---|---|---|---|---|
| | PLC (%) | MOR (MPa) | CCS (MPa) | AP (%) | BD (g/cm³) |
| CMA-(0) | 1.93 | 28.7 | 78.3 | 23.2 | 2.88 |
| CMA-(1) | 1.91 | 26.4 | 77.9 | 23.1 | 2.87 |
| CMA-(2) | 1.88 | 28.0 | 81.7 | 23.0 | 2.89 |
| CMA-(3) | 1.84 | 27.0 | 79.4 | 23.8 | 2.86 |
| CMA-(4) | 1.81 | 27.3 | 79.7 | 23.2 | 2.89 |

(2) Steel penetration resistance and thermal shock resistance

Alumina-magnesia castables is mainly used as the working lining for carrying molten steel in ladle Therefore, the steel penetration resistance is its most critical performance. In this study, the castables was poured into a mold to make a cup-shaped sample. After demoulding and drying, a steel block was put into the sample and then heat-treat at 1600°C/3hr. Next, the cooled sample is cut in half and the deepest penetration depth at the bottom (smaller-the-better) is measured as a criterion for judging the steel penetration resistance. The effect of adding CMA binder on the steel penetration resistance of alumina-magnesia castables is shown in Tab. 3. The deepest penetration depths of samples CMA-(0) to CMA-(4) are 12.1mm, 11.7mm, 11.1mm, 10.7mm and 10.2mm in sequence. The appearance of the sample after cutting is depicted in Fig. 2. The results indicated that the steel penetration resistance was enhanced as CMA binder increased when comparing to original alumina-magnesia castables. The thermal shock resistance of the castables is also one of the evaluation indicators because the operation of the ladle has frequent temperature alternation. The judgment method is by measuring the MOR before and after the thermal shock test to convert the recession rate (smaller-the-better).

The results of adding CMA binder on thermal shock resistance of alumina-magnesia castables is shown in Tab. 4. It revealed that the addition of CMA binder had no significant improvement on thermal shock resistance.

*Tab. 3: Effect of adding CMA binder on the steel penetration resistance of alumina-magnesia castables*

| Sample | Deepest penetration depth |
|---|---|
| CMA-(0) | 12.1 mm |
| CMA-(1) | 11.7 mm |
| CMA-(2) | 11.1 mm |
| CMA-(3) | 10.7 mm |
| CMA-(4) | 10.2 mm |

*Fig. 2: Cross-sectional photos of the samples for steel penetration resistance. (a). CMA-(0); (b). CMA-(4)*

*Tab. 4: Effect of adding CMA binder on thermal shock resistance of alumina-magnesia castables*

| Sample | Before test MOR (MPa) | After test MOR (MPa) | Recession rate (%) |
|---|---|---|---|
| CMA-(0) | 28.7 | 12.8 | 55.4 |
| CMA-(1) | 26.4 | 11.5 | 56.4 |
| CMA-(2) | 28 | 12.6 | 55.0 |
| CMA-(3) | 27 | 12.2 | 54.8 |
| CMA-(4) | 27.3 | 12.4 | 54.6 |

(3) Microstructure observation and erosion mechanism discussion

Among the above properties including fluidity, physical properties and steel penetration resistance, the sample CMA-(4) performed best. Therefore, samples from the experimental group CMA-(4) and the control group CMA-(0) were subjected to microstructure analysis to investigate the effect of adding CMA binder on alumina-magnesia castables. The polarizing optical microscope observation is shown in Fig. 3. The results found that CMA-(4) has a more obvious interface (orange area) than CMA-(0). It is speculated that this zone is mainly composed of Al-Mg spinel phase, which prevents further diffusion of the steel penetration area into the normal area. The penetration of molten steel into the refractories will cause qualitative changes in the composition and structure near the interface and accelerate the damage of the refractories. The penetration damage is directly proportional to the porosity of the castables. Furthermore, even the chemical composition of the castables is similar while the penetration rate is significantly different due to its varied structure. If the castables can produce obvious and thicker alumina-magnesia spinel phase at the interface, it can effectively block the further penetration of molten steel. Alumina-magnesia spinel phase is a dense structure with high melting point. In order to verify the above inference, SEM and EDS mapping were used to analyse the interface layer, as exhibited in Fig. 4. It verified that alumina-magnesia spinel phase does exist in the interface layer. Combined with the polarizing optical microscope observation results in Fig.3, CMA-(4) had a more obvious interface with alumina-magnesia spinel structure than CMA-(0).

405

Samples were taken from the interface area of CMA-(0) and CMA-(4) for XRD analysis. XRD Result is shown in Fig. 5. Fig. 5-(a) shows that while the main phases of CMA-(0) and CMA-(4) are corundum ($Al_2O_3$) and alumina-magnesia spinel ($MgAl_2O_4$), there are still traces of iron oxide ($Fe_2O_3$) and periclase ($MgO$) detected from the sample. Figure 5-(b) is the peak of spinel (311) plane. By comparing CMA-(0) and CMA-(4), CMA-(4) has an obvious peak shift which is caused by lattice distortion. The supposed cause is that the iron oxide produce from the oxidation of molten steel and then solid-solute into the alumina-magnesia spinel structure, as shown in the following reaction:

$$FeO + MgAl_2O_4 \rightarrow (Fe,Mg)O \cdot (Fe,Al)_2O_3$$

The lattice distortion is created as the atomic radius of Fe (156pm) being larger than that of Al (118pm) and Mg (145pm). It revealed that iron oxide was more solid-dissolved in the alumina-magnesia spinel at the interface area of CMA-(4). The XRD result is echoed with the microstructural observations.

*Fig. 4: SEM and EDS mapping analysis at the interface. (a). CMA-(0); (b). CMA-(4)*

*Fig. 5: XRD analysis of interface area*

The alumina-magnesia castables is mainly used as the working lining of ladle to carry molten steel, but it is still possible to contact with slag. The overall hypothesis of penetration and corrosion mechanism is illustrated in Fig. 6. A circulation cycle formed when the molten steel/slag reacts with the alumina-magnesia castables to form low melting point phases such as CA ($CaAlO_4$) and CA2 ($CaAl_2O_7$) [9] and adhere to the surface of the refractories. These low-melting substances penetrate and erode the castables. The new reactive layer adheres to the old layer to thicken the reactive layer and cause spalling. This cycle makes the residual thickness of the alumina-magnesia castables thinner. Furthermore, the matrix area of the aluminia-magnesia castables was found to be eroded first before the aggregate area is exposed. If the matrix area is eroded aggressively, the aggregate area will spall into molten steel/slag. In this study, the refractory matrix area was enhanced by the addition of CMA binder into the castables, thereby improved the ladle lifespan.

*Fig. 6: Hypothesis of penetration and corrosion mechanism. (a). CMA-(0)；(b). CMA-(4)*

**(4) Influence of steelmaking conditions on steel penetration depth**

The general operating condition for contacting molten steel in each round of steel ladle from the basic oxygen furnace (BOF) to the tundish is about 1550~1650°C and holding for 3~5 hours. In this study, the CMA-(4) with better steel penetration resistance was selected to investigate the influence of steelmaking conditions on the penetration depth of molten steel. The heat treatment condition is 1600°C±50°C for 4±1 hours. The result is exhibited in Fig. 7 and the formula obtained by linear regression of the experimental data is listed below. The deepest penetration depth of molten steel is $\Delta d$, the heat treatment temperature is T, and the heat treatment time is t.

If T=1550°C, $\Delta d = -0.1t^2 + 1.4t + 5.9$
If T=1600°C, $\Delta d = -0.15t^2 + 1.85t + 6$
If T=1650°C, $\Delta d = -0.05t^2 + 1.45t + 7.6$

The result revealed that since the coefficient value of $t^2$ was negative, which indicated that the steel penetration increased with the prolongation of the heat treatment time. However, the magnitude of penetration depth becomes smaller with the prolongation of heat treatment time. Furthermore, the depth of penetration of molten steel increases significantly with the increase of heat treatment temperature, which means the effect of operating temperature on penetration of molten steel is much greater than the effect of time. In order to increase the service life of the alumina-magnesia castables, the operating temperature and the time of the molten steel in the ladle should be reduced as much as possible under the premise of meeting the production conditions. If the operating conditions of the steel plant are difficult to change, it is recommended to use alumina-magnesia castables with better steel penetration resistance as the working lining in ladle.

Fig. 7: Influence of steelmaking conditions on penetration depth.

**Conclusions**

Improvements were traced in the properties of alumina-magnesia castables by adding Calcium-Magnesium-Aluminate (CMA) binder and reducing MgO powder addition. The steel penetration resistance was enhanced as CMA binder increased when comparing to original alumina-magnesia castables. However, the addition of CMA binder has no significant improvement on thermal shock resistance. The corrosion behavior was firstly occurred in the matrix region and then the aggregate area could have been exposed during high temperature service which resulted in spalling and reduced performance. It was also found that CMA binder added sample has a distinct interface layer (alumina-magnesia spinel phase), which was analyzed by SEM/EDS. This spinel phase could block the continuous penetration of molten steel. In this study, the refractory matrix area was enhanced by the addition of CMA binder into the castables, thereby improved the ladle lifespan.

# CHROME FREE BAKED MAGNESIA BRICK – A REALLY ENVIRONMENTALLY FRIENDLY PRODUCT FOR RH DEGASSERS

Patrícia Alves Silva de Resende Brum, Vladnilson Peter de Souza Ramos, Douglas Fernando Galesi, Ariovaldo do Nascimento, Haysler Apolinário Amoroso Lima, Hamilton Cesar Guimaraes of Shinagawa Refractories, Vinhedo, Brazil

## ABSTRACT

The companies' commitment to zero $CO_2$ emissions by 2050 has promoted a huge effort in the search for alternatives to replace conventional products, aiming to drastically reduce the carbon footprint. In refractory industry, for example, materials produced at low temperatures have been researched to replace high temperatures fired bricks, with significant $CO_2$ emissions in their processing. This is the case of $MgO-Cr_2O_3$ products, used as refractory lining at RH degassers. In addition to the environmental appeal for $CO_2$ reduction, the elimination of chromium is also a pursued objective, mainly due to the possibility of contamination of the environment by $Cr^{+6}$. Additionally, new possibilities for safe recycling can be explored with the absence of chromium. This work presents the efforts in the development of unfired Cr-free alternative refractories for application in RH degassers, to contribute with environmentally friendly products.

## INTRODUCTION

Currently around 70% of consumed refractories in the world are used by the steel industry, of which 1/3 are consumed during secondary refining operations [1]. The introduction of continuous casting, the growing demand for "ultra clean" steels [2] and the increased use of scrap as a raw material require additional treatment steps. Degassing – the main example of which is the Ruhrstahl Henrichshutte (RH) process – is one of these additional stages, incorporated for the elimination of hydrogen, carbon and oxygen, in addition to the homogenization of liquid steel.

Evidently, the stability of the refractories lining inside of equipment for steel refining is crucial for cleanliness of the final product, which includes minimizing its wear and eventual incorporation of refractory particles into the metal bath. In addition, the correct selection of lining material extends the operating cycle of the asset and avoids interruptions in production. For this, understanding the wear mechanisms of refractories subject to RH Degasser operation is essential.

Despite its performance when it comes to high corrosion resistance as a result from direct bonding between chromium ores and magnesium aggregates through which the grains are predominantly joined by a solid-state diffusion mechanism, current magnesia-chrome refractory linings have been replaced due to the toxicological and environmental risks associated with $Cr^{6+}$. Aiming at finding a potential substitute, compositions containing spinel $MgO\cdot Al_2O_3$ have been the focus of multiple studies to verify their applicability in industrial processes such as steel degassing (RH [3], VOD [4]), copper refining [5] and cement production [6].

Focusing mainly on thermal shock and corrosion, this work proposes to compare laboratory trials results between a proposal of new product unfired and based on $MgO-Al_2O_3$ without chromium in its composition with current fired with chromium content in RH operation. Initially, an exposition will be made of the physical-chemical, thermal and mechanical properties to which the lining is submitted during the industrial process. Based on these mechanisms, the experimental results of thermal shock and corrosion resistance tests will be discussed.

## EXPERIMENTAL PROCEDURE

Following the purpose of this paper to evaluate a more environmentally friendly product as an alternative to standard fired magnesia-chrome containing materials, a composition (here named as U1 presented on Table 1) of high-grade fused magnesia, high MgO content magnesia sinter and fused spinel of different grain sizes were made as the proposed formulation. Grain sizes of mentioned raw materials was defined to provide an optimized grain

sized distribution and higher densification. Due to thermal cycles and high FeO content slag the refractory lining of RH Degassers are submitted, two main properties of the product are necessary to achieve good field performance: high thermal shock resistance and high corrosion resistance. Aiming at having a product with high performance in both properties, ceramic additives were used in the mix and a chemical binder, activated at lower temperatures (below 500 °C), was used to provide non-fired bricks, in order to reduce $CO_2$ emissions.

Table 1 also presents two different chemical analysis of direct-bonded $MgO-Cr_2O_3$ products as commercial references, currently applied as RH Degassers lining: CR1 for lower vessel critical areas, such as impact pads, throat, and RH snorkels, and CR2 for RH lower vessel non-critical areas. Both are for high performance comparison available in the market as reference value of standard fired refractory bricks.

Tab. 1: Detailed description of samples used in this paper

| Samples: | U1 | CR1 | CR2 |
|---|---|---|---|
| **Components:** | | | |
| Fused Magnesia (-5,0 mm) | 80.5 | - | - |
| Magnesia Sinter (-1,0 mm) | 2.5 | - | - |
| Fused Spinel (-1,0 mm) | 12.5 | - | - |
| Ceramic Additive A | 2.0 | - | - |
| Ceramic Additive B | 0.5 | - | - |
| Chemical Binder | 2.0 | - | - |
| | | | |
| **Chemical Analysis (%)** | | | |
| MgO | 83.0 | 65.0 | 67.0 |
| $Cr_2O_3$ | <0.0 | 23.5 | 16.1 |
| $Al_2O_3$ | 9.3 | 3.3 | 7.9 |
| $SiO_2$ | 0.5 | 1.8 | 2.0 |
| $Fe_2O_3$ | 0.1 | 5.5 | 7.0 |
| Other | 7.1 | 0.9 | 0.0 |

Physicochemical properties measurements, presented on Table 2, were conducted on U1 sample after baking at 200 °C and after heat treatments at 1,000 °C and 1,450 °C, to analyze the evolution of properties at different temperatures. As CR1 and CR2 are commercial products, the samples taken as received were used as comparison for properties after 1,450 °C heat treatment. After each heat treatment conducted in reduced atmosphere, Bulk Density and Apparent Porosity were perfomed following the standard ABNT NBR 16661, Cold Crushing Strength follows standard ABNT NBR 10059, Modulus of Rupture follows standard ABNT NBR 5014 and Hot Modulus of Rupture standard ABNT NBR 9642.

Before thermal shock resistance characterization, samples were submitted at 1,450 °C in reduced atmosphere for 5 hours. Then 10 cycles of thermal shock at 1,000 °C for 1 hour each and air (forced convection) until reach room temperature were conducted with sonic elastic modulus measurement after cycles 1, 2, 4, 6, 8 and 10. All materials were compared considering the residual percentage of the original Young Modulus.

FactSage 8.0 software was selected to simulate the both F2 and C2 slags/refractory interface selecting FactPs, FToxid and Ftmisc databases for calculations. Equilibrium condition of a hypothetical interface varying from 100% of slag to a 100% of refractory was simulated, showing what phases could be expected for at a simulated condition considering an operation at 1,700 °C and 0.04 atm (approximately vacuum condition inside the RH).

The RH Degasser slag changes throughout the operating cycle, starting from a normal steel ladle slag, evolving into a FeO-rich slag, and ending up in a $CaO/Al_2O_3$ slag system [7]. Corrosion

resistance was then determined using a rotary slag test kiln, at 1,680 °C (±20 °C), using two slag compositions: a FeO rich slag (F2) and a CaO/Al$_2$O$_3$ slag (C2). For each trial, the slag was renewed, resulting in a two corrosion stages with new slag. The slag chemistry analysis is presented in Table 3.

Tab. 2: Physicochemical properties

| Properties | U1 | CR1* | CR2* |
|---|---|---|---|
| After baking (200 °C) | | | |
| Bulk Density (g/cm³) | 3.12 | - | - |
| Apparent Porosity (%) | 8.8 | - | - |
| Cold Crushing Strength (MPa) | 84.8 | - | - |
| Module of Rupture (MPa) | 18.3 | - | - |
| | | | |
| After firing (1,000 °C) | | | |
| Bulk Density (g/cm³) | 3.07 | - | - |
| Apparent Porosity (%) | 13.8 | - | - |
| Cold Crushing Strength (MPa) | 43.9 | - | - |
| Module of Rupture (MPa) | 4.4 | - | - |
| | | | |
| After firing (1,450 °C) | | | |
| Bulk Density (g/cm³) | 3.07 | 3.21 | 3.08 |
| Apparent Porosity (%) | 13.9 | 15.9 | 17.5 |
| Cold Crushing Strength (MPa) | 37.1 | 54.1 | 34.8 |
| Module of Rupture (MPa) | 5.0 | 5.9 | 4.4 |
| | | | |
| Hot Modulus of Rupture at 1,400 °C (MPa) | 2.2 | 7.6 | 5.9 |

*As CR1 and CR2 are commercial products used as reference, their samples were already fired.

Tab. 3: Chemical analysis of FeO rich slag (F2) and CaO/Al$_2$O$_3$ slag (C2)

| Compounds | F2 | C2 |
|---|---|---|
| Fe$_2$O$_3$ | 39.3 | - |
| CaO | 34.2 | 40.4 |
| Al$_2$O$_3$ | 16.8 | 55.8 |
| SiO$_2$ | 6.5 | - |
| MgO | 3.2 | 3.8 |

In addition, as the absolute values of wear at samples submitted to the rotary kiln corrosion trial was too low, a more agressive test was necessary tring to have a more representative of RH Degasser real operational conditions. The purpose of the lance erosion test was to evaluate FeO resistance at a high temperature (~2,000 °C) with an irradiation time of 30 seconds. The oxygen gas flows through a steel pipe which at high temperatures generates FeO that will erode the refractory brick. The volume of the eroded hole was measured by filling the eroded hole with silicon carbide grains and converting the volume from its weight.

**RESULTS AND DISCUSSION**
As previously presented, Tables 1 and 2 showed that the developed formulation of unfired brick has a lower porosity than commercial MgO-Cr$_2$O$_3$ products which can impact on slag penetration.
The different heat treatments applied to the developed product showed a good evolution of cold mechanical resistance, with the values after heat treatment at 1,450 °C at the same level as those observed for the MgO-Cr$_2$O$_3$ products. However, the developed product presented lower value of hot mechanical resistance when compared to commercial products containing chromium. As an isolated case, these lower values may not has great influence on refractory performance, but when associated with the resistance to thermal shock and to cracks appearance by thermomechanical stress, it becomes an important property to be achieved. These phenomena are very common in critical regions of RH Degasser, such as the throat and snorkels, especially in those cracks that occur at the interface between volumes impregnated with slag and volumes that still unaltered, which greatly contribute to the structural spalling of the bricks in operation.
As seen in Figure 1, the thermal shock resistance test showed that the developed unfired product (U1) showed a very similar behavior

to the commercial product containing chromium used in the critical parts of the RH furnace (CR1) and better performance than commercial chromium containing product used in the less noble regions (CR2). This shows the effectiveness of the ceramic additives on improving the thermal shock characteristics of the developed material.

Fig. 1: Percentage values of Modulus of Elasticity/Young's Modulus after 10 cycles of thermal shock at 1,000 °C

In both cases, using F2 or C2 slags, the developed formulation proved to be more resistant in the corrosion test when compared to fired references as shonw in Figures 2 and 3.

Fig. 2: Absolute and relative wear values after a FeO rich slag (F2) corrosion test in rotary kiln

Fig. 3: Absolute and relative wear values after a CaO/Al$_2$O$_3$ rich slag (C2) corrosion test in rotary kiln

After achieving good results at thermal shock and corrosion resistance tests, U1 proposal formulation and CR1 reference were

409

selected for a simulation of phases in equilibrium at the slag/refractory interface, at temperature and pressure similar to the operating conditions, using Factsage 8.0 thermodynamic simulation software. The results are shown in Figures 4, 5, 6 and 7.

Simulation using the FeO-rich slag, shown in Figure 4, indicates that the interface of the commercial product containing chromium shows an initial solubilization of the refractory of about 17%. After this point, MgO saturation occurs becoming stable. The saturation of chromium spinel, on the other hand, occurs later, in a fraction around 20% of refractory. During all simulated fractions, there is a small evolution of the gas phase, rich in $O_2$. There is no precipitation, in equilibrium, of phases other than those initially present in the refractory.

*Fig. 4: Equilibrium phases, at 1,700 °C and 0.04 atm, simulated by FactSage 8.0, considering chemical analysis of chromium containing CR1 brick, into hypothetical slag F2/brick interface, varying from 100% slag (Alpha=0) to 100% refractory (Alpha=1).*

The simulation (Figure 5) for U1 formulation results on initial refractory solubilization, at the FeO-rich slag interface, close to 15%. The additives ceramic phases A and B are completely solubilized, and the system, in equilibrium, presents, for proportions above 15% of refractory, 2 immiscible slags. The spinel phase only becomes stable in a proportion of above 90% refractory. There is also a presence of gas phase rich in $O_2$ in practically all refractory proportions.

*Fig. 5: Equilibrium phases, at 1,700 °C and 0.04 atm, simulated by FactSage 8.0, considering chemical analysis of unfired chromium free U1 brick, into hypothetical slag F2/brick interface, varying from 100% slag (Alpha = 0) to 100% refractory (Alpha = 1).*

Figure 6 ilustrates the simulation of interface between CR1 brick with the C2 slag ($CaO/Al_2O_3$). The commercial refractory containing chromium (CR1) has a lower solubility when compared with the simulation done with F2 slag, with chromium spinel already saturating the slag from about 7% of refractory fraction. No gas phase was detected.

*Fig. 6: Equilibrium phases, at 1,700 °C and 0.04 atm, simulated by FactSage 8.0, considering chemical analysis of chromium containing CR1 brick, into hypothetical slag C2/brick interface, varying from 100% slag (Alpha=0) to 100% refractory (Alpha=1).*

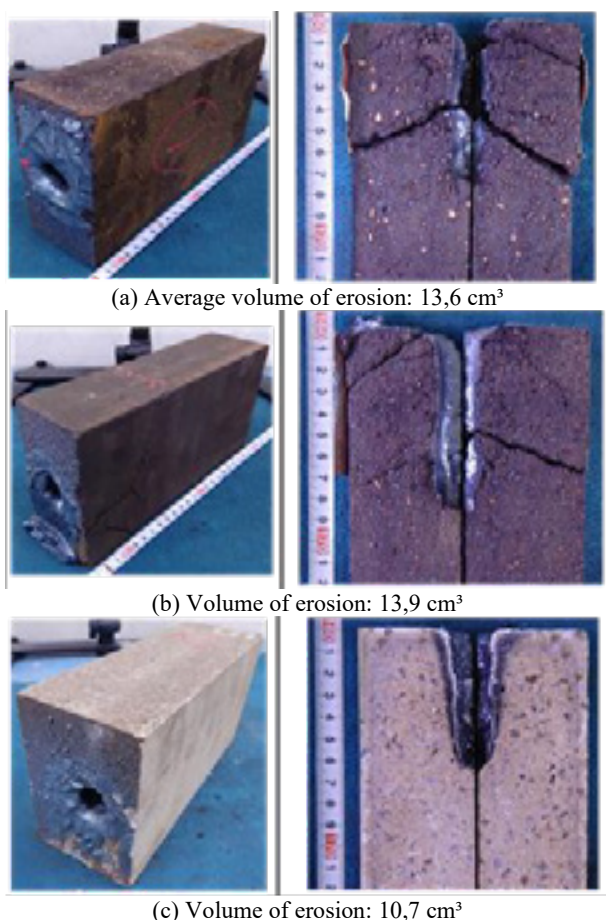
In the case of the refractory/slag interface for formulation U1, showed at Figure 7, the initial solubilization is much higher than for the product containing chromium, around 18%. Again, the additive ceramic phases A and B are not stable at all refractory ratios, and two immiscible slags are present up to the 70% refractory ratio. No gas phase is present at equilibrium conditions, and the spinel phase only becomes stable from a proportion of 88% refractory.

*Fig. 7: Equilibrium phases, at 1,700 °C and 0.04 atm, simulated by FactSage 8.0, considering chemical analysis of unfired chromium free U1 brick, into hypothetical slag C2/brick interface, varying from 100% slag (Alpha = 0) to 100% refractory (Alpha = 1).*

From achieved results at corrosion tests and in the phase equilibrium simulations, it is possible to indicate that the presence of two immiscible slag phases, present in the $MgO-Al_2O_3$ system, combined with the complete solubilization of additive ceramic phases A and B in these same slags, play a key role in the improved corrosion and slag penetration resistance.

410

Visual observation of the bricks after corrosion attack lance test, shows cracks in the holes of CR1 and CR2 bricks, but not in U1, according to the appearance and cross section surfaces. Figure 8 shows the detailed images of cross sections of the three products after lance teste and corresponding volume values caused by erosion.



(a) Average volume of erosion: 13,6 cm³

(b) Volume of erosion: 13,9 cm³

(c) Volume of erosion: 10,7 cm³

Fig. 8: Cross section surfaces of (a) CR1, (b) CR2 and (c) U1 bricks after corrosion attack by lance test.

The depth and volume of melt loss was the lowest for U1 unfired bricks when compared to CR1 and CR2. The appearance and cross sections surfaces of the fired bricks CR1 and CR2 showed cracks around the melted holes unlikelly unfired bricks. The thermal shock is considered to be high because the lance melt damage test rapidly reaches very high temperatures, around 2,000 °C. Therefore, it is considered that the unfired bricks with excellent heat spalling resistance have not presented cracks.

In addition, the amount of erosion loss tended to be lower for unfired bricks than for fired ones which can be justified by lower porosity of unfired compared to the fired ones. Contrariwise, the porosity of unfired bricks increases when heat treatment is applied. Therefore, the FeO resistance of unfired bricks used and heated in an actual furnace may differ from the trend of the lance erosion test results. Although fired bricks were also included in the comparison, caution should be exercised in comparing the test results of this study.

Ultimately all performed tests results indicate the good performance of unfired new development as a potentail substitution of fired chromium-based standard bricks. When we remove the heat treatment at high temperatures from the production process of the refractory bricks, there is potential of reduction of 357,1 kg of $CO_2$ emission per ton of brick due to removal firing step maintaing only baking [8].

## CONCLUSIONS

Highlighting toxicological and environmental risks associated with hexavalent chromium in $MgO-Cr_2O_3$ fired bricks – widely used in steel degassing equipment, such as in the Ruhrstahl Henrichshutte (RH) process – refractories based on $MgO-Al_2O_3$ have been considered in the literature as potential substitutes. Throughout this work, several characterizations were carried out, seeking to evaluate the feasibility of a refractory based on $MgO-Al_2O_3$ for the lower vessel RH.

The present paper showed a successful development based on $MgO-Al_2O_3$ proposal suitable with some of the most important properties conferred by chromium-containing products currently applied in RH degasser. This new product was developed using a lower heat treatment temperature, reducing $CO_2$ emissions in comparison to traditional chromium containing materials.

Satisfactory levels of resistance to thermal shock were achieved, compatible with a commercial reference product containing chromium, used in critical regions of the RH furnace, such as throat and snorkel.

A major corrosion resistance was achieved by new product, mainly by the addition of ceramic additives that, through their solubilization, provided lower extension in the impregnation by the evaluated slags. Even in more harsh conditions trials, the new product performance exceeded fired bricks on thermal shock resistance associated with higher temperature corrosion resistance.

Future studies aiming at focusing on improvement of hot mechanical resistance, necessary to prevent the appearance of cracks in current commercial products, due to the very characteristic thermomechanical effects present during the operation of RH degasser.

# EFFECT OF SPECIAL CARBON ADDITIVE ON THE PROPERTIES OF DOLOMITE–CARBON REFRACTORIES FOR STEEL LADLE APPLICATION

T. Mahata*, V. Jha, S. Das, B. Ghosh, A. Acharya, H. Nagata, S. Sengupta and P. B. Panda

TRL Krosaki Refractories Ltd., India

## ABSTRACT

Dolomite is well known for its use as refractory to produce cleaner steel. High thermodynamic stability of its oxides at elevated temperature, excellent corrosion resistance towards corrosive slag and good refractoriness makes dolomite suitable for above applications. Carbon containing dolomite bricks (Dolo-C) used in steel ladle where silicon killed grade steel produced and low $Al_2O_3$ containing slag is generated. Performance of Dolo-C refractory restricts due to poor hydration resistance of the material and generation of vertical crack due to less strength at higher service life.

In this present investigation, an effort has been made to improve the physical and thermomechanical properties by strengthening the matrix of the bricks. A special carbon additive has been introduced to improve the brick properties. Various trial recipes were prepared with varying percentage of additives and compared with recipes having no additive. The optimized recipe was characterized thoroughly, like thermomechanical, physical properties, hydration and oxidation behavior and compared with recipe having no additive. Improvement in physical properties along with oxidation and hydration behavior was observed due to the addition of the special carbon additive. Recipe with optimized property was considered to supply bricks for application in steel ladle metal zone. Performance improvement was noted along with less premature down compared to regular quality bricks in steel ladle application.

## INTRODUCTION

Dolo-C refractories are majorly used in steel ladle applications for Si killed steels, as the doloma is more thermodynamically stable and helps in the production of cleaner steel with low carbon pickup. The focus of research community has been majorly in the field of MgO-C refractories, but Dolo-C refractories share a lot of same characteristics as former. Therefore, multiple new developments in the field of MgO-C refractories can be directly used in the field of Dolo-C bricks. The knowledge of low melting phases in case of Dolo-C refractories are important for this.

Carbon is added as graphite flakes to the refractories, due to its non-wetting characteristics, excellent slag corrosion resistance and improved thermal shock resistance. However, the use of high amount of carbon has its own problems. Oxidation of carbon increases the porosity of the bricks, which in turn make the structure weak and reduces corrosion resistance. Higher carbon content also results in higher carbon pickup in molten steel. Efforts have been made by several researcher to introduce different carbon source in MgO-C refractories to improve properties of the bricks. In some research people tried to reduce total carbon content in the bricks by adding different source of carbon and additives to improve performance and reduce carbon emission. In this investigation we have identified two fine carbon source which can be used in combination with flaky graphite. Purpose of these fine carbon additives were to coat the grains and dust particles properly during mixing with binder. It was expected to reduce small voids inside the brick matrix and hence enhance hydration resistance and improve thermomechanical properties.

## EXPERIMENTAL PROCEDURE

High purity natural sintered dolomite and natural flake graphite are the main constituents to produce test refractory bricks. Novolac resin was used as binder. One standard recipe of Dolomite-C refractory was selected to study the effect of new additives. Two types of fine carbon additives having different particle size were selected to study the effect in the bricks. Two series of test bricks were prepared with additives A and B. Amount of these two additives varies from 0.25 % to 2% in the recipe and compared the properties with the brick sample prepared without any additive. All the recipes with nomenclature are described in **Table-1**. Laboratory scale mixer machine was used to mix the materials with binder and pressed in hydraulic press (SACMI-1600 MT) with 2T/cm² specific pressure. After pressing brick samples were cured at 300°C in tunnel dryer for 14 hrs. Bricks were cut after curing in different dimensions to measure different physical and thermomechanical properties.

Table 1: Recipes used for the experiments.

| Sample Name | Sintered Dolomite | Graphite | Additive -A | Additive-B |
|---|---|---|---|---|
| R | 97% | 3% | - | - |
| A-1 | 97% | 3% | 0.25% | - |
| A-2 | 97% | 3% | 0.50% | - |
| A-3 | 97% | 3% | 1% | - |
| A-4 | 97% | 3% | 1.5% | - |
| A-5 | 97% | 3% | 2% | - |
| B-1 | 97% | 3% | - | 0.25% |
| B-2 | 97% | 3% | - | 0.50% |
| B-3 | 97% | 3% | - | 1% |
| B-4 | 97% | 3% | - | 1.5% |
| B-5 | 97% | 3% | - | 2% |

Apparent Porosity (AP) and Bulk Density (BD) testing were carried out as per ISO 5017:1998. Cold Crushing Strength (CCS) of the samples were tested as per ISO 10059-2:2003. Coking of the brick samples was carried out at 1000°C for 3 hours soaking in reducing atmosphere (fired inside coke bed) and AP, BD and CCS were again tested as per the same standards described above. Modulus of Elasticity (MOE) testing was conducted after coking according to IS 13311, which is used for calculation of dynamic young's modulus of elasticity in concrete. For this test, samples with dimensions 50x50x100mm were prepared, and the transit time (T) was measured using an ultrasonic pulse generator and transducer. Pulse velocity (V) was calculated from transit time(T) and path length (L=100mm). Dynamic young's modulus was calculated using the following equation:

$$E = \rho\, f(\mu)\, V^2$$

Where, $\rho$ is the density in $kg/m^3$

$f(\mu)$ is the function of poisson's ratio which has value of 0.9 for the refractories and V is the pulse velocity in m/s

Hot modulus of rupture (HMOR) was conducted as per ISO 2478:1987. Oxidation resistance testing was performed using cuboid samples with 50x50x100 mm dimensions. Samples were set vertically in laboratory furnace and fired at 1400°C with 3 hours soaking. After firing samples were cut and measured the % of decarburised area. Hydration resistance test was conducted in humidity chamber maintaining the constant humidity 70% at 35°C temperature. 50*50*50 mm brick samples were taken and kept in humidity chamber for four days. After four days weight gain of the samples was measured. Amount of weight gain (%) was considered as hydration %. Slag corrosion test was carried out in static induction furnace with synthetic ladle slag. Slag chemistry was shown in Table 2. Bricks were cut and lined inside the furnace in hexagonal shape. Six no of samples (2 from each brick) with 120 mm height and 35 mm thickness was used to make the hexagon. Cylindrical steel bar (diameter 90 mm and height 125 mm) was put inside the furnace. After melting the steel, slag was charged in

412

every 30 min interval for 4 hrs. After 4 hours molten slag and metal was discharged. Corroded brick samples collected after cooling and measured the thickness of maximum corroded area. Rate of corrosion was calculated from the initial and leftover thickness after corrosion test.

Table 2: Slag Chemistry (wt%).

| CaO | MgO | SiO2 | Al2O3 | Fe2O3 | MnO | Cr2O3 |
|------|------|-------|-------|-------|------|-------|
| 56.7 | 2.21 | 35.01 | 2.23 | 0.47 | 1.51 | 1.7 |

## RESULTS AND DISCUSSION

*Fig.1: Variation of Apparent Porosity and Coked Apparent Porosity with increase in additive %.*

Apparent porosity variation of as such sample and coked samples with increase in A and B type Carbon additives in the recipe is shown in **Fig.1.** It has been observed that AP of as such sample decreased up to addition of 1% additive for both the additives. But further increase of additives did not continue the decreasing trend of AP further. In fact, these values become inconsistent beyond 1% addition of additives. Coked samples also has shown similar trends of AP, but variation is very less. This initial reduction in AP up to 1% addition due to filling the small voids between grains and

*Fig.2: Variation of Bulk Density and Coked Bulk Density with increase in additive %.*

matrix. This is possible as because fine particles of the additives distributed uniformly within the matrix. Beyond 1% addition of additives, AP increased due to agglomeration of excessive additives. During curing and coking of the bricks these agglomerates create fine pores and hence AP increases.

**Fig.2** shows the variation of Bulk Density with respect to the amount of additives A and B addition for as such and coked samples. There is no change in BD of the samples up to 1% addition of both the additives. But above 1% addition, BD decreased in both the cases. This indicates higher % of type A and B additives reduces the compactness of the bricks or not allow the brick matrix to get maximum compactness. BD of coked samples also showing the similar trend. Reduction of BD also due to low

density of the additives A and B. One point to be noted here that, compactness of bricks samples containing additive B shown better values compared to that of additive A.

**Fig.3** shows the variation of Cold Crushing Strength with respect to the amount of additives A and B addition for as such and coked samples. There is no such increase of CCS value was noted for additive A containing samples up to 0.5% addition. Addition of 1%

*Fig.3: Variation of Cold Crushing Strength (CCS) and Coked Cold Crushing Strength with increase in additive %.*

or more additive A, notable amount of CCS values has increased. Additive B containing samples showing improved CCS values upto 1% addition, further addition of additive B did not increase the CCS values further. This is due to better compactness and filling the smaller voids due to addition of fine additives. Coked CCS increases up to 1% and decreases above 1% addition of the additives. It is probably due to excessive addition of the additives, it got agglomerated and loosen during coking of the brick samples.

**Fig.4** shows the variation of HMOR/MOE ration of the brick samples. Higher value of this ratio indicates better thermal shock resistance of the bricks. This value increased up to 1% addition of additive A and for additive B added samples it increased up to

*Fig.4: Variation of HMOR/Modulus of Elasticity ratio.*

0.5% addition. After that this ratio of HMOR/MOE becomes constant.

**Fig.5** shows the cross section of the brick samples after oxidation test at 1400°C. Remaining black area measured and calculated the oxidised area (%) which is shown in **Fig.6.** Less oxidised area indicates better oxidation resistance. Oxidised area reduced initially due to small addition (0.25%) of both the additives. Addition of higher amount of additive does not improve the oxidation resistance further. This happens due to homogeneous distribution of fine additives and filling the void spaces.

413
Fig.5:Cross Section of Brick samples after oxidation test.

Fig.6: Variation of oxidised area with increase in additive %.

Table 3: Slag Corrosion rate.

| Sample Name | R | A-3 | B-3 |
|---|---|---|---|
| Corrosion Rate (mm/hr) | 4.5 | 2.5 | 4 |

Fig.8: Samples after slag corrosion test (a) R (b) A-3 (c) B-3

Hydration resistance improved due to addition of carbon additives, which is shown in **Fig. 7**. As the additives are very fine in nature and having high surface reactivity it is very easily adhere on the surface of grains. Also, small particles of the additives fill the small voids. It prevents the moisture to directly contact with dolomite grains up to some extent and improves hydration resistance.

Based on the findings in laboratory scale trial recipe A-3 was selected for commercial production for steel ladle metal zone application. Trial was conducted in one of the integrated steel plants, producing silicon killed steel in India. Spalling tendency of recipe A-3 bricks compared to regular (R) was reduced, which is evident in the photographs in Fig.9. and 10% performance improvement was reported.

Fig.7: Variation of hydration (%) with increase in additives %.

Analysis of physical and thermomechanical property indicates that 0.5-1.0% addition of both the additives (A & B) exhibits best results. Based on this analysis, 1% additive containing samples (A-3 & B-3) was considered for slag corrosion test along with the sample containing no additive. **Fig.8** shows the cross section of the samples after slag corrosion test. It was observed that sample A-3 has lowest corrosion rate (2.5 mm/hr) compared to sample B-3 (4 mm/hr) and R (4.5 mm/hr). Corrosion resistance of additive containing brick samples improved due to homogeneous distribution of fine carbon particles inside the matrix. It prevents the molten slag to penetrate the matrix. Although both the additives are showing similar type of improvement in physical and thermomechanical properties, but slag corrosion resistance is much superior in additive A containing sample (A-3). This is possibly due to more homogeneous distribution of additive A inside the brick matrix and better non-wetting property compared to additive B.

Fig.9: Ladle during repair of slag zone (a) with regular brick (b) brick with 1% additive A .

## CONCLUSIONS

In this study we have considered two types of carbon additives (A & B) to investigate their compatibility in Dolomite-C refractory. Initially physical and thermomechanical property of the bricks was studied with increase in additive content in the bricks (0.25% to 2%). Based on this study following conclusions were made:

- Optimum AP was observed in the bricks containing 0.5-1% of both the additives. There is no change in bulk density up to 1% addition, more than 1% addition of the additives reduce the bulk density. Which indicates that use of the additives is optimum up to 1%.

- CCS value of as such samples are showing higher value in 1% or more addition of both the additives. Coked CCS decreased due to more than 1% addition of the additives. It indicates 1% additive is the optimum quantity to get good brick strength.

- Oxidation resistance improved in both the cases with 0.25% addition. There is no further improvement due to extra addition of the additives.

- HMOR/MOE value increases in 0.5% or more additive containing (A & B both) brick samples, which indicates better thermal shock resistance in >0.5% additive containing bricks.

- Hydration (%) of bricks reduced gradually due to increase of additive additions, it indicates improvement of hydration resistance due to increase of additive %. It happens due to filling the small pores and coating of grain surfaced by the additives which prevents the moisture to react with the dolomite grains.

- Slag corrosion test of 1% additive (A-3 & B-3) containing bricks was conducted along with regular brick (R). It was observed that A-3 sample had significant improvement in corrosion rate (2.5 mm/hr) compared to regular sample (4.5 mm/hr). Whereas B-3 sample has corrosion rate (4.0 mm/hr) almost equivalent to regular sample.

- Plant scale trial conducted in ladle metal zone in one of the integrated steel plant in India with A-3 recipe and 10% performance improvement was reported.

# A STUDY ON THE FLUIDITY IMPROVEMENT OF QUICKLIME FOR DESULFURIZATION AGENT USED IN BOTTOM BLOWING FURNACE

Shin, Gil Jae of POSCO FUTURE M, Pohang-si , Korea, Lee, Nam Gil of POSCO FUTURE M, Sejong-si, Korea
Bae, In Kyung of POSCO FUTURE M, Pohang-si, Korea

## ABSTRACT

Extensive research is being carried out worldwide to reduce carbon dioxide ($CO_2$) emissions through various approaches. Even in the steel industry, which is one of the largest emitters of $CO_2$, research and development of steelmaking technologies to address this issue are being actively pursued. In order to reduce $CO_2$ emissions, the steel company is planning to achieve this through hydrogen reduction steelmaking, electric arc furnaces, and converter operations. The most practical and quickest solution to respond is considered to be reducing molten steel usage and increasing the amount of scrap, as this can effectively reduce $CO_2$ emissions. The technology involves injecting pure oxygen into the molten steel while adding quicklime to remove impurities such as carbon, silicon, manganese, sulfur, and titanium present in the molten steel inside the converter. For smooth injection, the quicklime used is coated with silicone oil on its surface to enhance its flow properties and water repellency. Research has been conducted on the dry coating technology of quicklime using silicone oil and its manufacturing processes.

## INTRODUCTION

This study investigates the processing method for the quicklime (CaO) powder used as a desulfurizing agent in the steelmaking process. Desulfurizing agents commonly used in the steelmaking process are classified into calcium carbide ($CaC_2$) based, sodium carbonate ($Na_2CO_3$) based, and quicklime (CaO) based. Calcium carbide has good reaction efficiency but is expensive to manufacture due to high power consumption. It also carries the risk of acetylene gas generation. Sodium carbonate has slightly lower reaction efficiency than calcium carbide but offers the advantage of desulfurization effect. However, it is more expensive than quicklime and has the disadvantage of generating white smoke during desulfurization and causing erosion of the refractory lining of the steelmaking vessel. Quicklime is inexpensive but has lower reaction efficiency. It reacts with moisture in the air to form calcium hydroxide ($Ca(OH)_2$) and has poor flowability in hoppers due to its high cohesiveness. It also causes clogging and circulation disturbances in the injection pipe. Therefore, increasing the pressure of the inflow gas is necessary, but it leads to waste of the gas and exacerbates the bubbling and rising velocity of the furnace, resulting in reduced desulfurization efficiency. Thus, this study aims to improve the reaction efficiency of the cheap quicklime-based desulfurizing agent, reduce the cohesiveness of the powder for easier injection, and prevent the generation of calcium hydroxide due to reaction with moisture during storage and handling. The approximate configuration of furnace is shown in Figure 1.

*Fig. 1-1: Top Blowing Furnace Process (Conventional Furnace)*

*Fig. 1-2: Bottom Blowing Furnace Processs*

In general, the conventional furnace is of the top blown type (Fig. 1-1). In the top blown type, quicklime is injected from the top. On the other hand, in a bottom blowing furnace, quicklime is injected from the bottom using high-pressure oxygen as a carrier medium(Fig- 1-2). If the quicklime particle size is large, there is a potential risk of sparks and explosions due to particle collisions in pipes and bends.

## EXPERIMENT

### Material

The materials used in this research are quicklime and silicone oil. The conditions for these materials are as follows. To achieve high-purity steel production, quicklime should meet the following properties as it is injected from the bottom

· High reactivity: The quicklime should have a high reactivity to Effectively remove sulfur and impurities from the steel.
· Low impurity content: The quicklime should have low levels of impurities such as silica, alumina, and iron oxide, as these impurities can negatively affect the steel quality.
· Proper particle size distribution: The quicklime particles should have a suitable and uniform size distribution to ensure effective mixing and reaction with the molten steel.
· Good flowability: The quicklime should have good flowability to ensure smooth injection.
· High thermal stability: The quicklime should exhibit high thermal stability to withstand the high temperatures in the furnace without significant decomposition or loss of reactivity.

These properties are essential to achieve efficient desulfurization and maintain high steel quality during the steelmaking process.

The specific desirable qualities of quicklime for injection from the bottom are as follows, as shown in Table 1

| Item | | Value, % |
|---|---|---|
| Chemical Properties | CaO | $\geq$ 90 |
| | $SiO_2$ | $\leq$ 3.0 |
| | S (Sulfur) | $\leq$ 0.05 |
| | Loss of ignition | $\leq$ 10.0 |
| Physical Porperties | $\leq$ 0.1 mm | $\geq$ 90.0 |
| | $\leq$ 1 mm | $\leq$ 100 |
| | water content | $\leq$ 1.0 |

*Table. 1: Quality data requirement for quicklime*

The silicon oil used in this study was a methylhydrogensiloxane product with reactive hydrogen groups. Conventional silicon oil, known as polydimethylsiloxane, was excluded from consideration as it lacks functional groups that can coat the surface of powders. The reactive hydrogen groups in methylhydrogen silicon oil act as functional groups that can chemically bond to the surface of powders, imparting hydrophobic properties to the coating material. Figure 2 shows the chemical structures of polydimethylsiloxane and methylhydrogen silicon oil and Table 2 provides details on the differences between them.

*Fig. 2: Chemical Structure of the Silicone oil*

| Silicone Oil | Properties |
|---|---|
| Polydimethylsiloxane | - Smoothing the surface , Enhancing color<br>- Water repellency , Compressibility, Compatibility<br>- Low environmental pollution and fire hazard<br>- Low surface tension, Excellent heat stability<br>- Odorless, tasteless, and non-toxic, water Solubility |
| Methylhydrogen Silicone Oil | - Water repellent treatment of powders and other particulate materials to achieve water repellency and excellent flowability while reducing agglomeration.<br>- Formulation of water repellent and hybrid coatings.<br>- Use of flexibilizers or water repellent treatments.<br>- Production of chemically reactive silicones and silicone copolymers.<br>- Acting as crosslinking agents and chain extenders |

*Table. 2: The Properties of Silicone Oil*

$$CaO + H_2O \rightarrow Ca(OH)_2 \qquad (1)$$
Calcium hydroxide causes scaling inside the injection pipeline, hindering accurate dosing and prolonging the injection time, thereby reducing operational efficiency. Moreover, it may result in significant accidents where the fluid overflows outside the furnace.

**Coating Device**

A typical equipment used for dry surface treatment of powders is a hansel mixer. The author also considered using a hansel mixer but due to insufficient productivity, a self-designed equipment was developed as follows.

*Fig. 3: Dry coating device for quicklime*

| | | |
|---|---|---|
| 100: Chamber (2.5 m³) | 110: Interior space | 200: Spray unit |
| 210: Oil supply unit | 220: Spray nozzle | 230: Gas supply unit |
| 300: Mixing unit | 310: Drive motor | 320: Shaft |
| 330: Impeller unit | 340: Frame | |

*Fig. 4: Silicone Oil Nozzle Spray System*

**Experimental method**

Put uncoated quicklime into chamber (100) and agitate while injecting silicone oil through a nozzle. Control the amount of silicone oil injection with the rotation speed of the diaphragm pump shown in Fig. 3. The injection pressure should be between 2 to 3 kgf/cm² and regulated by the air pressure. Operate the stirring speed (300) between 800 to 1,200 rpm. Below 800 ppm, the quicklime will not be properly agitated, resulting in uneven coating. Above 1200 rpm, the device will vibrate, produce noise, and overload.

After dry coating the powder with silicone oil, a curing process is necessary. Without the curing process, the oil will remain on the surface of the powder, making the coating film easily damaged even with light impact. Additionally, oil components can be adsorbed onto transfer pipes, leading to contamination issues. However, performing the curing process can reduce productivity and incur additional costs. In this study, during the dry coating process, the high stirring speed causes collisions between the quicklime particles, generating heat and naturally raising the chamber temperature above 80°C. This temperature increase allows for natural curing of the coated silicone oil, eliminating the need for a separate curing process. If necessary, the chamber can be thermally insulated to prevent heat dissipation.

The coating time is approximately 8 minutes when 0.3wt% silicone oil is injected. In order to provide curing functionality, an additional 32 minutes of stirring was performed for coating uniformity and stabilization purposes.

**RESULTS AND DISCUSSION**

**Viscosity of the silicone oil**

To ensure uniformity in spraying, the viscosity of silicone oil should be low. In one example, the viscosity of silicone oil can range from 20 to 100 cps. Viscosity above 100 cps can lead to poorer spray uniformity, while viscosity below 20 cps can result in reduced water repellency.

**Hydrogen Content (%) in the silicone oil**

The author investigated the moisture resistance of quicklime treated with surface-coated oil with varying hydrogen concentrations. The conclusion is that the minimum hydrogen concentration should be at least 1.4% to achieve adequate moisture resistance. Figure 5 demonstrates the impact of hydrogen concentration on the moisture variation of quicklime.

*Fig. 5: Moisture increase rate over time of quicklime according to hydrogen concentration. (25°C, Relative humidity 75%)*

**Flowability**

We have reviewed the amount of silicone oil coating on the quicklime. Insufficient coating of silicone oil leads to decreased flow characteristics

and moisture repellency. On the other hand, if it is excessive, it causes an increase in cost. The most appropriate oil coating amount for quicklime is 0.3~0.5wt%. If it is below 0.3 wt%, the moisture repellency decreases, and the quicklime absorbs moisture, converting to calcium hydroxide. This can result in process troubles such as pipe clogging when injected into the lower part of the furnace. Additionally, the flowability of the quicklime powder decreases. The flowability of the powder is evaluated using the angle of repose. The lower the angle of repose, the better the flowability of the powder. As the silicone oil coating amount increases, the angle of repose decreases, but it reaches a constant value at 0.5wt% or higher. Table 3 provides the data of the angle of repose according to the silicone oil coating amount.

| silicone oil coating amount, % | 0 | 0.1 | 0.3 | 0.5 | 0.7 | 0.9 |
|---|---|---|---|---|---|---|
| Angle of repose, ° | 61 | 55 | 43 | 42 | 41 | 41 |

*Table. 3: The change in angle of repose of limestone with respect to the amount of silicone oil coating.*

## CONCLUSIONS

Research is underway in various fields worldwide to reduce the emission of carbon dioxide, the main contributor to greenhouse gases. Among the industrial sectors, the steel industry is known to have the highest carbon dioxide emissions. It is generally understood that producing one ton of steel results in the emission of two tons of carbon dioxide. In the steel field, research is being conducted on technologies such as hydrogen reduction ironmaking and furnace modification to reduce carbon dioxide emissions. However, it is expected that it will take some time for these technologies to be fully developed. Therefore, reducing the use of molten steel and increasing the use of iron scrap are realistic alternatives to reduce carbon dioxide emissions. The silicon oil-coated quicklime, which is the result of this study, has excellent fluidity and water repellency compared to ordinary quicklime when used in a bottom blowing furnace

# DEVELOPMENT OF AL$_2$O$_3$–MGO–C REFRACTORIES CONTAINING LIGHTWEIGHT TABULAR ALUMINA AGGREGATES USED FOR STEEL LADLES

Qilong Chen, Tianqing Li*, Jie Gao, Qixiu Zuo, Qian Zhang
Puyang Refractories Group Co., Ltd., Puyang, China

## ABSTRACT

The lightweight of ladle lining refractories is of great significance to energy saving and consumption reduction. In this work, the lightweight alumina aggregates were selected to partially replace traditional tabular alumina aggregates to prepare lightweight Al$_2$O$_3$-MgO-C refractories used for steel ladle linings. And, the influence of lightweight alumina aggregates on the comprehensive properties of Al$_2$O$_3$-MgO-C refractories was investigated in detail. The results illustrated that the introduction of lightweight alumina aggregates can improve the strength of Al$_2$O$_3$-MgO-C refractories, due to the optimized interface bonding between aggregates and matrix. In addition, the thermal shock resistance of Al$_2$O$_3$-MgO-C refractories was also enhanced after adding lightweight alumina aggregates, which should be attributed to that the addition of lightweight alumina aggregates reduced the thermal expansion coefficient of such refractories, and micron-sized pores of lightweight alumina aggregates absorbed partial thermal stresses during thermal shock test. Furthermore, the addition of lightweight alumina aggregates improved the slag corrosion resistance of Al$_2$O$_3$-MgO-C refractories remarkably, which can be ascribed to the formation of continuous CA$_6$ protective layer and densified matrix.

## INTRODUCTION

Al$_2$O$_3$-MgO-C (AMC) refractories are mainly used as the working linings of steel ladle due to their superior hot mechanical properties, thermal shock resistance and slag corrosion resistance [1]. Different from traditional MgO-C and Al$_2$O$_3$-C refractories, Al$_2$O$_3$-MgO-C refractories were able to close the joints of working linings effectively by sustainable in-situ formation of MgAl$_2$O$_4$ spinel during their service life, which impeded the further corrosion and penetration of aggressive slag and enhanced overall integrity of refractory linings [2].

In recent years, with the growing demand for reduction of ladle heat loss, lightweight ladle working lining refractories with low thermal conductivity and bulk density was proposed, which was expected to decrease the ladle heat loss and specific refractory consumption per ton of steel [3]. However, ladle working lining refractories were inevitable to suffer from slag erosion, frequent thermal shocks and mechanical impacts of hot metal during ladle operation. Thus, the lightweight refractories were required to possess better comprehensive properties, especially the slag corrosion resistance and thermal shock resistance to guarantee the safety of steel ladle.

Taking the large proportion of alumina aggregates in the composition of Al$_2$O$_3$-MgO-C refractories, it was feasible to prepare lightweight refractories by introducing lightweight alumina aggregates into such refractories. Nevertheless, very limited reports about the application of lightweight alumina aggregates in Al$_2$O$_3$-MgO-C refractories are available at present, especially the comprehensive study on the thermal shock resistance and slag corrosion resistance of lightweight AMC refractories. Therefore, lightweight alumina aggregates were chosen to replace common tabular alumina aggregates of the Al$_2$O$_3$-MgO-C refractories in the current work, and the effects on the phase compositions, microstructure, mechanical properties, thermal shock resistance and slag corrosion resistance were studied.

## EXPERIMENTAL

Common tabular alumina (Al$_2$O$_3$≥99wt%, namely TA, Haicheng, China) and lightweight porous alumina aggregates (Al$_2$O$_3$≥99wt%, namely PA, Haicheng, China) were used in this experiment. The phase compositions of two series of alumina aggregates were shown in Figure 1. It was found that the two types of alumina

aggregates possessed similar chemical composition and phase compositions. In addition to the main corundum phase, a small amount of β-Al$_2$O$_3$ phase can also be observed in XRD patterns of TA and PA aggregates. The SEM images of TA and PA aggregates were exhibited in Figure 2. As shown, more numerous micro-sized pores were uniformly distributed in PA aggregates, while relatively few pores were observed in TA aggregates. Meanwhile, the pore size of PA aggregates was slightly lower than that of TA aggregates. Compared to TA aggregates, PA aggregates showed higher apparent porosity (7.3%), lower bulk density (3.44 g/cm$^3$) and lower true density (3.85 g/cm$^3$) as listed in Table 1.

*Fig. 1: XRD patterns of tabular alumina and porous alumina aggregates.*

*Fig. 2: SEM images of tabular alumina and porous alumina aggregates.*

Tab. 1: The physical properties of alumina aggregates.

| Index | TA | PA |
|---|---|---|
| Apparent porosity (%) | 3.4 | 7.3 |
| Closed porosity (%) | 3.6 | 3.3 |
| Total porosity (%) | 7.0 | 10.6 |
| Water absorption (%) | 0.9 | 2.1 |
| Bulk density (g/cm$^3$) | 3.59 | 3.44 |
| True density (g/cm$^3$) | 3.86 | 3.85 |

Three series of Al$_2$O$_3$-MgO-C refractories containing different content of porous alumina aggregates were designed according to the initial particle grading. Specifically, 0, 15wt% and 32wt% PA aggregates were introduced to Al$_2$O$_3$-MgO-C refractories, and named them TC, LC1 and LC2 respectively. All series mentioned above are maintained the same particle grading, equal flake graphite (6wt% C) and antioxidant (1wt% Al). The liquid phenolic resin was chosen as the binder, and their amount was 3wt% (additionally added). Also, 5wt% magnesia aggregates were selected as the raw materials of specimens to provide MgO.

The raw materials were set in the mixer and mixed evenly for 20 min. Then, the rectangular bricks (300 mm×150 mm×100 mm) were fabricated by using friction press (600 t). After that, the bricks were tempered at 200 °C for 10 h and processed into standard specimens with required shape and size. Finally, the $Al_2O_3$-MgO-C samples were coked at 1600 °C for 3 h.

The apparent porosity and bulk density of $Al_2O_3$-MgO-C specimen after treating at different temperatures were measured based on the Archimedes' Principle with kerosene as medium. The cold compressive strength (CCS) of specimens was tested using an electronic digital control system. In order to obtain the hot modulus of rupture (HMOR), the bar specimens tempered at 200 °C were examined under coking atmosphere at 1450 °C for 0.5 h based on the three-point bending test.

The cubic specimens coked at 1600 °C were used to evaluate the thermal shock resistance of refractories by cyclic air-quenching method. These specimens were set in the 1100°C furnace for 30 min under air atmosphere. Then, these cubes were immediately placed at room temperature to cool for 5 min. After repeating the above process three times, the CCS and residual strength ratio of specimens were obtained. Also, the thermal expansion coefficient of $Al_2O_3$-MgO-C specimen tempered at 200 °C was determined according to push rod method using the thermal dilatometer.

Static cup method was adopted to determine the slag corrosion resistance of $Al_2O_3$-MgO-C refractories. 25 g of the slag ($CaO/SiO_2$=2.40) was placed into the hole of the crucible samples cured 200 °C. Then, the crucible samples were treated at 1600 °C for 3 h under air atmosphere.

## RESULTS AND DISCUSSION

### Phase compositions and microstructures

The phase compositions of different $Al_2O_3$-MgO-C specimens after treated at 200 °C and 1600 °C were shown in Figure 3. It was found that the phase evolution of all samples showed the same change with increase of the heating temperature, indicating that addition of PA aggregates had no obvious influence in the phase compositions of the $Al_2O_3$-MgO-C specimens. Specifically, $\alpha$-$Al_2O_3$, periclase, graphite, Al and a small amount of $\beta$-$Al_2O_3$ derived from the raw materials were found in all specimens tempered at 200 °C. When the heating temperature was increased to 1600 °C, the new $MgAl_2O_4$ phase was formed while the diffraction peaks of the original Al phase were not detected, indicating that the Al phase should be completely transformed to Al-containing ceramic phases under coking atmosphere, such as $MgAl_2O_4$ and AlN [4]. Meanwhile, the sustainable in-situ reaction between MgO and $Al_2O_3$ in $Al_2O_3$-MgO-C system was promoted, which also led to the formation of more $MgAl_2O_4$.

The microstructure of polished $Al_2O_3$-MgO-C specimen tempered at 200 °C were shown in Figure 4. The obvious difference lied in the bonding interface between the aggregates and matrix. In TC specimen, a number of gaps were found at the edges of common tabular alumina aggregates, indicating the poor bonding between TA aggregates and the matrix. Different from TC specimen, LC1 and LC2 specimen containing lightweight alumina aggregates showed optimized interface. Noteworthy, the indistinguishable interfaces between the aggregates and matrix were observed in such specimens, which was attributed that PA aggregates with rough surface were more likely to form interlocking structures with the matrix [5].

### Physical properties and mechanical properties

The physical properties and strength of $Al_2O_3$-MgO-C refractories after treated at different temperatures were listed in Table 2. It was not difficult to find that all the specimen tempered at 200 °C showed the lowest apparent porosity and the highest bulk density. After heating treatment at 1600 °C, the apparent porosity of all the specimen increased sharply and their strength also decreased. Instead of organic bonding, a synergistic combination of graphite and ceramic reinforced phases was formed in AMC specimen, which was due to the pyrolysis of resin and in-situ chemical reactions [6]. As expected, both LC1 and LC2 specimen showed higher apparent porosity and lower bulk density due to addition of lightweight porous aggregates. Interestingly, the $Al_2O_3$-MgO-C specimen containing 32wt% PA aggregates had the highest strength, and their strength reached 63.4 MPa and 37.8 MPa after treated at 200 °C and 1600 °C, respectively. Similarly, the HMOR of different specimen exhibited the same change with the increase of PA aggregates content as depicted in Figure 5. Therefore, it can be believed that the introduction of lightweight alumina aggregates led to the enhanced mechanical properties of $Al_2O_3$-MgO-C refractories by forming optimized interface. Meanwhile, the larger contact area between porous alumina aggregates and matrix might contribute to the formation of the sintering neck at elevated temperatures, which facilitated the sintering process and ultimately improved the strength of such refractories [7].

Tab. 2: The physical properties and mechanical properties of $Al_2O_3$-MgO-C specimens.

| T | Index | TC | LC1 | LC2 |
|---|---|---|---|---|
| | AP (%) | 5.5±0.1 | 6.7±0.3 | 7.0±0.2 |
| 200°C | BD (g/cm³) | 3.25±0.01 | 3.20±0.01 | 3.19±0.02 |
| | CCS (MPa) | 57.7±3.6 | 59.7±1.6 | 63.4±0.8 |
| | AP (%) | 14.4±0.1 | 15.1±0.1 | 15.4±0.1 |
| 1600°C | BD (g/cm³) | 3.12±0.02 | 3.08±0.01 | 3.04±0.01 |
| | CCS (MPa) | 31.9±2.2 | 33.1±1.4 | 37.8±0.2 |

**Thermal shock resistance**

The thermal shock resistance of different Al₂O₃-MgO-C refractories coked at 1600 °C was provided in Figure 6. It can be clearly seen that the LC1 (29.1 MPa) and LC2 specimen (29.9 MPa) containing PA aggregates showed higher CCS than TC specimen (27.4 MPa) after thermal shocks. Meanwhile, the AMC specimen containing 15wt% lightweight alumina aggregates had the highest residual strength index (87.9%), indicating that the improved thermal shock resistance of AMC refractories could be obtained by adding proper content of lightweight alumina aggregates. However, AMC specimen with 32wt% PA aggregates showed poor thermal shock resistance, which might result from LC2 specimen with high apparent porosity suffered from the more aggressive oxidative damage during the thermal shock test.

*Fig. 6: The CCS of Al₂O₃-MgO-C specimens before and after thermal shocks and their residual strength ratio.*

The expansion of different Al₂O₃-MgO-C specimens were given in Figure 7. It can be seen that there were little obvious differences in the thermal expansion rates between different AMC specimens below 1000 °C (Figure. 7(a)). As for the thermal expansion rates of AMC refractories from 1000 °C to 1250 °C (Figure. 7(b)), LC1 and LC2 specimen had lower thermal expansion rates than TC specimen. The above results demonstrated that the thermal expansion coefficient of AMC refractories was decreased effectively, which provided key evidence for the better thermal shock resistance of AMC refractories containing lightweight alumina aggregates. Meanwhile, a large number of micro-sized pores in PA aggregates might also be beneficial to absorbing the thermal stresses in the materials [8].

**Slag corrosion resistance**

In order to investigate the influence of lightweight aggregates on the slag resistance of AMC refractories, the cross-sections of specimens after slag corrosion test and corresponding slag corrosion index were diagrammed in Figure 8 and Figure 9, respectively. With the increase of lightweight alumina aggregate content, the slag corrosion index of the AMC specimen decreased first and then increased. The specimen containing 15wt% PA aggregates showed the lowest slag corrosion index (3.8%), indicating that the slag resistance of Al₂O₃-MgO-C refractories can be improved after adding proper content of lightweight alumina aggregates.
