Figure 10 illustrated the microstructure of different Al₂O₃-MgO-C specimens after slag corrosion test. The EDS results of relevant points in Figure 10 were also listed in Table 3 to analyze the possible reaction products. As for the SEM images of corroded AMC specimens (Figure 10), the yellow circles and arrows referred to pores and cracks, respectively, and the obvious stratified structure was observed in all specimens. With the increase of distance from the hot face, it can be divided into slag layer, reaction layer and origin layer in all Al₂O₃-MgO-C specimens (as shown by the red and white lines). Apparently, the largest differences between such specimen lied in the following two aspects: (1) the continuity and densification of the reaction layer; (2) the distribution and the number of the pores and cracks in the origin layer. In TC specimen (Fig. 10(a)), the structure of some common alumina aggregates has been damaged seriously due to the dissolution of alumina to the slag. Meanwhile, the relatively dense protective CA₆ layer (Point 1) on the surface of alumina aggregates and MgAl₂O₄ spinel were formed by reacting with the slag, which prevented the further penetration of the slag. In addition, a large number of pores and cracks were found in TC specimen, especially at the interface between the common alumina aggregates and the matrix, indicating the poor bonding and relatively loose matrix. In LC2 specimen (Figure 10(b)), the number of cracks and pores in the origin layer decreased obviously due to the optimized interface. But many widely distributed pores were observed in the reaction layer, even though CA₆ layer (point 3) also formed at the surface of the lightweight alumina aggregates. It was considered that the loose decarburization layer containing numerous pores might weaken the isolation effect of CA₆ layer, leading to the poor slag resistance of LC2 specimen. Different from TC and LC2 specimen, LC1 specimen (Figure 10(c-d)) possessed the continuous and dense CA₆ isolation layer (Point 4). Combined with the mapping results, the CA₆ isolation layer formed on the surface of lightweight alumina aggregates bonded tightly with the slag layer, which effectively

421

impeded the penetration of slag into the relatively weak matrix. Considering the PA aggregates had relatively lower mean pore size demonstrated by the microstructure, $CA_6$ phase with high melting point was easier to precipitate during the interaction between the slag and PA aggregates [9], which provided favorable conditions for the formation of continuous dense protective layer at the hot face of the $Al_2O_3$-MgO-C refractories. Hence, the formation of continuous $CA_6$ isolation layer and the densified matrix should be responsible for the better slag resistance of $Al_2O_3$-MgO-C refractories containing 15wt% lightweight alumina aggregates.

*Fig. 10: The SEM images of $Al_2O_3$-MgO-C specimens after slag corrosion test: (a) TC; (b) LC2 and (c-d) LC1.*

Tab. 3: EDS results of points in Figure 10 (wt%).

| Element | O | Al | Mg | Ca | Possible phase |
|---------|-------|-------|-------|------|----------------|
| Point 1 | 44.79 | 46.42 | - | 8.79 | $CA_6$ |
| Point 2 | 45.09 | 38.74 | 16.16 | - | MA |
| Point 3 | 44.91 | 46.75 | - | 8.34 | $CA_6$ |
| Point 4 | 44.92 | 46.77 | - | 8.31 | $CA_6$ |

## CONCLUSIONS

The effects of lightweight tabular alumina aggregates addition on the phase compositions, microstructure, mechanical properties, thermal shock resistance and slag corrosion resistance of $Al_2O_3$-MgO-C refractories were investigated. The following conclusions were made.

(1) The addition of lightweight aggregates had no obvious effect on the phase composition of AMC refractories, but they could effectively optimize the boding interface between the aggregates and matrix due to their rough surface and more pores, which enhanced the strength of the $Al_2O_3$-MgO-C refractories.

(2) The lightweight $Al_2O_3$-MgO-C refractories possessed better thermal shock resistance, which was related with the decrease of thermal expansion coefficient and thermal stress absorption of a large number of micron-sized pores.

(3) The dense and continuous $CA_6$ isolation layer was formed between the slag layer and the origin layer in lightweight $Al_2O_3$-MgO-C refractories after slag corrosion test. Moreover, lightweight alumina aggregates containing $Al_2O_3$-MgO-C refractories presented denser matrix, which could prohibit the further penetration of slag. Consequently, the lightweight AMC refractories achieved better slag corrosion resistance.

## ABSTRACT

$Al_2O_3$-MgO and $Al_2O_3$-spinel low cement castable (LCC-AM and LCC-AS) have been extensively used in steel ladles as working linings. Nevertheless, the use of alumina-magnesia gunning mixes has been mainly kept for maintaining these castable linings, because of high rebound loss, poor green strength, high porosity and short life-span.

Thanks to a MC-G (high BET alumina), it is now possible to develop a series of high-performance non-cement and low-cement alumina-magnesia gunning mixes (NCG-AM and LCG-AM). The paper focuses on the BOF slag resistance of NCG-AM, LCG-AM, LCC-AM and LCC-AS. The corrosion mechanisms of rotary slag specimens are studied by Scanning Electron Microscopy.

The results reveal different microstructure around MgO particles, depending on the four used compositions. Continuous and thicker spinel phases were formed in NCG-AM, which proved to have the best corrosion resistance. It resulted from MC-G made $J_{Al3+}$ larger and hence inhibited Kirkendall porosity around MgO particles. In addition, continuous spinel phase acts like a pinning nail to reinforce the matrix and thus decrease erosion by slag.

In contrast to NCG-AM, we found porous spinel phase around unreacted MgO particles and some particles had been were carried away near the interface of LCC-AM and slag.

The NCG-AM composition with MC-G had been tested in two steel plants, and it extended the service life of the ladles up to 50%. In addition, this study suggests the potential application of NCG-AM as steel ladle linings.

## MATERIALS AND METHODS

As shown in Tab. 1, different compositions were designed to investigate the effects of various factors on the performance of dynamic rotary slag corrosion test.

Tab. 1: General information of the specimen compositions.

| Designed composition | LCC-AM | LCC-AS | NCG-AM | LCG-AM |
|---|---|---|---|---|
| Raw materials | | | | |
| Tabular(d<6mm) | 71 | 59 | 75 | 72 |
| 97-grade fused MgO | 5 | - | 7.5 | 7.5 |
| Alumana rich spinel) | - | 23 | - | - |
| Bimodal Reactive alumina (PBR) (d50:2~4μm) | 19 | 13 | 10 | 5 |
| High BET alumina (MC-G) (d50=5.5μm) | - | - | 7.5 | 7.5 |
| Calcium aluminate cement | 5 | 5 | - | 7.5 |
| Silica fume | 0.2 | - | - | 0.5 |

Dynamic rotary slag corrosion test was carried out to compare the corrosion resistance in following sequence:

Fig. 1: Re-charging the slag

1. Test pieces were prepared using a special casting method and cured for 48 hours at 25°C, followed by drying at 110°C.
2. Converter slag was used for the test, and compotation was shown in Tab.2.
3. Test temperature was at ~1650℃ for 1 hour and re-charging the slag for 6 cycles.

5. After cool down, sample's cross section was then measured to evaluate the corroded depth.

Tab. 2: Converter slag composition(wt%)

| % | CaO | $Al_2O_3$ | $SiO_2$ | $Fe_2O_3$ | MgO | $MnO_2$ | $P_2O_5$ |
|---|---|---|---|---|---|---|---|
| % | 49.7 | 2.5 | 6.7 | 26.7 | 7.1 | 2.3 | 3.6 |

The specimen's physical properties were analysed followed in JIS R2205 and R2553. In order to discover the spinel formation and corrosion mechanism, scanning electron microscopy (JEOL JSM-6360) microstructure images and X-ray diffractometer figures (Rigaku miniflex300) of the specimens after dynamic rotary slag corrosion test were attained.

## RESULTS AND DISCUSSION

From Tab.3, NCG-AM gives an outstanding property, its low apparent porosity and high bulk density were similar to LCC-AM and LCC-AS.

Tab. 3: Physical properties of the specimen compositions.

| Designed composition | LCC-AM | LCC-AS | NCG-AM | LCG-AM |
|---|---|---|---|---|
| After dried: | Physical Properties | | | |
| Bulk density(g/cm³) | 3.12 | 3.01 | 3.00 | 2.79 |
| Open porosity (%) | 10 | 18 | 18 | 20 |
| CCS(MPa) | 51 | 30 | 29 | 36 |
| MOR(MPa) | 12 | 4 | 5 | 8 |
| After-firing at 1200℃: | | | | |
| Bulk density(g/cm³) | 3.05 | 3.00 | 3.01 | 2.73 |
| Open porosity (%) | 17 | 19 | 18 | 27 |
| CCS(MPa) | 82 | 91 | 99 | 26 |
| MOR(MPa) | 17 | 21 | 22 | 5 |
| PLC (%) | 0.15 | -0.16 | -0.20 | -0.01 |
| After-firing at 1550℃: | | | | |

| Open porosity (%) | 23 | 20 | 21 | 31 |
| CCS(MPa) | 109 | 82 | 85 | 42 |
| MOR(MPa) | 30 | 24 | 26 | 13 |
| PLC (%) | 2.19 | 0.84 | 0.99 | 2.01 |

**Dynamic rotary slag corrosion test**

According to Fig. 2, the cross-section and thickness loss of the corroded samples are shown. The dotted line indicates the refractory-slag interface from the chamber to the feeding port. NCG-AM had by far the lowest thickness loss, at 7.7mm (85% residual thickness), and the dotted line is relatively straighter than the others.

Fig.2: Dynamic rotary slag test result
In contrast, LCG-AM and LCC-AM showed much worse corrosion resistance, with thickness losses of 17.24mm (66% residual thickness) and 15.44mm (70% residual thickness) respectively, and the curvature of the dotted line is larger, which indicates different corrosion mechanisms among these samples.

423

## Microstructure characterization
*Uncorroded microstructures*

In Fig. 3(a), the microstructure around the MgO particles of LCC-AM is shown. It consists of MgO particles, a porous spinel phase with an Al/Mg atomic ratio of 1.63:1, a spinel phase with an Al/Mg atomic ratio of 1.96:1 and a matrix phase. Based on the BEI figure, the MgO particles are trapped by a dark region, which is the porous spinel. The diffusion length of $Mg^{2+}$ from the particles is approximately 20μm.

In contrast, a clearly continuous structure was found in NCG-AM, as shown in Fig. 3(c), with $Mg^{2+}$ diffusing further from the MgO particles to the matrix, approximately 50μm. The spinel phase in NCG-AM, which had an Al/Mg atomic ratio of 2.18:1, appeared much brighter in the BEI image compared to LCC-AM, indicating a dense spinel phase.

Fig. 3(d) displays LCG-AM, which has a microstructure similar to NCG-AM but with a shorter $Mg^{2+}$ diffusion distance.

*Fig.3: SEM of uncorroded microstructures, (a)LCC-AM; (b)LCC-AS; (c)NCG-AM; (d)LCG-AM.*

*Corroded microstructures near slag line*

The microstructure of the refractory/slag interface after six rotary tests reveals different corrosion mechanisms among four compositions. These images focus on the reaction of MgO particle in the refractory and slag.

(1) LCC-AM: Fig. 4(a) shows that a MgO particle wrapped up by in-situ spinel was pulled out from the matrix and remained in a hole occupied by slag. The weak bonding between MgO particle and the matrix due to porous spinel was the cause of the evulsion of unreacted MgO particle.

(2) LCC-AS: Although the matrix with spinel grain and tabular alumina both have excellent corrosion resistance, there is relatively weak bonding between them, resulting in the slag penetrating along the interface.

(3) NCG-AM: The original MgO particle was dissolved into the matrix and formed a continuous reaction region that has strong bonding. It indicates that an alumina-rich spinel with an Al/Mg atomic ratio 2.65:1 was detected at the boundary, and higher levels of Si and Ca elements were found in the core compared to the boundary. This suggests that monticellite ($CaMgSiO_4$) may have formed.

(4) LCG-AM: Fig. 4(d) shows that corrosion was more severe in the matrix, and the MgO particle was taken away when the surrounding matrix was lost. The MgO particle was also wrapped up by in-situ spinel, but it was thinner than the others, leaving most of the unreacted particle in the slag.

*Fig.4: SEM of corroded microstructures, (a)LCC-AM; (b)LCC-AS; (c)NCG-AM; (d)LCG-AM.*

## Corrosion Mechanisms Model

By comparing the appearance of slag corrosion among different samples, it can be inferred that the bonding strength between MgO particles and the matrix can affect the material's resistance to slag. In the case of the superior performing NCG-AM, the thickest dense spinel layer (~50um) was formed in the non-corroded region, which bound the unreacted MgO particles to the matrix and reduced the possibility of MgO particles detaching from the matrix during slag corrosion. The thicker spinel layer could absorb more manganese and iron ions from the slag, resulting in higher slag viscosity and reducing slag penetration, as shown in Fig. 5(a). Therefore, a distinct interface was maintained between NCG-AM and the slag. This phenomenon provides more time for the unreacted MgO particles to undergo ion diffusion, resulting in the formation of thicker spinel layers, further enhancing the slag resistance performance of NCG-AM.

On the other hand, due to the formation of porous spinel and a thinner spinel layer, LCC-AM experienced more pronounced slag infiltration, causing the MgO particles to be washed away and leaving behind holes. This led to a higher degree of erosion in LCC-AM compared to NCG-AM, as shown in Fig. 5(b).

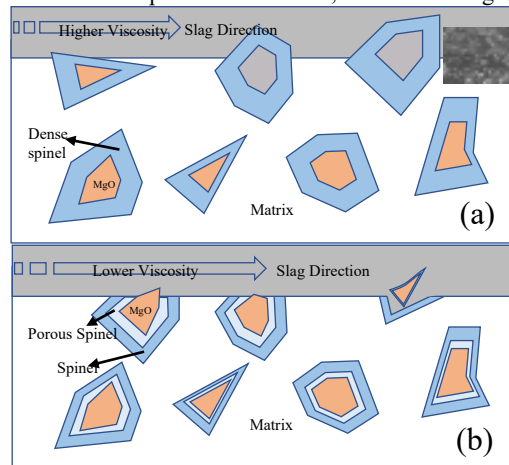

*Fig. 5: Corrosion mechanisms model of (a)NCG-AM; (b)LCC-AM*

## What is the main cause of the porous spinel in LCC-AM?

According to E.Y. Sako et al. [1], the faster mobility of $Mg^{2+}$ ions and their reaction with a higher thickness ratio seem to induce the Kirkendall effect during in-situ spinel formation, especially with MgO <45um. They finished the slag attack experiment using a cylindrical container after firing it at 1500°C for 5 hours, which relatively provided a homogeneous temperature field and sufficient time for ion diffusion to form in-situ spinel. Thus, they discovered remaining pores. On the other hand, a dynamic rotary slag corrosion test was carried out with dried specimens under quick heating, reaching 1450°C within 1 hour and kept around 1650~1700°C during the experiment. This may have made the ions diffuse rapidly, especially $Mg^{2+}$, thus resulting in a high-porosity spinel region around the MgO particles.

On the other hand, NCG-AM and LCG-AM, which had the addition of MC-G, do not exhibit such phenomenon. It is speculated that alumina with high specific surface area can provide a larger flux of $Al^{3+}$ in terms of kinetics, reducing the diffusion rate difference between $Mg^{2+}$ and $Al^{3+}$ ions to avoid the generation of high-porosity spinel region around MgO particles.

## CONCLUSIONS

NCG-AM had the superior performance with the thickest dense spinel layer (~50um) in the non-corroded region, which bound the unreacted MgO particles to the matrix and reduced the possibility of MgO particles detaching from the matrix during slag corrosion.

# MICROSTRUCTURAL EVOLUTION AND CORROSION BEHAVIOR OF REBOUNDED MAGNESIA–CHROMITE REFRACTORIES USED IN STEELMAKING RH FURNACES

M. Khanzadeh jouryabi[1,3], M. Bavand-vandchali[1,3], A. Kazemi-nafchi[1], S.M. Tabatabaie-hedeshi[2,3]

1.Department of Materials Engineering, Science and Research Branch, Islamic Azad University, Tehran, Iran.

3.Almas Alborz Refractory Co., Tehran, Iran.

## ABSTRACT

In the Ruhrstahl Heraeus (RH) furnaces during vacuum-degassing process, the amount of impurities such as solved gases and carbon decreased. The magnesia-chromite refractories used as lining of RH furnaces exposed to the severe thermo-mechanical and chemical stresses which can have a critical role in the final quality of molten steel[1-2].

In the present study, microstructure and corrosion behaviour of magnesia-chromite refractories used as working lining in the RH furnaces evaluated.
## Research materials and methods

chemical and phase analysis of the samples were taken from different reaction zone in the current research, a magnesia-chromite rebounded refractory produced by RHI Company used in the RH furnace of Mobarakeh Steel Company (MSCo.) has been considered.

## Chemical and phase analysis of refractory sample

The chemical analysis of the examined refractory from the RH furnace is given in Table 1.

*Tab. 1: Chemical analysis of refractory sample.*

| Oxide | MgO | $Cr_2O_3$ | $Al_2O_3$ | $Fe_2O_3$ | CaO | $SiO_2$ |
|-------|-----|-----------|-----------|-----------|-----|---------|
| % | 64 | 18 | 2.6 | 8.6 | 1.15 | 0.6 |

One of the important issues in the production of magnesia-chromite refractories is the low percentage of SiO2, which should be less than 1%. Regarding magnesia-chromite refractories that are used for furnaces such as the RH furnace of steelmaking. The high percentage of SiO2 above 1% due to the formation of calcium silicate phases causes the connection between periclase crystals in co-clinker aggregates, as well as the connection between coclinker particles and chromite particles to move towards quasi-silicate and silicate connections [3-5]. Due to the low melting temperature of these phases, this can cause a decrease in the thermomechanical properties of the refractory, such as hot bending strength, creep and finally increase the corrosion rate [6-7].

Fig. 1 shows the X-ray diffraction pattern of the rebounded magnesia-chromite refractory sample. Chemical analysis of this sample also showed that it contains 0.6% SiO2 (Table 1). Therefore, we cannot expect to detect a small amount of silicate phases in the XRD pattern. A closer examination of the peaks with high spinel intensity shows that the MgAl2O4 spinel ratio has some peak shift (2θ in the 100 MgAl2O4 peak is about 36.1° and in (Mg,Fe)(Cr,Al,Fe)2O4 spinel, 2θ is about 74/36°) which is due to

the dissolution of Fe, Al and Cr ions inside the normal spinel structure and the presence of complex spinel in the structure.

*Fig. 1: X-ray diffraction pattern of refractory sample.*

## Chemical and phase analysis of refractory sample

Fig. 2 shows the microstructure of the healthy refractory sample. As can be seen, the white chromite particles are placed between the large and small co-clinker particles and the interconnected background caused by the sintering of the fine magnesia co-clinker particles.

*Fig. 2: Microstructure of magnesia-chromite sample- M: MgO Coclinker; Ch I: primary chromite; Ch II: Secondary chromite.*

*Fig. 3: Map analysis of magnesia-chromite sample in Fig.2.*

Examining magnesia coclinker particles also shows that bright spots are formed in three separate areas. The EDS analysis performed on these areas shows that these areas have spinel complex compounds (Fe, Mg)(Fe, Al, Cr)2O4. SP2 and SP3 spinel

425

phases, in addition to being located in magnesia aggregates in the regions of grain boundaries and triple points, are also formed between magnesia and chromite particles and the boundary between them.

*Fig. 4: different types of spinel formed in microstructure. SP1: intragranular spinel, SP2: grain boundary spinel, SP3: triple zone spinel.*

The presence and accumulation of areas with a very bright and white contrast in the inner areas of the sample, as shown in Fig 6, indicates the penetration of molten steel into the refractory due to its low viscosity. The penetration of melt and slag into the refractories has been well done due to the presence of existing discontinuities in the refractories field, which leads to the filling of the pores, therefore, due to the penetration in the layer, the coefficient of thermal expansion will change compared to the healthy part of the refractories sample. In alternating thermal cycles and due to uneven expansion and contraction in this area, transverse cracks are created, which can be clearly seen in Fig 5.

*Fig. 5: Corroded refractory sample of RH degassing furnace.*

Fig 6 shows the microstructure of the reaction interface between the slag refractory and the steel melt.

*Fig. 6: Micrograph of refractory/slag interact area*

Fig 7 shows this reaction interface at a higher magnification. As can be seen, on the left side of the image, a particle of chromite (Ch) and next to it a coclinker aggregate is shown, which has reacted with melt and slag.

Fig 8 shows the reaction between coclinker magnesia and molten slag in two different magnifications. As a result of the reaction of the aggregate with the molten slag, a continuous magnesian phase

has formed in the aggregate, and as a result of the reaction of the molten slag and the spinel phases.

*Fig. 7: Co-clinker & chromite grains corrosion.*

*Fig. 8: Reaction products due to chromite grains corrosion.*

*Tab. 2: Oxidative analysis of different areas marked in Fig. 8*

| Element | Wt % | | |
|---|---|---|---|
| | A | B | C |
| MgO | 59 | 17.01 | 17.9 |
| $Al_2O_3$ | - | 5.7 | 24.1 |
| $Cr_2O_3$ | 1.4 | 7.8 | 36.3 |
| MnO | 1.5 | 2.2 | 1.9 |
| $Fe_2O_3$ | 38.1 | 65.5 | 19.8 |
| $SiO_2$ | - | 1.3 | - |

Chemical analysis was done and the results are presented in Table 2. Fig 9 shows the image of a chromite aggregate in the reaction zone with melt and slag. Elemental analysis with the help of EDS showed that inside the chromite particle there is an accumulation of small white dots along with small hollow holes. The points with bright contrast are metallic Fe particles and possibly the small uniform holes can be caused by the decomposition of a component in the chromite structure.

*Fig. 9: The formation of holes due to the evaporation of $Cr_2O_3$ and the formation of Fe metal particles due to the decomposition of FeO.*

According to the working conditions in RH furnaces, a very strong vacuum is created to remove impurities in the work process and causes the possibility of decomposition of FeO and Cr2O3 from inside the chromite aggregates. The decomposition of FeO and Cr2O3 depends on the temperature (T) and oxygen potential and the activity of FeOx and Cr2O3 in chromite spinel, so it can be concluded that the corrosion probability of chromite aggregate,

which actually has a (Mg, Fe)(Cr, Al, Fe)$_2$O$_4$ spinel structure, Generally, it is due to two reasons:

1)    The decomposition of FeOx or Cr2O3 inside the chromite aggregate at high temperatures.

2)    The penetration of melt and slag into the chromite aggregate and its dissolution. In general, the chemical decomposition of FeOx and Cr2O3 takes place through the following two reactions, which in the metallurgical conditions governing the refractory at the working temperature of the RH furnace are the thermodynamic conditions for the following reactions[2].

$$FeO\ (s) = Fe\ (l) + 1/2\ O_2\ (g) \qquad \Delta G = 287340 - 73/7\ T$$
$$Cr_2O_3\ (s) = 2Cr\ (s) + 3/2\ O_2\ (g) \qquad \Delta G = 1110000 - 247\ T$$
## CONCLUSIONS

1. The phase and microstructural studies of magnesia-chromite rebounding refractory showed that direct bonding prevails in this refractory and proper formation of spinel phases and very low amount of silicate phases are its prominent characteristics.

2. Due to the infiltration of slag and melt through the pores into the refractory structure, it leads to severe breakdown of the refractory during operation.

3. Corrosion of magnesia co-clinker aggregates due to the infiltration of molten iron into the structure of magnesia and complex spinel, lowering their melting temperature and dissolution, which takes place in the next step.

4. Corrosion of chromite aggregates occurs due to the decomposition of FeO and Cr$_2$O$_3$ in the structure and its weakening and chemical corrosion on its surface.

# IMPROVEMENT OF THERMO–MECHANICAL PROPERTIES OF DIRECT BONDED MAGNESIA CHROME REFRACTORIES FOR RH DEGASSER

S. Das*, A. Chakraborty, B. Ghosh, H. Nagata, S. Sengupta, P. B. Panda

TRL Krosaki Refractories Limited, India

## ABSTRACT

Due to increased demand for higher quality steel, RH degassing process gains importance in the secondary steel-making process for its higher productivity and low processing time. The performance of the refractories in the leg, bottom, snorkel, and lower vessel of the RH degasser is very crucial to reduce downtime and increase the degree of steel cleanliness. Direct bonded magnesia chrome brick is generally used in critical areas for a long time due to its excellent thermo-mechanical, and corrosion resistance properties. Refractories in these areas are facing high abrasion by liquid metal and hot gas, thermal shock, skull formation, attack of FeO and MnO-rich slag & oxidation-reduction reactions. In this paper, the effect of different additives in DBMC refractories with respect to thermo-mechanical properties has been studied. Different batches were made with fused magnesia chrome, chromite, and DBM and fired in different firing schedules. Physical and thermomechanical evaluations of different batches were done. Slag corrosion with different slag was also studied. SEM and XRD analysis was done to identify the formation of different phases and correlate with the use of different additive and firing schedules. A batch with novel spinel forming additive and fired at ultra-high temperature shows very good thermo-mechanical properties due to its high degree of direct bonding and fine pore size distribution.

428

## INTRODUCTION

Snorkel is the most critical part of the RH degasser, as it governed the downtime of the degasser. Direct bonded Magnesia chrome bricks are used in the snorkel lining. Circulation speed, lifting gas pressure, FeO%, and heat per day affect the performance of the DBMC bricks in the snorkel. The main degradation mechanism is FeO attack and spalling. So, refractories with very good hot strength are required for superior performance.

In this paper, the recipe for DBMC bricks is designed with varying percentages of spinel-forming additives and observed the effect in correlation with spalling and corrosion resistance. Developed bricks show very good strength at high temperatures and good corrosion resistance. Snorkels manufactured with newly designed bricks were sent to an integrated steel plant for performance evaluation.

## EXPERIMENTAL PROCEDURE

Different batches were made using Fused Magnesia Chrome (FMCR), Chromite Sand, Magnesia, and Spinel forming additives with varying percentages. All the batches are fired at high temperatures with prolonged cooling cycles. Batches are evaluated in terms of physical, mechanical, chemical, and thermal properties. A slag corrosion test was performed at 1650°C for 3 h in an induction furnace with RH degasser slag. SEM and XRD are also done to correlate the different properties.

## RESULTS AND DISCUSSION

All the batches show porosity of less than 16 and BD of more than 3.2 gm/cc. The lowest AP and highest BD are achieved through using of fused raw material and novel granulometry. The HMOR of all the compositions was measured using a three-point bending test at 1400°C and reported in Fig. 1. The composition C6 has shown the highest HMOR value compared to the others.

*Fig. 1: Hot Modulus of Rupture of all the composition measured at 1400 °C for 30 min.*

The MOE of all the compositions was measured by ultrasonic method, are reported in Fig. 2. Samples C5 has shown the highest MOE value whereas the C6 composition has shown the lowest MOE value. High MOE indicates the higher rigidity of the C5 refractory whereas low MOE indicates the high flexibility of the C6 material.

*Fig. 2: Modulus of elasticity of all the compositions.*

Fig. 3 represents the data obtained from the spalling test.

Composition C6 has shown the highest spalling resistance compared to the others. It is due to its low MOE value.

*Fig. 3: Thermal shock resistance tested at 950 °C.*

The slag corrosion test was performed at 1650 °C for 3h in an Induction furnace using RH slag. Fig. 4 represents the rate of slag corrosion of all the compositions. Composition C6 has shown the highest corrosion resistance. The microstructure of the C6 composition is examined after the slag corrosion test as represented in Fig. 5. All types of grains are distributed evenly. The compactness of the brick is good in unaffected areas.

*Fig. 4: Slag corrosion resistance tested at 1650 °C for 3h.*

MgO and Cr2O3 both dissolved in the slags. FeO% increase in the slag-refractory affected area to 18% from 9.2%. Repeated heating and cooling cycles also faster the rate of slag corrosion. The high degree of direct bonding due to a higher percentage of secondary spinel, reduces the rate of slag corrosion in C6. Slag corroded area shows a large no of pores.

Snorkel made with C6 formulation was sent to integrated steel plant shows improvement in performance. No initial cheap-off is found in this snorkel and life improved to 126 heats. Previously, it was 90-102 heat. Where initial cheap-off is the major phenomenon and sometimes, snorkel down prematurely due to this reason. Which is absent in this revised recipe. Fig. 6 shows the regular vs trial situation in this integrated steel plant.

*Fig. 5: Evaluation of Microstructure of sample from C6 batch.*

*Fig. 6: A few photographs of the field trial.*

## CONCLUSIONS

In the present work, attempts have been made to develop a novel refractory for the snorkel of RH degasser. The developed material possesses superior hot strength, high slag corrosion resistance, and good spalling resistance. A special spinel-forming additive was added to improve the spalling resistance. With a unique firing schedule, the degree of spinalization increases thus helping in developing the degree of direct bonding between periclase and primary chromite. This affects the actual performance in field trials.

# PERFORMANCE IMPROVEMENT OF STEEL LADLE MGO–C REFRACTORIES BY USING NOVEL CARBON ADDITIVES

S. Das*, A. Chakraborty, B. Ghosh, H. Nagata, S. Sengupta, P. B. Panda

TRL Krosaki Refractories Limited, India

## ABSTRACT

In the last few decades, the steel manufacturing industries have upgraded their technology to produce high-purity steel which is demanded by end customers in recent years. This has given severe challenges to the refractory industries for better performance without sudden failure. MgO-C refractory is generally used in the steel ladle as a major consumable refractory with respect to other steel-making furnaces. Different carbon-containing MgO-C refractories are used in different areas of the steel ladle as per process requirements. To increase the performance of the steel ladle refractory, different types of additives are used in MgO-C bricks to increase the oxidation & slag corrosion resistance. In this paper, the effect of a new novel carbon-bonded additive is studied with respect to slag corrosion and oxidation resistance. Different batches were made with varying carbon percentages and thermomechanical properties were evaluated. It is observed that the presence of novel carbon bonded additive alters the thermomechanical properties. SEM and XRD analysis was done to identify the different phases at high temperatures and correlated them with the different thermomechanical properties and slag corrosion resistance.

**Keywords:** MgO-C refractory, Low carbon refractories, Metal powder, antioxidants, Steel plant Refractory.

430

## INTRODUCTION

In Iron and Steel Industries, MgO-C (Magnesia Carbon) refractories are dominated because of the high thermal shock resistance, high slag corrosion resistance, excellent resistance to metal penetration, and good hot properties. Magnesia-carbon refractories typically contain between 8 to 20 weight percent of carbon. The primary reason for using graphite is to improve the thermal shock resistance of Magnesite-based refractories and to improve the slag corrosion resistance. However, low strength, oxidation, higher carbon peak up in steel, and heat loss limit its usage percentage. [1,2] Various metal powder and alloying elements are used as antioxidants to retard oxidation and improve strength at high temperatures. [3] The use of these antioxidants also imparts negative effects like high MOE etc. In the present work, attempts have been made to improve the slag corrosion resistance and oxidation resistance of MgO-C refractories by using a novel carbon-containing additive that fills the pore between the pores of graphite and the matrix and developed a stronger matrix that helps in increasing the slag corrosion resistance and also the thermal shock resistance by lowering the MOE.

In the present work, the properties of MgO-C refractories made with novel carbon additives are compared with the proven recipe of TRL Krosaki Refractories Ltd. Novel carbon additive is added through suspension in a liquid. The formulated composition has been characterized and found that the developed recipe shows better slag corrosion resistance compared to the existing composition.

## EXPERIMENTAL

Different batches were made using various grades of fused magnesia, graphite, antioxidants, additives, and binder (shown in Tab.1). All the materials were mixed thoroughly in an inclined mixer and pressed in a high-capacity electric screw press (650 MT) and tempered in a Tempering Kiln at a temperature of 200 °C.

Tab. 1: Batch Composition

| Components (%) | A1 | A2 | A3 | G1 | G2 | G3 |
|---|---|---|---|---|---|---|
| **Fused Magnesia** | * | * | * | * | * | * |
| **Graphite** | * | * | * | * | * | * |
| **Antioxidant** | * | * | * | * | * | * |
| **Novel Additive** | - | - | - | * | ** | *** |
| **Resin** | * | * | * | * | * | * |

After tempering, physical, chemical, and thermomechanical testing was performed on the bricks made of all the batches. XRD & SEM analysis was done to identify the phases present. A slag corrosion test was carried out using LRF slag at 1650°C for 3h in an Induction Furnace.

## RESULTS AND DISCUSSIONS

Among six numbers of batches, G3 shows the lowest AP, and A1 shows the highest BD. The lowest AP is achieved by filling the pores with microfine novel carbon additives. As the porosity is less, the lowest-coked AP and highest-coked BD are achieved by G3. AP and BD of different samples are shown in Fig, 1.

*Fig. 1: Hot Modulus of Rupture measured at 1400 °C for 30 min.*

*Fig. 2: Hot Modulus of Rupture measured at 1400 °C for 30 min.*

Fig. 2 shows the HMOR of all the samples, measured at 1400degC. The highest strength is shown by A2 due to spinel-forming antioxidants and less graphite percentage. G3 shows average strength at high temperatures. Composition G3 has shown the least oxidation. The presence of less porosity is the reason for the highest oxidation resistance.

*Fig. 3: Photographs showing the oxidation test samples.*

The slag corrosion test was performed with LRF slag (Al killed) at 1650 °C for 3 h in an Induction furnace. The corrosion rate of all six MgO-C refractories is shown in Fig. 4. All the MgO-C samples have shown significant resistance against the slag. Although sample G3 shows better slag corrosion resistance among all the samples. Fig. 5 shows the photograph of the corroded samples.

*Fig. 4: Slag corrosion rate of all the compositions in contact with LD slag at 1650 °C for 3 h.*

*Fig. 5: Photographs of the corroded samples after performing a slag corrosion test in the induction furnace.*

The microstructure of the novel carbon-added samples was seen using SEM. Fig. 6 shows the microstructure of sample G3. Corse fine and dust are uniformly distributed throughout the sample. Novel carbon additive and Graphite were evenly coated on the FM grains of the MgO-C samples. A dense matrix was seen in the samples. Due to less pore size, slag penetration is limited, and infiltration of the air is also less. So due to less oxygen partial pressure, oxidation of graphite is limited, and both this factor i.e. low pore and a higher percentage of residual carbon limits the slag corrosion. Also, the presence of a dense matrix with novel carbon additive shows low

MOE after cooking which explained the good spalling resistance also.

*Fig. 6: SEM microstructure of the MgO-C refractory of G3 composition.*

**CONCLUSIONS**

The developed recipe shows good corrosion and oxidation resistance due to low porosity. Also, the presence of highly conductive novel carbon additive, developed product shows good spalling resistance also. So due to the good spalling resistance and thermal shock resistance developed products can be used in the slag zone for betterment of service life.

# STUDY ON CHROME-FREE PURGING PLUG FOR STEEL LADLES

Sebastian Klaus, Andreas Buhr
Almatis GmbH, Frankfurt, Germany

Zhou Yunpeng, Tian Zhongkai, Wang Feng
Almatis Qingdao Ltd, Qingdao, China

Chatterjee Shankha
Almatis Alumina Pvt Ltd, Kolkata, India

## ABSTRACT

Purging plug refractories in China typically contain around 3% of super-fine chromium oxide in the matrix in order to improve the performance of the purging plugs, primarily, slag corrosion and wear resistance. Alternatives to chromium oxide containing refractories have gained interest due to health concerns related to the formation of soluble chromium compounds over long storage periods of refractory wastes. Super-ground reactive alumina can replace chromium oxide in purging plug refractories and this paper discusses the new reactive alumina E-SY 88 in comparison to chromium oxide in a typical purging plug castable. The results prove that E-SY 88 is an economically viable technical alternative to chromium oxide in purging plug refractories.

## 1 INTRODUCTION

Purging plugs in the steel ladle bottom are used for stirring the steel in the ladle during metallurgical treatment. Their use is essential for the process. Clogged purging plugs cannot perform their function and therefore the hot surface of the purging plug is examined after each heat to ensure the gas channels/slits are open. In the case of residual steel or slag being present on the surface, pure oxygen is blown through a lance onto the surface to melt and wash any residue. During that process an iron oxide slag is formed which attacks the refractories at temperature above 2000 °C [1-4].

Ultra-low cement bonded alumina-spinel-chromium oxide ($Cr_2O_3$) containing castables are dominantly used in purging plug for steel ladles in China due to performance demands, such as thermal stability, thermo-mechanical stability, thermal shock resistance, and erosion and corrosion resistance[5-7].

$Cr_2O_3$, reacting with other components in refractory castable forming solid solution with corundum or spinel, is used in various refractories applications such as for RH snorkel, as chromium ore grit in ladle filler sands in steel plants, coal gasifier furnace, sintering zone in cement kiln, etc. When chromium oxide containing refractory waste is deposited for long periods and exposed to e.g. alkalies, $Cr^{3+}$ can be transformed to water soluble and hazardous $Cr^{6+}$.

In Europe chromium oxide in purging plugs has been replaced after the introduction of alumina-rich spinel in most cases over the past 30 years due to health concerns and increasing problems to deal with chromium-containing refractory waste. In China the addition of around 3% $Cr_2O_3$ is still considered necessary for this application.

In this work, reactive alumina E-SY 88 is used as alternative to $Cr_2O_3$ in ultra-low cement bonded refractory castable and technical features like castable workability, strength development, bulk density, permanent linear change, hot modulus of rupture, thermal shock and slag corrosion resistance and creep behaviour are compared.

## 2 EXPERIMENTAL

### 2.1 Raw Materials

Tabular Alumina (T60/T64, Almatis), Spinel (AR 78, Almatis), reactive alumina with bi-modal particle size distribution (CL 370; Almatis), reactive alumina (E-SY 88; Almatis), Chrome oxide ultrafine (China source), alumina cement (CA-270; Almatis) and dispersing alumina (ADS 1 and ADW 1; Almatis) were used as the raw materials for the experiment.

Reactive alumina E-SY 88 is developed from Almatis Qingdao Co., Ltd for refractory castable applications. As reactive alumina and dispersing alumina became key products in the matrix, ongoing development took place with particular attention given to the ease of mixing, quick castable wet-out and straightforward on-site installation with easy workability at lowest castable dilatancy [8]. E-SY 88 was developed to fulfill the criteria for castable's robustness-in-use. Its non-dilatant rheology supports castable mixing and reduces the risk of excessive water addition to castables. Castable concepts based on E-SY alumina in the matrix have shown good thermal shock properties in other applications. Particle size distribution by CILAS laser granulometry and specific surface area by BET method of E-SY 88 and $Cr_2O_3$ used in the experiment are shown in **Table 1**.

**Table 1 Cilas PSD and specific surface area for $Cr_2O_3$ and E-SY 88**

| | Particle Size Distribution | | | BET/$m^2 \cdot g^{-1}$ |
|---|---|---|---|---|
| | D10/μm | D50/μm | D90/μm | |
| $Cr_2O_3$ | 0.20 | 1.10 | 2.82 | 2.2 |
| E-SY 88 | 0.23 | 1.57 | 12.59 | 3.9 |

### 2.2 Specimens preparation and testing

Dry castable mixes were prepared according to formulation given in **Table 2**. $Cr_2O_3$ 3% was included in first formulation (hereinafter named as Cr2O3), whereas 5% of E-SY 88 was added in chrome-free formulation (hereinafter named as ESY88). Meanwhile, 2% of T60/T64 -45micron was reduced in the ESY88 formulation to keep matrix weightage balance in both the formulations.

**Table 2 Experiment formulations**

| Raw materials | | Cr2O3 | ESY88 |
|---|---|---|---|
| T60/T64 aggregate | ≤ 6mm | 72 | 72 |
| T60/T64 fines | -45micron | 7 | 5 |
| Spinel AR78 | ≤ 0.5mm | 10 | 10 |
| Reactive alumina | CL 370 | 6 | 6 |
| | E-SY 88 | - | 5 |
| $Cr_2O_3$ | | 3 | - |
| Cement | CA-270 | 2 | 2 |
| Dispersing alumina | ADS1+ADW1 | 1 | 1 |

Another group of castable bar specimens with size 25mm×25mm×125mm were cast, cured and dried with the same procedure above, then pre-fired at 1500°C for 3 hours, and tested at 1500°C with dwelling time of 0.5 hour for hot modulus of rupture (HMoR).

Thermal shock resistance (TSR) was determined by water quenching method for specimens pre-fired at 1000°C for 3 hours and 1600°C for 3 hours respectively. The slag corrosion resistance was

evaluated by static crucible method filled with synthetic slag listed in **Table 3**.

**Table 3 Composition of synthetic stainless-steel slag**

| Items | CaO | SiO₂ | MgO | MnO | CaF₂ | Total | CaO/SiO₂ |
|---|---|---|---|---|---|---|---|
| WT/% | 53 | 28 | 7 | 2 | 10 | 100 | 2.1 |

Creep under compression was tested for 1600°C pre-fired specimens.

## 3 RESULTS AND DISCUSSION
### 3.1 Castable Workability
**Figure 1** shows the flow value at 10min,30min and 60min from the time of water addition in castables with Cr2O3 and ESY88 respectively. **Figure 2** shows the exothermal curve and **Table 4** shows the exothermal data.

Wet out time is the time it takes in mixing after water addition until a castable becomes homogeneously wet in appearance. Typical sequences during mixing process are: dust and fine fraction disappear, coarse fraction becomes visible, noise of mixing is reduced, dry pellets of about 8mm diameter are formed, and finally pellets form clusters or lumps and get a shiny surface. Shorter wet out times are preferred as they increase the confidence of the operator in the mixing process and prevent adding more respectively too much water to the mix.

The wet out time was 90 seconds for castable ESY88, a bit shorter than castable Cr2O3 whose wet-out time was 120 seconds. Both castables behaved good flow values around 170mm and very little flow decay up to one hour. The water addition was 3.6% for castable ESY88, 0.2% less compared to castable Cr2O3 to achieve comparable flow values. And during the experiment, it was observed that wet mix with E-SY 88 is very soft, while wet mix with Cr₂O₃ is much stiffer, thus increasing the risk of remaining air bubbles in the form during vibration. This clearly indicated that castable workability with E-SY 88 has significantly improved even water addition is reduced by 0.2%.

**Fig.1 Flow property of castables**

The time of exothermal curve reaching the peak was 358 minutes for castable ESY88; and 566 minutes for castable Cr2O3. For high temperature pre-fired purging plugs, the pieces need to be demoulded after curing for drying and firing. Therefore, shorter setting times are preferable for more frequent use of the moulds and higher productivity in manufacturing.

**Fig.2 Exothermal curve of castables**

**Table 4 Exothermal data of castables**

| | Cr2O3 | | ESY88 | |
|---|---|---|---|---|
| | Time/min | Temp./°C | Time/min | Temp./°C |
| Start1 | 236 | 21.1 | 164 | 21.3 |
| Start2 | 482 | 21.4 | 284 | 21.4 |
| Max | 566 | 21.9 | 358 | 21.9 |

### 3.2 Apparent Porosity and Bulk Density
**Figure 3** shows apparent porosity and bulk density for castable after treated at 110°C for 24 hours, 1000°C for three hours and 1600°C for three hours, respectively. After drying at 110°C, castable ESY88 showed apparent porosity of 8.1%; whereas it was 11.5% for castable Cr2O3. The dried bulk density was 3.29g/cm³ for castable ESY88 and 3.26g/cm³ for castable Cr2O3. The broad particle size distribution of E-SY 88 supported by its submicron distribution better fitted for optimized overall particle packing from the matrix and helped for effectively filling the pores formed by coarser particles. Accordingly, 0.2% lower water demand contributed to better castable densification and decreased apparent porosity for castable ESY88. After firing at 1000°C, apparent porosity of castable ESY88 was slightly lower than that of castable Cr2O3 – 12.2% against 13.5%; whereas bulk densities were comparable between the two castable. After firing at 1600°C, apparent porosity of castable ESY88 remained lower at 14.0% when compared to 14.7% for castable Cr2O3, whereas bulk densities remained comparable between the two castables.

**(a) Apparent porosity**

**(b) Bulk density**
**Fig. 3 Apparent porosity and Bulk density**

### 3.3 Permanent Linear Change

**Figure 4** gives permanent linear change of castables at different temperatures. After drying at 110°C, there was comparable minor shrinkage in both the castables. After firing at higher temperatures up to 1600°C, both castables showed comparable shrinkage due to sintering.

**Fig.4 Permanent linear change**

### 3.4 Strength Evolution

**Figure 5** shows cold modulus of rupture and cold crushing strength for castables after treated at 110°C, 1000°C, and 1600°C. **Figure 6** gives the hot modulus of rupture for castables at 1500°C.

Strengths after curing at 20°C and drying at 110°C were both slightly higher for castable ESY88. This is because of better particle packing arising from optimized particle size distribution in the matrix. Lower water addition contributed to better densification for castable ESY88 and also result in slightly higher castable strength.

After firing at 1000°C, CMoR and CCS of castable Cr2O3 were higher than that of castable ESY88. This is because $Cr_2O_3$ initiated solid solution reaction with corundum, which was also reflected from the faded green colour at the body inside and on the surface of castable specimens. Although strengths after firing at 1000°C from castable ESY88 were lower, they are considered sufficient for practical application as would apply for just tempered purging plugs (at 350 - 450°C) common in Europe. In China, where purging plugs are pre-fired at 1500-1650°C during production, the strength at 1000°C is not important anyways.

After firing at 1600°C, both castables were fully sintered for very high strength development with CMoR above 40MPa and CCS above 300MPa.

**(a) Cold Modulus of Rupture**

**(b) Cold Crushing Strength**
**Fig. 5 Cold strength development**

**Fig.6 Hot Modulus of Rupture**

**Figure 6** gives hot modulus of rupture for castable at 1500°C with dwelling time of 30 minutes, whose specimens were pre-fired at 1500°C for three hours. Result showed both castables had comparable HMoR of 25MPa, suitable for high erosion resistance during application in the steel ladle.

Pre-firing at high temperatures with strong sintering of the material is advantageous for the strength. However, the material is also becoming more brittle and sensitive against thermal shock, which is discussed in the following chapter.

### 3.5 Thermal Shock Resistant Property

**Figure 7** shows residual strength after one, three, and five cycles of quenching as described above. Both, absolute values and residual strength as percentage of starting strength are given.

Residual strength is higher when samples were pre-fired at 1000°C when compared to 1600°C. At both pre-firing temperatures, the residual strength is clearly higher for ESY88 than for Cr2O3. This indicates a higher resistance against thermal spalling of purging plugs based on ESY88 when compared to Cr2O3. And that can be considered a clear advantage of ESY88 vs. Cr2O3 especially for the high temperature pre-fired purging plugs in China.

**(a) TSR for specimens pre-fired at 1000°C**

**(b) TSR for specimens pre-fired at 1600°C**
**Fig. 7 Residual strengths after thermal shock**

### 3.6 Slag Resistance

**Figure 8** shows slag resistance test crucibles for both castables with synthetic stainless-steel slag at 1600°C with dwelling time of five hours. Erosion percentage from crucible ESY88 is 8.5%, slightly lower than crucible Cr2O3 which is 9.0%. Overall slag corrosion resistant performance was slightly better for castable ESY88 than castable Cr2O3. But, having done only the static slag corrosion test,

434

it can be indicated as comparable between the two castables for actual dynamic conditions for purging plug application.

Overall, erosion pattern as visually observed, was comparable between the two castables. More severe erosion occurred on crucible body at the interface area between slag and air for both castables. There is no clear boundary between penetrated layer and slag, but clear boundary between penetrated layer and original layer is observed. Almost similar erosion among bigger grains and matrix part can be seen for both castables, especially at the bottom area.

| Cr2O3 | ESY88 |
**Fig.8 Crucible slag test**

### 3.7 Creep Resistance

**Figure 9** shows creep under compressive curve of specimens under the load of 0.2MPa at 1550°C with dwelling time of 50 hours. **Table 5** shows the average creep rate from 25 to 50 hours at the later stage of the test. Result proves a higher creep resistance for castable ESY88. The average creep rate per hour was 0.0019%, almost half compared to castable Cr2O3 which was 0.0032% from 25-50 hours.

**Fig.9 Compressive creep resistance**

**Table 5 Creep rate at 25~50 hours**

|  | Cr2O3 | ESY88 |
|---|---|---|
| Creep rate 25~50H (%/H) | 0.0032 | 0.0019 |

### 4 CONCLUSIONS

Reactive alumina E-SY 88 replacing $Cr_2O_3$ in ULC based castable for purging plug application provided encouraging results.

- Castable workability has improved by replacing Cr2O3 with E-SY 88 alumina. Less water addition is required to achieve comparable flow value, while wet mix is much softer, which reduces the risk of air bubbles and inhomogeneity in the matrix. The shorter setting time with E-SY 88 is advantageous for higher productivity in manufacturing.
- Strength development meets purging plug application requirement. Cured and dried strength developments of E-SY 88 containing castable are comparable to $Cr_2O_3$ contained castable, so is high temperature fired strength.
- Permanent linear change is comparable for both types of castables.
- Usage of E-SY 88 alumina, replacing Cr2O3 has improved thermal shock resistance both for 1000°C and 1600°C pre-fired castables. This is beneficial for both high temperature fired and tempered purging plug.
- Slag corrosion resistance of E-SY 88 containing castable is comparable to $Cr_2O_3$ contained castable.
- Creep resistance has also improved by usage of E-SY 88 alumina replacing $Cr_2O_3$.

Overall, using E-SY 88 alumina to replace $Cr_2O_3$ in purging plug could improve purging plug performance and would eliminate the hazards related to chromium oxide usage. Besides this, the cost of reactive alumina E-SY 88 is lower than fine synthetic chromium oxide, and thus E-SY 88 is an economically viable technical alternative to chromium oxide in purging plug application.

SHORT COMMUNICATIONS
# IMPROVEMENT OF GAS HOLDER SYSTEM

Takafumi Imaeda, Kimihiro Yasui, Takafumi Kaminishi,
Tomomi Soeda
TYK Corporation., Tajimi City, Japan

## ABSTRACT
Approximately 20 years ago, our company developed a gas holder system (hereinafter referred to as GHS) for securing serviceability of purging plugs used for stirring molten steel with inert gas in teeming ladle. In the business activities to supply GHS to many customers, varieties of improvements or modification works have been made on GHS. In recent circumstances in which achievement of SDGs and/or establishment of carbon-neutral society is called for, it is thought that improvement of purging plug's service life would contribute to the global environment. Improvement or modification works which have been made on GHS are reviewed in this report.

## Outline of GHS
GHS was developed for securing serviceability of purging plugs. That is, even when inert gas for molten steel stirring is not supplied from the main gas supply source to a purging plug, inert gas supply to the purging plug is continued from a gas storage tank in GHS so as to suppress molten steel penetration into the plug and to minimize purging plug damages caused by oxygen gas cleaning required for removing adhering steel. As schematically illustrated in Fig. 1, GHS is configured with a gas storage tank and a control unit. During secondary refining treatment in teeming ladle, inert gas provided from the main gas supply source is used for molten steel stirring through purging gas and is stored into the gas storage tank simultaneously. When inert gas supply from the main gas supply source is shut off during transportation or standby of teeming ladle, inert gas is automatically supplied to the purging plug from the gas storage tank for suppressing molten steel penetration into the purging plug.

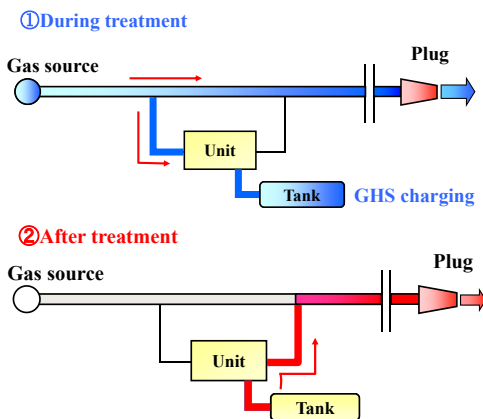

*Fig. 1: Concept of GHS*

## Problem of GHS
Various problems have been turned up in GHS operation. Typical examples are incidental change of needle valve opening by mechanical vibration during teeming ladle transportation, or damages to several components of needle valve by thermal load. When this situation occurs, it is impossible for the GHS to perform, so we decided to start improving it.

## Improvements of GHS
Fig. 2 shows a GHS unit of an old design that includes a needle valve.

This needle valve was damaged by vibration and thermal load, GHS often did not work well.
So we replaced the needle valve with a small pore tube joint, as shown in Fig. 3, to control unintended changes in needle valve opening and minimize thermal damage to the component.

*Fig. 2:Old Design of GHS*

*Fig. 3:New Design of GHS*

## Result of dispensing test
We conducted having tests at room temperature and at 450°C to confirm the effect of the new design, which changed from a needle valve to a small pore tube.
As shown in the graphs in Fig. 4 and 5, the old designs with needle valves show a decrease in initial discharge flow rate at 450°C.
This is thought to be because the needle valve has been damaged by heat and is not functioning properly.
As shown in the graphs in Fig. 6 and 7, no change in the initial discharge flow rate was observed in the new design using the small pore tube joint, even at 450°C.
This is thought to be due to the fact that the change to a small pore tube suppressed thermal damage.
*Fig. 4: Pressure and flow rate curve of old design at R.T.*

*Fig. 5: Pressure and flow rate curve of old design at 450℃*

*Fig. 6: Pressure and flow rate curve of new design atR.T.*

*Fig. 7: Pressure and flow rate curve of new design at 450℃*

## CONCLUSIONS

This improvement by changing from needle valves to small pore tube joint will greatly improve the serviceability of the GHS against vibration and high temperatures, and will enable the GHS to be used in a more stable condition.

In the future, we will continue to confirm the results of use under various conditions and consider further improvements to the GHS.

## ABSTRACT

There is a need for adjustments across the entire steel industry due to competitive pressures such as global demand, high energy costs, environmental and safety laws, competing materials, consumer demand for high quality, and the high cost of capital. Therefore, it is important to reduce refractory material consumption. There are numerous studies regarding improving refractory materials' performance in this concept. In recent years, the limits of raw material quality have been pushed. The research to be done here is carried out in a very limited scope. Therefore, the studies on MgO-C-based bricks are generally based on additives rather than the raw material quality. In this context, KUMAS is working on additives in its MgO-C-based bricks. With the studies, it has been able to prevent the infiltrations that will occur by achieving to delay the oxidation of the MgO-C-based bricks under the working conditions, and the customers have observed increases in the brick performances. This work aims to present the properties of these newly designed MgO-C-based bricks compared to the KUMAS commercial product range with customer trials.

## INTRODUCTION

The steel industry is confronted with a variety of factors that necessitate adjustments to enhance competitiveness and operational efficiency. Among these factors are global demand fluctuations, escalating energy costs, stringent environmental and safety laws, increasing competition from alternative materials, consumer expectations for high-quality products, and the high cost of capital. In this context, reducing refractory material consumption has emerged as a critical area for improvement [1, 2]. Refractory materials play a crucial role in the steel industry, providing essential lining solutions for furnaces, ladles, and other high-temperature applications. Therefore, efforts to enhance the performance and durability of refractory materials can significantly impact overall operational efficiency and cost-effectiveness. To achieve this, previous research has mainly focused on exploring additives for MgO-C-based bricks, while the importance of improving the raw material quality has received limited attention [3, 4].

To address this research gap, KUMAS R&D Center has conducted studies on additives for MgO-C-based bricks, aiming to prolong their resistance to oxidation under operational conditions. By successfully delaying oxidation, KUMAS anticipates a reduction in unwanted infiltrations and improvements in brick performance. This paper presents the properties of the newly designed MgO-C-based bricks, comparing them with KUMAS' existing commercial product range, through customer trials.

## MATERIALS AND METHODS

The experimental investigation involved the preparation of newly designed MgO-C-based bricks using KUMAS' proprietary additives. The composition of the additives, along with the specific additives used, was optimized based on extensive laboratory testing and analysis. The production process adhered to industry standards and employed state-of-the-art equipment to ensure consistent brick quality. Customer trials were conducted in collaboration with steel manufacturers across different operational environments. The trial setups involved the installation of both the newly designed MgO-C-based bricks and the KUMAS commercial product range in relevant furnace and ladle applications. Operational parameters, such as temperature, duration, and working conditions, were carefully monitored throughout the trials. Key performance indicators, including refractory wear, oxidation resistance, thermal shock resistance, and mechanical strength, were measured and compared.

## RESULTS AND DISCUSSION

The results obtained from the customer trials demonstrated notable improvements in the properties of the newly designed MgO-C-based bricks compared to the KUMAS commercial product range. These improvements were observed across multiple performance indicators, validating the efficacy of the developed additives. The presence of residue carbon after coking plays a crucial role in the performance and properties of MgO-C-based bricks. In this study, residue carbon acts as a protective barrier against oxidation. When the bricks are exposed to high temperatures and oxidizing atmospheres, the residue carbon reacts preferentially with oxygen, forming a protective layer that shields the underlying matrix from direct oxidation. This delayed oxidation helps maintain the structural integrity and performance of the bricks over extended periods, reducing infiltrations and preventing premature failure. Also, the presence of residue carbon significantly improves the thermal shock resistance of MgO-C-based bricks. The carbonaceous material possesses a high coefficient of thermal expansion, which effectively absorbs and dissipates thermal stresses generated during rapid temperature changes. This characteristic allows the bricks to withstand thermal cycling conditions without experiencing cracks or structural damage, ensuring their durability and longevity. Overall, the additives provide enhanced resistance to oxidation, superior thermal shock resistance, and improved mechanical strength. These properties ensure the bricks can withstand harsh operating conditions, maintain their structural integrity, and deliver long-lasting performance.

The positive outcomes observed during customer trials highlight the potential of the newly designed MgO-C-based bricks to contribute to refractory material consumption reduction in the steel industry. By prolonging the service life of refractory linings, steel manufacturers can achieve cost savings and improve operational efficiency while maintaining high-quality standards.

## CONCLUSION

In conclusion, this study focused on the development of additives for MgO-C-based bricks to enhance their performance and reduce refractory material consumption in the steel industry. The customer trials conducted in collaboration with steel manufacturers revealed significant improvements in the properties of the newly designed bricks compared to the KUMAS commercial product range. The achieved delay in oxidation, attributed to the developed additives, resulted in reduced infiltrations and increased resistance to wear. Additionally, the newly designed bricks demonstrated superior thermal shock resistance and improved mechanical strength, indicating enhanced durability and longevity. These findings emphasize the potential of the newly designed MgO-C-based bricks as a viable solution for steel manufacturers seeking to optimize refractory material usage and improve operational efficiency. Further research and development in this area hold promise for advancing the field of refractory engineering and addressing the competitive challenges faced by the steel industry.

# MECHANICAL AND CHEMICAL BEHAVIOR OF MGO–C BRICKS UNDER NEAR–SERVICE CONDITIONS

Delia Gutiérrez-Campos[1]; Pablo Galliano[2]; M.N. Moliné[3]; S.E. Gass[3]; A.G. Tomba Martínez[3]

[1]Universidad Simón Bolívar, Caracas, Venezuela; [2]Tenaris Siderca, Campana, Venezuela; [3]INTEMA, Argentina

In spite of the long use of MgO-C bricks in the steelmaking industry, there are still issues, regarding the influence of compositional variables on the behavior of this kind of refractories, that have to be better understood. For instance, the effect of graphite content or the addition of antioxidants has been extensively studied and well established; but less is known about the interactions between those components. With the aim of contributing to clearing up these relationships, different non-commercial MgO-C materials were tested under near-service conditions. The bricks were formulated with 83-85 wt% of magnesia (fused/sinter: 70/30), with various contents of graphite (8 and 12 wt.%) and types of binder (phenolic resin or soft binder). The addition of 2 wt.% of a metallic additive was also considered as a variable. A comprehensive characterization of bricks was performed by using several techniques (XRD, XRF, ICP-OES, DTA/TGA, density, porosity and permeability measurements, mercury intrusion porosimetry, and SEM/EDS). Compressive tests between RT and 1400°C (Ar atmosphere) were performed to study the mechanical behavior. The chemical response of bricks to the attack of a typical steelmaking ladle slag at 1600°C was determined by static and dynamic tests (cup and dipping tests), and the oxidation resistance was evaluated by thermal treatments at 1000°C using gaseous atmospheres with different oxygen contents.

# THE CHOICE OF MAGNESIA–CARBON REFRACTORIES FOR STEEL LADLE LINING: A LIFE CYCLE PERSPECTIVE

Md Jubayed[1]; Rinus Siebring[2]; Angélique Léonard[1]

[1]PEPs, Laboratory of Chemical Engineering, Department of Applied Chemistry, University of Liège, Building B6a, Sart-Tilman, Liège, Belgium; [2]Ceramics Research Centre, Tata Steel, IJmuiden, Netherlands

Steet ladle is the single most consumer of refractories in the steel industry. Various magnesia-carbon refractory bricks are widely utilized for the slag line part of a steel ladle. Unfortunately, in literature, very few life cycle assessment (LCA) studies are found regarding magnesia-carbon refractories, most of which were focused on manufacturing while ignoring the use phase. Since the properties of refractories (such as density and thermal conductivity) have a significant effect on steel production volume and energy efficiency of steel ladle processes, it is essential to include the use phase when the choice of refractories is subject to question.

Therefore, this study aims to evaluate the environmental impacts of various magnesia-carbon refractories considering their use phase. Cradle-to-grave attributional LCA will be implemented to quantify the environmental impacts of refractories, maintaining a consistent system boundary. Data will be collected from industrial partners involved in the consortium of the CESAREF research project. Uncertainty will be investigated through Monte Carlo simulations and scenario analysis. The results of the study will help to choose magnesia-carbon refractories for steel ladle lining based on their environmental performance.

# FORMATION OF ISOLATION LAYER BETWEEN THE REFRACTORY LINING AND MOLTEN STEEL/SLAG: INDUSTRIAL TRIALS IN REFINING LADLE

Junfeng Chen[1]; Shaowei Zhang[2]; Nan Li

[1]Wuhan University of Science and Technology, The State Key Laboratory of Refractories and Metallurgy, Wuhan, China; [2]University of Exeter, College of Engineering, Mathematics and Physical Sciences, Exeter, United Kingdom; [3]Wuhan, China

Direct dissolution and corrosion during refractory service should be avoided because it leads to metal contamination and a lower service cycle. Forming a liquid phase isolation layer or high viscosity phase on a refractory surface against steel/slag's attack always be desired which has been observed and discussed in many cases. In this work, the corroded microstructures of two types used refractory lining in industrial ladles, including MgO/$Al_2O_3$-C brick and $Al_2O_3$-MgAl2O4 castable both for metal bath areas, were investigated. The formation of different liquid-phase/high-viscosity isolation layers was discussed based on chemical composition design and erosion process control. Furthermore, based on the microstructural characterizations, the interactions/reactions between the refractory lining and the molten steel/slag (rather than a single slag or steel) should also be considered to have a better understanding of the overall degradation mechanism of refractory lining served in an industrial trial

# EFFECT OF TUNDISH PLATE REFRACTORY EROSION ON STEEL QUALITY AND DEVELOPMENT OF EROSION MEASUREMENT SYSTEM

Janghoon Kim[1], Yonggu Lee[2]
POSCO Technical Research Lab.[1]
POSCO Gwangyang Refractory Group[2]

## ABSTRACT

In the recent years, to respond ever-growing demands in high quality steels, steel cleanliness during continuous casting process is one of main areas of focus in steelmaking. The presence of inclusions adversely affects the cleanliness of molten steel. Because these are considered to be detrimental to the mechanical properties of steel. Types of non-metallic inclusions include indigenous inclusions generated by reoxidation in molten steel and extrinsic inclusions introduced from the outside of molten steel. It is known that extrinsic inclusions are easy to remove by buoyancy because they have a large size.

In the present study, a method for measuring the amount of erosion to tundish plate refractories and its impact on the cleanliness of molten steel were investigated.

## Measuring the erosion of tundish plate

The plate refractory was scanned using a line laser and the distance was measured as shown Figure1.

*Fig. 1: Schematic of Plate Erosion Measurement Device.*

The volume of the erosion part was measured by setting the zero point based on the non-contact area of molten steel, measuring the distance against the zero point, and then performing integration as shown Figure 2.

*Fig. 2: Schematic diagram of erosion volume measurement.*

To confirm the accuracy of the developed plate erosion measurement device, an experiment was conducted. A new plate was prepared and its weight was measured. Then, the plate was artificially damaged and weighed again to determine the damaged weight. The results from comparing the measured/calculated damaged weight obtained through the developed device with the actual damaged weight are presented in Table 1. The error between the actual and calculated damage values was found to be at the level of 0.4-1.4%.

Tab. 1: Caption for table 1.

| Number of experiments | Weight of damage(g) | | Mating rate (%) |
|---|---|---|---|
| | actual | Device measurement | |
| 1 | 1.3 | 1.28 | 98.54 |
| 2 | 2.7 | 2.69 | 99.59 |
| 3 | 3.6 | 3.58 | 99.50 |

As shown in Figure 3, 2D and 3D images of the scanned data are displayed on the monitor, and the calculated total erosion amount is presented together with the weight of the corrosive substance multiplied by the specific gravity, providing information on the weight of the damage.

*Fig. 3: Display of Measurement Results*

## A discussion on the measurement results of damages to plate

The used tundish middle plate was analyzed using the developed device. According to Figure 4, the upper surface of middle plate commonly experiences severe damages due to the significant force generated by steel pouring.

*Fig. 4: Measurement results of erosion on a used middle plate*

However, as shown in Figure 5, occasional cases have been observed where the lower side of the middle plate undergoes significant damage, and traces of air intrusion, along with big cracks, are found on the surface of the plates. It is suspected that gaps between the plates caused the intrusion of external air, which is believed to be the main cause of the damage to the lower side of the middle plate.

*Fig. 5: Example of lower side erosion on lower side of middle plate*

443

As illustrated in Figure 6, it can be observed that the lower carbon content in the steel results in higher damage on the middle plate. It is considered that this is caused by the decarburization of the refractory material due to the dissolution of C into the molten steel.

*Fig. 6: Middle plate erosion according to the level of carbon content in molten steel.*

**Molten steel cleanliness according to plate erosion**

Figure 7 demonstrates a clear connection between the amount of erosion in the plate refractory and the growing incidence of slab defects. It was evaluated based on the amount of plate refractory erosion measured by the above method. When the total erosion to the middle plate was categorized into three tiers: over 10g, 3-5g, and less than 3g, it was observed that cases with a erosion exceeding 10g exhibited a significantly higher occurrence of slab defects. As a result of these findings, it can be inferred that the erosion to the plate refractory can have a direct impact on the quality of the slab.
*Fig. 7: Relationship between TD plate erosion and slab defect.*

**CONCLUSIONS**

A device was designed to measure the extent of damage to the plate refractory and it was confirmed that the measurement accuracy is above 99%, indicating a reliable performance of the device. Damage to the middle plate refractory typically occurs more on the upper side. However, there are cases where the damage is more significant on the lower side, specifically in plates that exhibit traces of air inflow between the plates or have a big crack. After observing greater plate damage in the casting of alloys with lower carbon content, it has been confirmed that decarburization of the plate may also have a major impact on plate damage. And It was confirmed that as the erosion to the middle plate increases, the quality of the slab deteriorates.

From this result, it can be seen that the extrinsic inclusions originating from the tundish plate are difficult to remove from the mold. This means that inclusions introduced from the top of the mold do not have enough opportunities to separate and float, and it can be seen that the development of technology that can minimize damage to plate refractories can help improve steel quality.

# MINERALOGICAL FEATURES OF TUNDISH MGO–SPRAY AND THEIR INFLUENCE ON THE REOXIDATION OF AL–KILLED STEEL

C. Milot, C. Ganser, L. Loison, R. Belissont, J. Jactard,
ArcelorMittal Maizières Research, Maizières-les-Metz, France

## ABSTRACT

The tundish is the last vessel in contact with liquid steel before solidification into semi-finished products. The working lining of this container is usually a 30 mm thick layer of sprayed material which must achieve sufficient workability and dryability with simultaneously high insulative properties and low mechanical strength to allow deskulling. Its role is crucial in the steel quality since reoxidation inclusions generated in the tundish are hard to remove before steel solidification. With price increase of Chinese sintered Magnesia, steel plants tend to use lower MgO-content sprays to lower the cost, containing either lower quality of Magnesia, or higher Olivine content. After characterizing the mineralogy of different material formulations, the high temperature reactions were addressed thanks to XRD and quantitative Rietveld analysis. To assess the influence of the mineralogy and of the microstructural features, a lab test in contact with liquid steel was carried out Inclusion analysis was performed to reveal the reoxidation of killing aluminum and its dependance on lining material quality.

## INTRODUCTION

At the continuous caster for flat production, the tundish working lining can experience up to 3000t of steel during one casting sequence. Depending on sequence length, the sprayed refractory is in contact with liquid steel for duration from 4h up to 24h right before solidification in the mold. Added to the high contact surface with liquid steel, the refractory material exhibits a real risk of contamination of the steel. This refractory material is a blend of Magnesia and Olivine used to provide the thermal insulation, be easily disposable after use and at competitive price. It must also guarantee a low reactivity with the liquid steel because late reoxidation inclusions generated in the tundish are hard to remove and strongly impacts the semi-finished product quality. However, the price increase of Chinese Magnesia raw materials forced the suppliers to lower the MgO content and find alternatives to remain competitive. The strategy adopted consists in replacing the sintered Magnesia by Olivine which is a natural raw material mainly composed of a solid solution of Fayalite and Forsterite with the formula $2(MgO, FeO)SiO_2$.

Reactions between disposable MgO material and steel have been examined and different mechanisms are described in the literature. Beside Hydrogen pick up or contamination with other elements (Si, B, …), the main risk for steel quality is the generation of slivers due to reoxidation of Aluminum used for killing. For tundish refractory lining, reoxidation occurs mainly by transferring oxygen from reducible oxides contained in raw materials ($Fe_2O_3$ and $SiO_2$) to Aluminum dissolved in the steel. The reduction reaction forms additional Alumina inclusions which are difficult to remove before solidification. As observed by Lehmann et al. oxygen comes mainly from Iron oxide contained in the refractory rather than Silica [1]. The same study also showed that quality of the drying and of the preheating is crucial for steel reoxidation, with more reoxidation when the lining is only dried at 180°C instead of being preheated at 1200°C. This operation should be controlled carefully to reduce not only risk of H-pickup but also oxygen transfer to the steel. After alteration in contact with steel, reduction of Olivine generates Fe metal exsolution. Those droplets of metal are dispersed throughout the Olivine grains [2]. Although iron oxide and chemically bonded water are the two main sources of oxygen, Lehman et al. showed that the reoxidation of steel is activated by the formation of an interfacial liquid silicate phase which releases oxygen and speeds up the reactions between the refractory and the steel constituents. This silicate phase can be found between periclase grains in the magnesia raw materials or at the edge of Olivine which is enriched in lime [1][3].

According to Kalantar et al. the melt formation in the refractory microstructure, in the case of reaction with tundish slag, could be avoided by addition of Olivine [4]. In Olivine, the refractory phase Forsterite protects the grain from the formation of low melting phase like Monticellite. When slag penetrates into pores of lining, low melting point phases develop around MgO grains and provide continuous dissolution of Periclase during steelmaking process. Despite introducing reducible oxides, replacing part of the Magnesia by Olivine could have a positive influence to decrease dissolution of Periclase.

The present study aims at determining the differences found in the mineralogy of tundish lining products and their effect on the reoxidation of killing Aluminum contained in the steel. Therefore, several products were characterized with X-Ray Diffraction analysis before and after thermal treatment at 1600°C to enlighten the differences of mineralogy. Those mineralogical features were linked with a lab reoxidation study performed in contact with Al-killed steel

## MATERIALS AND METHOD

### Materials selection

The materials selected for this study have different chemistries measured with X-Ray Fluorescence (XRF). The product A has a high MgO content of 74,4% while the other ones have MgO contents between 62,1% et 67,5%. The product A has also a high CaO (6,0%) and a high $Na_2O$ (0,5%) content.

Tab. 1: X-Ray Fluorescence analysis of the tundish lining samples

| Sample # | A | B | C | D |
|---|---|---|---|---|
| $Fe_2O_3$ (%) | 3,4 | 4,4 | 4,9 | 3,9 |
| $SiO_2$ (%) | 14,3 | 28,9 | 30,5 | 25,3 |
| CaO (%) | 6,0 | 0,9 | 0,9 | 1,9 |
| $Al_2O_3$ (%) | 1,1 | 0,6 | 1,0 | 0,8 |
| MgO (%) | 74,4 | 64,8 | 62,1 | 67,5 |
| $P_2O_5$ (%) | 0,3 | 0,3 | 0,2 | 0,2 |
| $K_2O$ (%) | 0,1 | 0,1 | 0,1 | 0,0 |
| $Na_2O$ (%) | 0,5 | 0,1 | 0,2 | 0,3 |
| LOI (%) | 3,59 | 1,52 | 3,92 | 4,41 |

The materials were fired at two temperatures in a resistive furnace:
- 450°C/12h on 500g of powder material placed in a stainless steel plate
- 1600°C/6h on 100g of formed material (mixed with water, cast in a mold, dried at 110°C and demolded)

### X-Ray Diffraction (XRD)

The mineralogical composition and the origin of raw materials is determined using powder X-ray diffraction (XRD). The samples are milled to a 63µm top size using tungsten carbide vibrating disc mill. X-ray diffractograms, or scans, are collected using a Bruker D2 Phaser equipped with a Co source (Co Kα 1.789 Å) and a Lynxeye 1D silicon strip detector in Bragg-Brentano geometry. Primary and secondary beam focusing is performed using 2.5° Sollers and a 1mm divergence slit. A 3mm anti-scattering screen and a Fe-filter is set in front of the detector to reduce Co Kβ emission. Scans are acquired on the 7-80° 2θ range, with increments of 0.02 2θ. A dwell time of 1.5s is used for initial

445

qualitative mineralogical evaluation of the samples, while 0.5s is proven sufficient for phase quantification. Phase identification is performed using Bruker's EVA software with the ICDD PDF-2 database, and quantitative phase analysis is obtained using Rietveld refinement in Bruker's TOPAS software.

**Reoxidation test and inclusions analysis**
The samples were put in contact with a liquid steel grade containing 0,85 wt.% of Al. The test consisted in covering the bottom of an $Al_2O_3$ crucible with the tundish spray after mixing 200g of dry material with 27% water. After drying at 600°C for 2h in a resistive furnace, the crucible is used for steel melting. A reference crucible without any MgO spray is used as baseline. The assembly was heated in an induction melting furnace. For the beginning of the manipulation, a mass of electrolytic iron (90-99.99% of pure iron) is placed in the crucible. Vacuum is pulled and Ar is flushed to ensure the neutral atmosphere. The inductor is started to complete the melting. Afterwards, an addition of 1g of carbon is performed for deoxidizing the bath. The steel sample is alloyed to the targeted composition. A quartz sampling rod is used to sample the steel and check the chemical composition thanks to gas fusion and analysis for O, S, N and C and with spark spectrometry for all other elements. A residence time of 2h is completed at 1600°C before stopping the inductor and cooling down. After the melting, the ingot is extracted from the crucible to sample the solidified steel. A central slice of 1cm thickness is cut, and three parallelepiped samples are retrieved from this slice, according to Fig.1.

*Fig. 1: Sampling for Scanning Electron Microscopy for inclusions analysis.*

The samples are then coated with Bakelite-type conductive resin and polished to be observed with SEM Tescan Mira 3. The inclusion analysis was performed automatically via Intelissem automatic analysis software developed by the company RGLee Group to quantify and characterize the inclusions. The raw data of inclusions analysis are post-processed by an internally developed software using machine learning After a correction of the data considering the steel matrix composition, a clustering is performed to yield groups with similar features. This software is used to identify and quantify the $Al_2O_3$ inclusions. The quantity of the $Al_2O_3$ inclusions is compared to the total number of inclusions detected on each sample.

**RESULTS**
**Mineralogy after thermal treatment at 450°C**
The mineralogical composition after firing at 450°C is depicted in Fig.2 . The major phases were:
- Periclase (MgO) from the Magnesia
- Forsterite ($2MgO \cdot SiO_2$) and Enstatite ($MgO \cdot SiO_2$) from the Olivine

For simplification, other minor phases of Olivine were grouped under the category "Serpentines", namely:
- Talc ($3MgO \cdot 4SiO_2 \cdot H_2O$)
- Clinochlore ($5(Mg,Fe)O \cdot 3SiO_2 \cdot Al_2O_3 \cdot 4H_2O$)
- Lizardite ($3MgO \cdot 2SiO_2 \cdot 2H_2O$)

The category "Others" contains impurities from Magnesia as Quartz ($SiO_2$), Cordierite ($2MgO \cdot 2Al_2O_3 \cdot 5SiO_2$), Merwinite ($3CaO \cdot MgO \cdot 2SiO_2$), and even Larnite ($2CaO \cdot SiO_2$) for product A.

*Fig. 2: Mineralogical composition quantified from XRD analysis thanks to Rietveld analysis after firing at 450°C/12h*

The XRD revealed that only forsteritic Olivine is used in the investigated samples. No Fayalite was detected, but EDX analysis with Scanning Electron Microscopy (SEM) showed $Fe_2O_3$ in the Olivine grains:

*Fig. 3: SEM micrograph of an Olivine grain with EDX analysis of its chemical composition*

The ratios Periclase/Forsterite is different between the products, in agreement with the chemical MgO content (Tab.1). The mineral impurities content is higher for the product A with "Others" containing mostly Merwinite and Larnite. The Enstatite content is the highest for the product D, but the Periclase content is high, indicating that the high Enstatite is due to the poor quality of the Olivine rather than its content.

**Mineralogy after thermal treatment at 1600°C**
Samples were cast in cylindrical molds before firing at 1600°C for 6h. After cooling down, a part of the sample was cut and grounded for XRD quantitative analysis.
*Fig. 4: Mineralogical composition quantified from XRD analysis thanks to Rietveld analysis after firing at 1600°C/6h*

Tendencies in the evolution of the mineralogy are observed:
- Decrease of the Periclase content, due to the dissolution in low melting phases and reaction with Enstatite to form Forsterite
- Dehydration of the Serpentines to form Enstatite which further reacts with Periclase to form Forsterite
- Increase of Forsterite due to the above-mentioned reactions
- All impurities form Magnetite, Magnesioferrite and Monticellite

**Reoxidation of Al-killed steel lab test**

Based on the mineralogic characterization performed after firing at 1600°C, lab test was performed to assess the reoxidation of Al-killed steel in contact with the tundish lining materials. The four samples and a reference crucible without MgO spray were tested.

*Fig. 5: Inclusions quantification on steel samples retrieved after 2h in contact with refractory at 1600°C. The error lines represent the deviation between botton/middle/top samples. The bars are the average of inclusions quantity between bottom/middle/top samples.*

On Fig. 5, the total inclusions and the $Al_2O_3$ inclusions are depicted. The inclusions which are not $Al_2O_3$ were mainly MnS.

The formation of $Al_2O_3$ inclusions is depending on the refractory used. There is a strong difference between the product A (22 ppm), with reoxidation level comparable to the crucible without sprayed material, and the product D, which shows a strong reoxidation of the killing Aluminum (415 ppm). While the product with the highest MgO content shows the lowest reoxidation (product A), the product D with 67,5% MgO shows higher reoxidation (415 ppm) than the product C with 62,1% MgO (107 ppm). This emphasizes that the chemical MgO content is not reliable enough to estimate the risk of reoxidation in contact with liquid steel. The deviation between bottom, middle and top can give an indication on the speed of the reaction. For product D with low deviation, it can be estimated that the reaction is fast and that the liquid steel bath had time to be homogenized during the duration of the lab test (2h). However, for products B and C with high error bars, the oxygen transfer might still be ongoing at the end of the test, with strong discrepancy in the inclusions content between bottom, middle and top samples. Concerning the tundish residence time, not only the extent of the oxygen transfer but also the reaction kinetics should be considered.

A sample used for preliminary test was retrieved for examination with Scanning Electron Microscopy (SEM). The distribution of the mineral phases were observed:

*Fig. 6: SEM micrograph of tundish lining after performing lab reoxidation test at 1600°C/2h in contact with Al-killed steel*

Tab. 2: EDX measurements from Fig.6:

| [wt.-%] | MgO | $SiO_2$ | FeO | $Al_2O_3$ | CaO | Constituent |
|---|---|---|---|---|---|---|
| 1 | 100 | | | | | Periclase |
| 2 | 49,5 | 43,8 | 6,6 | 0,1 | | Olivine |
| 3 | 26,4 | 36,2 | | | 36,3 | Monticellite |

| [wt.-%] | Fe | Mg | Al | $O_2$ | Constituent |
|---|---|---|---|---|---|
| 4 | 82,3 | 11,2 | 2,3 | 3,3 | Steel |

The micrograph shows both Olivine and Magnesia constituents. The solid solution of Fayalite and Forsterite is visible in the region 2. Metallic exsolutions can be observed at the periphery of the Olivine grain. In the region of the Magnesia, crystals of Periclase are embedded in a low melting phase matrix with Monticellite composition.

Considering the hypothesis of [1], $Fe_2O_3$ should be the main source of oxygen and the presence of a liquid silicate phase activates and speed up the oxygen transfer toward the steel. It was first decided to focus on the correlation between the [Monticellite%] formed at 1600°C and the reoxidation of killing aluminum. However, the product with the highest Monticellite content (product A with 10,4% Monticellite) shows low reoxidation (22 ppm of $Al_2O_3$ at the

same level than the reference crucible). This sample had also the specificity to exhibit no Magnetite ($Fe_2O_3$), which is suspected to be the main source of oxygen for reoxidation of Al-killed steel. Based on those considerations, the reoxidation $Al_2O_3$ inclusions were plotted depending on the content of both Monticellite and Magnetite after firing at 1600°C:

*Fig. 7: Correlation between the $Al_2O_3$ inclusions formed during lab reoxidation test and the product [%Monticellite] x [%Magnetite] contained in the product after firing at 1600°C/6h*

The formation of $Al_2O_3$ during lab test seems to be correlated with the mineral impurities quantified after thermal treatment [Monticellite%]x[Magnetite%]. This confirms the hypothesis enunciated by Lehman et al and this correlation could be a used to assess the risk of reoxidation without performing a test in contact with liquid steel.

**CONCLUSIONS**

Based on XRD analysis before and after lab firing at 1600°C, different features were retrieved to assess the mineralogical quality and high temperature stability of the tundish working lining. It was observed that after firing at 1600°C, the mineral impurities are reacting to form three phases: Monticellite, Magnetite and Magnesioferrite. During heating, while the Periclase peak decreases due to dissolution in low melting phase and reaction with minor phases from Olivine, the Forsterite peak increases, lowering the amount of molten phases generated in the material.

To understand further the link between the mineralogy and the reoxidation, lining materials were put in contact with Al-killed steel during lab experiment. The test showed that the mineral purity has a great influence on the reoxidation of the killing Aluminum. The determining factor to assess the risk of reoxidation based on the mineralogy of the lining is likely to be the product of Monticellite and Magnetite contents after firing at 1600°C. The Magnetite can be considered as the reservoir of oxygen to be transferred to the steel while the Monticellite activates and accelerates this transfer by forming liquid silicate phase. The knowledge of this parameter can support the reduction of cost for the raw material composition while ensuring the chemical inertia of the lining.

## ABSTRACT

The state-of-the-art magnesia-based dry vibrateable tundish linings are predominantly bonded by resin. However, besides high energy consumption, the pyrolysis of the resin-containing lining during the tundish heat-up process generates hazardous gases and carbon residues, resulting in an unwanted carbon pick by the molten steel after the finished ladle treatment. For water-based or spray-coated tundish linings, similar energy consumption can be anticipated since the remaining water of the hydraulic bonding need to be removed during the heat-up process to avoid damage of the lining by released steam or H2 dissolution by the steel melt. In contrast to resins or water-based binders needing a heat-up at high temperatures, there are binders with a cold or a low-temperature bonding behaviour such as sol/gel, acid-base, or thermally (low temperature) activated systems.

Hence, the aim of this study was to combine acid-based with thermally activated binder systems to develop new resin-free tundish linings. Therefore, Ca-, Na-, and P-containing chemicals/hydrates as well as organic acids were used to promote the thermally activated acid/base bonding reaction. Their influence on the physical and mechanical properties such as density and compressive strength of the lining was investigated. Additionally, utilizing a unique steel casting simulator, the influence of newly developed lining compositions on the steel quality compared to a reference binder system was tested and analysed. The influence on the inclusion population in the molten steel as well as the elemental composition of the steel was evaluated.

Results showed that the reaction time is strongly dependent from the solubility of the acids. Lower dissolution results in an increased strength development with increasing temperature. Newly developed compositions showed no significant influence on the steel cleanliness, only a minor change in the population could be detected.

## INTRODUCTION

Impurity and inclusion reduction in the steelmaking industry have become extremely important in the past few years [1–3]. To challenge this issue, filters can be used for melt filtration [4–7]. However, a significant reduction of inclusions can be also achieved by improved refractory lining materials[8], which also influence the service life. These improvements should fulfil the customer requirements.

Lately, the tundish in the continuous casting process has assumed the role of an inclusion removal device and metallurgical reactor [9]. Depending on the steel grade, inclusions in the form of alumina or spinel can be found. They influence the steel castability and cleanliness [8]. Beside, reducing the CO2 emission and footprint and lowering the energy demand is one of the key and challenging issues of the XXI century to follow the Kyoto protocol. Furthermore, health-related issues i.e. avoid the evolution of hazardous gases during the process, is of high importance. Therefore, refractory materials and systems with new developments are in continuous reconsideration.

MgO and/or olivine with a novolac or resin bond is state of the art for tundish linings. During the tundish heat up, with increasing temperatures resin releases smelly and hazardous gases. It undergoes pyrolysis, which leaves carbon residues in the lining, that later could cause unwanted carbon pickup in the steel. Novel bonding systems use a two component (2K) or cold binder system based on sodium silicate [10]. These systems allow both a cold and hot start. Spray linings are an alternative to the dry mixture, which, however, still need to be dried and cured between 150 and 250 °C.

Not only the binder system but the MgO quality of the tundish lining plays an important role for the steel quality. Reoxidation reactions between molten metal and the refractory according Lehmann et al. [11] increases when the MgO content of the refractories decreases. The triggering reaction for this reoxidation is the reduction of the iron, that is influenced in turn by the silica content. Furthermore, the water content is an important aspect. Refractories fired at 1200°C before liquid metal contact provide less reoxidation than dried at 180°. As an indirect prove, Kerber et al. presented immersion results for different MgO-C qualities, showing a decreasing size of Al2O3 inclusion with increasing MgO quality [12,13]. Furthermore, the overall inclusion chemistry was dependent on the MgO qualities. Many authors described the inclusions, their form and the influence on the steel properties [14–16]. Generally, it can be said that hard inclusions such as Al2O3 are the most detrimental for the steel quality and can lead to critical failure in the casted parts. Novel improvements try to fit the requirements for no carbon or silicate borate addition in the tundish lining mixtures. Since the last key process stage before casting occurs in the tundish, the requirements for the tundish lining simultaneously include short service time and long service life at a low price.

In this paper, the development of novel binder systems and their differences in comparison to a conventional resin-based tundish lining composition are presented. Beside of the basic properties, their contact with liquid steel was investigated and their influence on the steel quality in terms of the inclusion population

## EXPERIMENTAL PROCEDURE

MgO from Chinese source (CM) with fractions of 0-1 mm and fine <63 µm (F) fractions were used. The chemical analysis is given in Tab. 1. As binder system, acids Oxalic acid (Oxs) Adipic acid (Ads) and Salicylic acid (Salics) in combinations with different trisodium-phosphate -6 hydrates (NaPH6H) and -12 hydrates (NaPH) were tested. All components were supplied from the Chemische Fabrik Budenheim Kg. Furthermore, in perspective of the high temperature phase composition to avoid Phosphor contamination as far as possible, calcium source in form of calcium hydroxide and calcium carbonate was introduced. As reference, a state-of-the-art (SoA) MgO composition with 4 wt.-% of novolac powder resin and hexamethylentetramine as hardener was used.

The mixtures were prepared with an Eirich EL1 intensive laboratory mixer using the following settings: 15 m/s rotor speed and 5 minutes mixing time.

449

Tab. 1: Chemical composition of the used MgO

| GRAIN SIZE | content in % | | | | | |
|---|---|---|---|---|---|---|
| | $Al_2O_3$ | $CaO$ | $Fe_2O_3$ | $MgO$ | $MnO$ | $SiO_2$ |
| 0-1 MM | 0.7 | 1.9 | 1.1 | 92.5 | 0.1 | 3.4 |
| < 63 μM | 0.9 | 2.0 | 1.1 | 92.3 | 0.1 | 3.4 |

Cylindrical steel moulds with a diameter of 50 mm and a height of approx. 50 mm were used. The powder mixtures were filled and the samples were compacted with a compaction tool, adapted from a compressed air tamper. A defined weight was crushed onto the surface area from 50 cm height 5 times. The maximum applied compaction force was approx. 0.005 MPa.

For the steel casting simulator tests, bars with dimensions of 120x25x25 mm³ were prepared the same way.

The reference samples with powder resin were cured at 180 °C using the traditional heating schedule with 2 steps in between. The newly developed sample compositions were cured with a heating rate of 2 K/min and a final dwell time of 3 hours at 150 °C. The density and the cold crushing strength (CCS) (Tiratest 28100) of the specimens were then measured.

For "finger" tests, reference sample with resin binder were coked up to 1000 °C in coke grid. Samples with the newly composed binder system were preheated up to 1100 °C in oxidizing atmosphere.

Tests in the steel casting simulator were carried out while samples were immersed in approx. 38 kg of steel (42CrMo4) at 1600 °C with an immersion time of 20 minutes. The test took place under fully controlled argon atmosphere, see Fig 1.

Fig. 1: Immersion test: a - Scheme of the steel casting simulator (1 – rotatable revolver system, 2 – chamber for sample handling, 3 – sample holder, 4 – sample in melt contact, 5 – melting crucible, 6 – induction coil, 7 – gas tight reservoir for additives, 8 – feeding mechanism, 9 – pyrometer) according to [17]; b – exemplary specimens before (left) and after (right) the immersion test.

For the generation of inclusions, the steel melt was firstly oxidized with 0.5 wt.% FeOx powder and then deoxidized with 0.05 wt.% aluminum chippings (both related to the total steel mass) prior the immersion of the refractory specimen. After the immersion, the steel was cooled down inside the crucible. For each specimen, a fresh steel sample and a fresh crucible was used.

Samples 50x50 mm2 with a height of approx. 10 mm were cut out form the solidified steel blocks, lapped and polished to identify the inclusions and its population in a defined area with the aid of automated feature analysis using an automated scanning electron microscope equipped with energy dispersive X-ray spectroscopy (ASPEX PSEM eXpress, FEI, USA). The inclusion size distribution was analyzed by means of population density functions relating the inclusion count in a bin to the corresponding bin width [18]. The steel quality was further analyzed via optical emission spectroscopy analysis (OES).

**CONCLUSION**

Temperature activated novel acid-base binder systems were developed for the tundish lining. The influence of the acid source and the influence of calcium addition were investigated. The solubility of the acid plays a major role for the strength development. Calcium addition up to a certain level also increases the strength. It was observed that the samples prepared with the novel binder systems present comparable results to the resin-bonded tundish linings. There was no increase irregularity for S and B content in the samples. Interestingly the raw steel sample and samples from the immersion experiment performed with the specimens containing the new binder system with CaCO3, NaPH6H and Ads/Oxs show the highest P and Al content, followed by the sample without Ca content. Despite, all result are within the tolerance.

The results of the quantitative inclusion analysis can be summarized as follows:

- The main inclusion types were alumina, and Mn-Si containing inclusions, either with pronounced Al-rich regions or without

- The frequency of Mn-Si containing inclusions appeared to be highly sensitive to oxygen content and also sensitive to the steel melt temperature.

- A higher initial oxygen content resulted in a higher frequency of Mn-Si containing inclusions indicating that such inclusions are formed by reoxidation of the steel melt.

- A higher steel melt temperature tends to reduce the number of Mn-Si containing inclusions, supporting the assumption of Mn-Si dissolution in the steel melt.

- Additional factors might affect the Mn-Si formation, which were not identified yet. Based on the collected data, no type-dependent influence of the immersed specimen on the Mn-Si inclusion formation was observed.

- The size distribution of Al2O3 appears to be highly sensitive to the steel melt temperature, showing an increasing size (larger right sided tail in the PDF curves) with increasing temperature.

- Despite, a type-related effect of the immersed specimen was identified, showing an increasing inclusion size with increasing proportion of Ca contained in the immersed specimen.

- Nevertheless, the inclusion size distribution was comparable or even shifted to a smaller inclusion size compared to the reference experiment performed with a resin-bonded specimen.

- Therefore, the usage of the new binder system containing CaCO3, NaPH6H and Ads/Oxs revealed no adverse effect on either inclusion size distribution or inclusion chemistry.

**ABSTRACT**

In this study, a total of 4 improvements were made to reduce large inclusions in the billet. First, the opening rate of molten steel for ladle was improved by developing ladle filler components and shape. Second, oxygen concentration is reduced through Ar purging in the tundish before casting the molten steel from ladle to tundish. Third, erosion of stopper head is reduced by improving the material. Finally, tundish slag composition is improved to reduce the reoxidation of molten steel in the tundish. To evaluate the effect of this study after casting, the mold level, molten steel cleanliness (total O, N), and billet UT were conducted.

**Keywords** : Tundish, Stopper, TD Slag, opening rate of ladle, Re-oxidation, lancing(O2)

## INTRODUCTION

In general, not only steelmaking operation conditions, but also casting operation conditions and refractory material/shape are very important for automobile steel sheets and special steels that require high quality First, if the ladle opening is not properly performed, casting is performed through oxygen opening, and in this process, the molten steel is seriously reoxidized. Since ladle opening is generally affected by filler particle size, composition, shape of ladle well block, inner diameter of ladle SN nozzle, and steelmaking lead time, it is important to use an appropriate refractory material and filler for operating conditions. Second, the oxygen concentration in the tundish immediately before casting of molten steel from ladle to tundish is an important factor in re-oxidizing molten steel in tundish. This is affected by the tundish capacity, the Ar purging amount, and the purging position, and especially this is a technique used to improve the quality of first billet. Third, stopper erosion and clogging are the biggest factors that cause large inclusions in the final product, and it is important to select an appropriate shape and material depending on the molten steel composition and continuous casting conditions. In general, MgO material is selected for Ca treated steel, and Al2O3 material is used for high carbon and ultra-low carbon steel. In particular, in the case of steel with high carbon and high Ca content, it is very important to select an appropriate material through closely analysis. Lastly, it is very important to use rice ash and B-flux alone or properly mixed for tundish slag, which is used to block the air contact of tundish molten steel, considering the molten steel temperature and composition. In this study, the four factors mentioned above were evaluated and improved to reduce large inclusions in billets for special steel in manufacturing the automobiles.

## CONCEPT OF DEVELOPMENT, RESULTS AND DISCUSSION

1) Improve the opening rate of molten steel for ladle

Four improvements were conducted to improve the opening rate of molten steel for ladle (Fig.1). First, the fine particle was reduced

and the SiO2 component was reduced to suppress the sintering ability of the ladle filler. Second, the upper diameter of the ladle well block was enlarged so that the filler could more easily pass through the well block. Third, the lead time from steelmaking to continuous casting was reduced by adjusting the amount of steel tapping in the electric furnace. Lastly, after casting of ladle, the test was conducted by reinforcing the O2 washing of metal or slag in the well block. The evaluation was carried out by sampling the molten steel of the case with and without oxygen, respectively, and analyzing the total O and nitrogen pick-up. In the case of total O pick-up, it decreased by about 4ppm, and in the case of nitrogen pickup, the result was reduced by 5ppm. (Fig.2)

*Fig. 1. improvement of opening rate of Ladle*

*Fig. 2. result of Total O, Nitrogen pick up*

2) Reduce the oxygen concentration in tundish immediately before casting of molten steel to tundish

Two improvements were conducted to reduce the oxygen concentration. First, the Ar purging flow rate was increased, and

second, hole on tundish cover was sealed. (Fig.3) In general, by controlling the oxygen concentration inside the tundish before casting of molten steel from ladle to tundish, the inclusion quality of first billet can be improved, and the oxygen concentration needs to be maintained at 1% or less. The oxygen concentration is mainly determined by the flow rate of Ar gas and the sealing method, and should be appropriately selected according to the capacity and shape of the tundish. We increased the Ar amount to about 3,500lpm, and sealed hole on the thudish cover. Results of the oxygen concentration measurement was controlled to about 0.1%, and amount of total O pick-up decreased by about 28% and the nitrogen pickup amount decreased by about 56%. (Fig. 4)

Fig. 3. improvement of Ar flow rate, sealing for tundish

Fig. 4. result of Total O, Nitrogen pick up

3) Reduce the erosion of stopper tip

The refractory material was changed to reduce the erosion of the stopper head. In general, in the case of MgO refractory reacts with C (refractory/molten steel) and is decomposed into a gas and formed pore in the structure. during casting, molten steel penetrates the formed pores and refractory erosion is occured by structural spalling. In contrast, Al2O3 refractory reacts with CaO in molten steel and forms a liquid compound at casting temperature and refractory erosion is occured. In this study, as shown in Table.1, steel grades with high C content and high Ca content were evaluated.

Table . 1. chemical Composition of steel grade

| C | Si | Mn | Al | Ca |
|---|---|---|---|---|
| 0.36~0.39% | 0.1~0.4% | 0.7~1.1% | 0.02~0.06% | 10~15ppm |

As a result of this evaluation on the existing product, it was confirmed that erosion occurs due to the MgO decomposition reaction. As shown in Fig.5, the stopper material of MgO(50%)-Al2O3(30%)-C(15%) is changed to Al2O3(70%)-MgO(20%)-C(3%) to improve the erosion reaction with molten steel and an erosion improvement test was conducted. As a result of the test, it

was improved by about 60% compared to the conventional item, and as a result of billet MIDAS evaluation, it was As a result of tissue evaluation on the existing product, it was confirmed that erosion occurs due to the MgO decomposition reaction. As shown in Fig.5, the stopper material of MgO(50%)-Al2O3(30%)-C(15%) is changed to Al2O3(70%)-MgO(20%)-C(3%) to improve the erosion reaction with molten steel and an erosion improvement test was conducted. As a result of the test, it was improved by about 60% compared to the conventional item, and as a result of billet MIDAS evaluation, it was confirmed that large inclusions were also improved. (Fig.6)

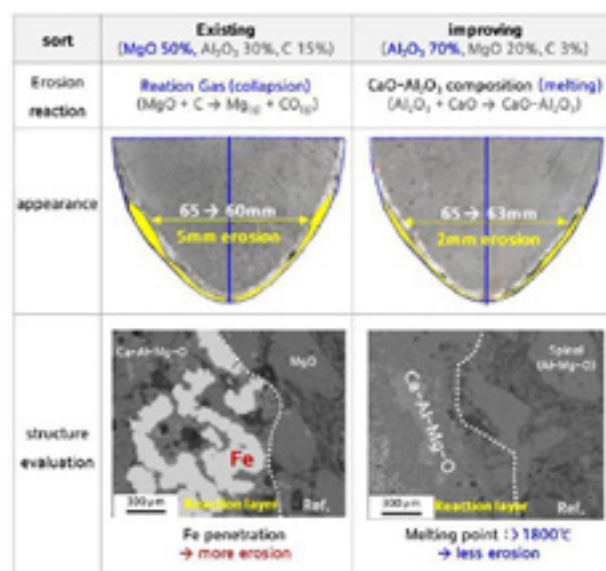

Fig. 5. Improvement Concept of materials and Erosion result of test.
Fig. 6. Results of MIDAS after rolling billets

4) Improve the tundish slag composition

In order to block the contact between air and molten steel during casting, the tundish flux input standard was changed. Previously, the standard was to use only rice ash, but both rice ash and B-flux were put in the tundish and the improvement effect was confirmed through the FeO content in the slag after using. When only rice ash was used, FeO was detected at 9.8%. On the other hand, FeO was

detected at 1.8% when both rice ash and B-Flux were used. (Fig. 7) Rice ash and B-flux components are shown in Table.2.

Table . 2. chemical Composition of rice ash and B-Flux

| Sort | CaO | $Al_2O_3$ | $SiO_2$ | $Fe_2O_3$ | C |
|------|-----|-----------|---------|-----------|---|
| Rice ash | - | <5% | >75% | - | 10~20% |
| B-Flux | 53~59% | 30~38% | <4% | <1.5% | - |

## CONCLUSIONS

In this study, a total of 4 improvements were evaluated to reduce large inclusions in the billet (special steel for automobiles), and the results are as follows.

1) Improve the opening rate of molten steel for ladle

In the case of total O pick-up, it decreased by about 4ppm, and in the case of nitrogen pickup, the result was reduced by 5ppm.

2) Reduction of oxygen concentration in tundish immediately before casting of molten steel to tundish

Results of the oxygen concentration measurement was controlled to about 0.1%, and amount of total O pick-up decreased by about 28% and the nitrogen pickup amount decreased by about 56%.

3) Reduce the erosion of stopper tip

As a result of the test, it was improved by about 60% compared to the conventional item, and as a result of billet MIDAS evaluation, it was confirmed that large inclusions were also improved.

4) Improve the tundish slag composition

When only rice ash was used, FeO was detected at 9.8%. On the other hand, FeO was detected at 1.8% when both rice ash and B-Flux were used.

## ABSTRACT

The purpose of this work was to compare and investigate the deterioration mechanism of Al$_2$O$_3$-MgO refractory castable under industrial condition. After structural optimization, the average corrosion rate of every cycle deceased to 0.31 mm/cycle from 0.46 mm/cycle. Corroded microstructure of the optimized Al$_2$O$_3$-MgAl$_2$O$_4$ refractory castable after server 195 cycles was explored. An adhered slag layer comprising mainly (Fe, Mg)Al$_2$O$_4$ spinel was observed on the refractory's surface. Iron beans and iron/manganese oxides mainly occurred in the reaction layer, and penetrating cracks occurred at the corroded interface which would cause potential structure spalling for refractory lining. Based on the observed microstructural characteristics, corrosion mechanism of refractory lining in a commercial ladle was proposed.

**Keywords:** Al$_2$O$_3$-MgO refractory; RH refining ladle; Corroded microstructure; Degeneration mechanism

## INTRODUCTION

The interaction between refractory lining and molten slag/steel in refining ladle is drawing much more attention from both refractory engineers and metallurgist. From a metallurgical point of view [1, 2], refractory lining in refine ladle is considered as the main sources of exogenous oxide inclusions. However, from the perspective of refractory, refractory lining in refining ladle is a typical complex steel/slag contact application and suffers from a harsh server environment [3-5]. Up to now, Al$_2$O$_3$-MgO system refractory castables are the mainstream choice for metal bath area and bottom in refining ladle, particularly large size ladles. Incorporation of aluminum-magnesium spinel powders and fine spinel particles into corundum based castables, corundum-spinel refractory castables processed a higher resistance to slag penetration and thermal shock when compared with pure corundum based castables [6].

One heat cycle of ladle treatment is compounded from three stages, including process of molten iron poured into ladle, refining and alloying process, and steel tapping. Hence at the different stages of ladle treatment, the Al$_2$O$_3$-MgO refractory lining needs to subject to chemical attack form molten slag/steel in the refining process, mechanical erosion from molten steel and intense thermal shock during tapping and pouring of steel processes [1, 2, 7]. For this reason, the degeneration process of Al$_2$O$_3$-MgO refractory castable during server in a commercial ladle is quite complex and dependent upon a large number of parameters. So it is difficult to achieve a deeper understanding of such degradation behavior with the laboratory scale testing, though it is contributed to estimate the service performance of potential refractory materials, assist further structure and composition optimization [8, 9].

Considering the above issues, Al$_2$O$_3$-MgO per-formed refractory bricks with alumina-silica gel powder as binder were fabricated and industrial trials in RH refining ladle after structural optimization. After that, a post-mortem analysis on the used Al$_2$O$_3$-MgO per-formed refractory brick was carried out, and compared with our previous work. Corroded microstructures were explored in detail, and degeneration mechanism governing the degeneration process was proposed and discussed in this work.

## 2. EXPERIMENTAL PROCEDURE

### 2.1 Service conditions the used refractory brick and testing process

Chemical composition of Al$_2$O$_3$-MgO refractory castable before/after structural optimization is shown in Table. 1. After pre-casting into refractory bricks (thickness: 210mm) and masonry construction, the above-preformed Al$_2$O$_3$-MgAl$_2$O$_4$ castable bricks lined the wall of a 300-ton industrial ladle. After 195 cycles in the ladle for RH operations, the residual Al$_2$O$_3$-MgAl$_2$O$_4$ refractory of trial sample was removed from the refining ladle.

Tab. 1: Chemical composition of Al$_2$O$_3$-MgO refractory castable

|  | Al$_2$O$_3$ | MgO | CaO | SiO$_2$ | FeO$_x$ | R$_2$O | TiO$_2$ | MnO |
|---|---|---|---|---|---|---|---|---|
| Trial sample | 91.92 | 5.35 | 0.28 | 1.08 | 0.86 | 0.02 | 0.04 | 0.02 |
| Contrast sample | 96.03 | 3.25 | 0.02 | 0.87 | 0.01 | 0.26 | 0.01 | - |

### 2.2 Examination of corroded microstructure

In order to obtain a whole corroded interface for microstructure analysis, the residual Al$_2$O$_3$-MgAl$_2$O$_4$ refractory was cut along corrosion direction using a diamond saw blade. A whole corroded sample (75mm in length and 25 mm in width) was characterized by a scanning electron microscope (SEM, Apreo S HiVac, ThermoFisher), along with energydispersive X-ray spectrometer (EDS, Oxford Ultim Max 100 EDS) and X-ray diffraction (XRD) analysis (Bruker D8 Advance; using Ni-filtered, Cu Kα radiation). Furthermore, the corroded interface of the used Al$_2$O$_3$-MgAl$_2$O$_4$ castable was examined by an X-ray computed tomography (CT, Phoenix v|tome|x s, GE Inspection Technologies, GmbH, Germany).

## 3. CORRODED MICROSTRUCTURES AND DISCUSSION

The residual thickness in this optimization work was approximately 150mm after 195 server cycles (initial thickness: 210 mm), which shown a g significant enhancement compared with the contract sample (residual thickness 126mm, 184 cycles). The average corrosion rate of every cycle deceased to 0.31 mm/cycle from 0.46 mm/cycle, it indicated that the corrosion resistance of optimized Al$_2$O$_3$-MgO castable improved by ~30%. For contract sample, a wide reaction layer and a through crack observed on the corroded interface which just located at the boundary of infiltration layer (figure 1).

Fig. 1: *Cross-sectional image of the used Al$_2$O$_3$-MgAl$_2$O$_4$ castable after service in a commercial RH refining ladle for 184 cycles, (a) X-ray CT scanning images of the corroded sample, 3D reconstructed profile of overall corroded sample*

Compared with the previous work [10], a clearly visible difference was observed in the corroded microstructures of sample after 195 cycles after structural optimization, particularly the microstructure corroded in infiltration layer. Cross-sectional image of the used Al$_2$O$_3$-MgO per-formed bricks after 195 cycles in the refining ladle is presented in figure 2(a), revealing three main different regions

455

along the corrosion direction, reaction layer (black area), infiltration layer (gray area) and un-reaction layer. And there are several transverse and longitudinal cracks at corroded interface. The crystal phase composition in the surface layer (slag and reaction layer) and infiltration were confirmed by XRD and shown in figure 2 (b) and (c), indicating that the main phases in surface layer were gehlenite, spinel, iron oxide and calcium aluminum oxide. Moreover, it was confirmed that the infiltration layer was composed mainly of calcium magnesium aluminum silicate, gehlenite, calcium aluminum ($CA_6$), spinel and remained corundum. The detailed microstructures and phases morphology the corroded interface would be presented in the coming section.

*Fig. 2: (a) Cross-sectional image of the $Al_2O_3$-MgO per-formed bricks after 195 cycles in the refining ladle, (b) XRD pattern of the surface layer (black area in (a)), (c) XRD pattern of infiltration layer (gray area in (a))*

The overall corroded microstructure of used $Al_2O_3$-MgO castable refractory is depicted in figure 3, showing four different regions including adhered slag layer, reaction layer, infiltration layer and original layer based on microstructural characterization. A thin slag layer with macro-pore structure adhered on the castable's surface, and there were many small iron beans and several iron belts in the dense reaction layer. The infiltrated slag had react with grains in the matrix and blurred the boundaries of aggregates/matrix and grains in the matrix. Besides, a through crack occurred in the boundary of the infiltration/original layer and closed to the latter.

Moreover, the chemical compositions of different regions in the used per-formed brick were analyzed by chemical titration method and the results showed in Table 2. Compared with the chemical compositions in different layers, the CaO and $SiO_2$ content in the infiltration layer is higher than that of original layer. And iron oxides as corrosive compositions main occurred in surface layer (reaction layer). The result indicated that CaO and $SiO_2$ possessed the strongest permeability in this case.

*Fig. 3: Backscattered electron image (BEI) of the overall corroded microstructure of used $Al_2O_3$-MgO castable refractory after 195 heats, showing four different layers*

Tab. 2: Chemical compositions of different regions at corroded interface (wt%)

|  | $SiO_2$ | $Al_2O_3$ | $FeO_t$ | CaO | MgO | $K_2O$ | $Na_2O$ | $TiO_2$ | MnO | LOI |
|---|---|---|---|---|---|---|---|---|---|---|
| Surface layer | 6.73 | 64.62 | 11.79 | 7.72 | 4.95 | 0.043 | 0.035 | 0.15 | 1.74 | 2.43 |
| Infiltration layer | 5.02 | 85.05 | 0.77 | 2.71 | 5.25 | 0.051 | 0.045 | 0.055 | 0.025 | 0.08 |

A high magnification BEI of refractory castable's surface is presented in Fig. 4 (a), revealing a continuous adhered layer with macro-pore structure on the surface. Based on the analysis of XRD (figure 2 (b)) and the corresponding EDS in Table.3, the main components in the adhered slag layer were ferrospinel ((Fe,

Mg)$Al_2O_4$), iron and manganese oxides and CaO-$SiO_2$-$FeO_t$-$Al_2O_3$ glass phase.

The microstructure of corroded aggregate in the reaction layer is shown in Fig.5, revealing that the calcium hexaaluminate ($CA_6$) with strip structure formed on the aggregate's surface and isolated island-liked alumina and spinel grains inside aggregate were surrounded by low-melting phase. The corroded microstructure indicated that the aggregate suffered an intergranular corrosion process which meant that slag infiltrated along the grain's boundaries in the aggregates and led to a further attack.

*Fig. 4: High magnification BEI of the slag layer in Fig. 2; (a) showing a continuous adhered layer*

*Fig. 5: High magnification BEI of the aggregate in the reaction layer, showing the slag infiltrated along the grain's boundaries*

Tab. 3: EDS results in Fig.4 and Fig.5 (atomic %)

| Elements | Al | Mg | Ca | Fe/Mn | Si | O | Possible phase |
|---|---|---|---|---|---|---|---|
| Point 1 | 16.3 | 3.7 | - | 27.6 | - | 52.4 | (Fe,Mg)$Al_2O_4$ spinel |
| Point 2 | 4.4 | - | 15.3 | 8.5 | 9.9 | 61.9 | - |
| Point 3 | - | - | - | 48.2/4.1 | - | 47.7 | Iron and manganese oxides |
| Point 4 | 41.5 | - | 3.9 | - | - | 54.6 | $CA_6$ |
| Point 5 | 56.1 | - | - | - | - | 43.9 | $Al_2O_3$ |
| Point 6 | 42.2 | - | - | - | - | 57.8 | $Al_2O_3$ |
| Point 7 | 35.9 | 11.8 | - | 0.8/0.7 | - | 50.8 | (Fe,Mg,Mn)$Al_2O_4$ |

The generated cracks on the corroded interface can cause the structural spalling on refractory lining. The formed cracks in the infiltrated and original layer all grew along the interfaces of aggregates and matrix. The macro-image of the formed crack in the infiltrated layer shown in figure 6 (a), suggesting the infiltrated slag reacted with matrix compositions and caused densification and volume change in matrix structure. The aggregate/matrix bonding interface (weak-binding state) was prone to deterioration when suffering from the above densification and volume change process during slag infiltration. figure 6 (b) gives a high magnification image of the interface between the infiltration and the original layer, confirming that permeated slag led to a densification process with shrinkage pores structure in the matrix. The differences in the structural and chemical composition of infiltrated layer and the original layer led to various physicochemical properties. That was the primary reason for the formation and growth of cracks in corroded interface.
*Fig. 6: (a) Cracks generated in the infiltrated layer; (b) High magnification image (BEI) of the interface between the infiltrated layer and the original layer*

## CONCLUSIONS

A post-mortem analysis on preformed $Al_2O_3$-MgO castable with alumina-silica gel powder as binder after industrial trials was studied. Deterioration process and corrosion mechanism were discussed based on the observed microstructural characteristics. The main conclusions are as follows:

(1) After structural optimization, the trial $Al_2O_3$-MgO pre-cast bricks after server 195 cycles in RH refining ladle had a residual thickness of ~150 mm from the initial thickness of 210 mm. It indicated that the optimized one displayed a ~30% improvement in corrosion resistance after industrial application when compared with the conventional ones (184 cycles). It was attributed to the corroded behaviors and slag infiltration behaviors of $Al_2O_3$ based aggregates in the corroded interface.

(2) Four separate layers, including adhered slag layer, reaction layer, infiltration layer and original layer, was fully characterized on the used alumina-silica gel powder bonded $Al_2O_3$-MgO castable. A wide infiltration layer with ~30mm was observed on the corroded interface, the boundaries between aggregates and matrix are blurred because of slag infiltration.

(3) A penetrating crack formed on the corroded interface, which is located on the boundary between infiltration and original layer. The formation of that penetrating crack could be ascribed to the difference in physicochemical properties and sintering degree. Corroded microstructure indicated that slag infiltrated inside the $Al_2O_3$ aggregates along the grain boundaries and confirmed the aggregates suffered from an intergranular erosion process.

# DEVELOPMENT OF UNFIRED AND NON-IMPREGNATED SLIDE GATE PLATES AS A CONTRIBUTION TO REDUCING EMISSIONS OF CARBON BONDED REFRACTORIES

Dominic Helmus, Sylvia Schwartz, Marcus Blumenberg, Peter Stein, Jochen Kattwinkel

Knöllinger Keramische Verschleißteile GmbH, Hillscheid, Germany

## ABSTRACT

Knöllinger Keramische Verschleißteile GmbH (Knöllinger) is a well-known and established supplier of alumina based, carbon bonded slide gate plates especially for the German steel market. Approx. 35.000 pieces are delivered annually, of which the biggest share belongs to the group of fired and tar pitch impregnated slide gate plates. In order to contribute towards reducing greenhouse gas emissions Knöllinger is going to launch a new product line of unfired and non-impregnated slide gate plate ceramics. Beside the lower energy consumption especially due to curing as the only thermal treatment, pitch tar free carbon bonded ceramics almost show no hazardous emissions during manufacturing and service. First trial results of unfired and non-impregnated slide gate plates in comparison to the standard products used in an electrical steelworks are presented in this paper.

## INTRODUCTION

Slide gate valves for steel ladles have been put in operation about 60 years ago. They essentially consist of a mechanical housing and several refractory components such as well block, sleeve, slide gate plates and nozzle (Fig. 1). For continuous casting slide gate valves containing two slide gate plates are the state of the art.

Fig. 1: refractory components of a ladle slide gate valve
a: well block; b: sleeve; c: upper slide gate plate, d: lower slide gate plate, e: nozzle

To open and close the slide gate valve, the lower slide gate plate is moved linearly against the upper plate by the help of a hydraulic or electric actuator. Thus, the steel flow rate from the ladle to the tundish is regulated. Fig. 2 illustrates the movable lower slide plate inside the slide gate valve's mechanical housing.

Fig. 2: detail of slide gate valve mechanism consistent of a fixed upper plate and a movable slide gate plate

## Refractory materials for slide gate plates

The chemical composition of slide gate plates can be regarded as the most important differentiating and selecting criterion for a particular application. The most commonly used grades are based on alumina due to their relatively good abrasion, thermal shock and corrosion resistance. Slide gate plates based on magnesia and zirconia normally show superior corrosion resistance along with reduced thermomechanical properties. Tab. 1 shows one possibility to group available slide gate plate materials:

| Raw material basis | Type of binding | |
|---|---|---|
| | Ceramic bonded | Carbon bonded |
| Alumina, fired | X | X |
| Alumina, unfired | | X |
| Magnesia | X | |
| Zirconia | X | |

Tab. 1: overview of slide gate plate materials

Fired and thus ceramic bonded slide gate plate materials regularly get impregnated with a carbon-based liquid, i.e., tar pitch, to further enhance mechanical and corrosion resistance properties. Unfired qualities may be impregnated as well. Also, to improve performance and to prevent the carbon bond and/or impregnation from oxidation, metallic and non-oxide compounds are added to the raw material mixes. Common additives are silicon, aluminium, silicon carbide, boron carbide etc. Other solid carbonaceous materials, i.e., graphite or carbon black, can be included as well.

## Processing of fired and unfired carbon bonded alumina plates

About two third of the slide gate plates distributed by Knöllinger belong to the group of alumina based, carbon bonded, fired and double pitch impregnated plates. These products are marketed under the brand "AC-Technology", the compositions of which were developed entirely by Knöllinger. Fig. 3 illustrates the processing route for this type of slide gate plates. During the production process four temperature treatments are carried out:

1. curing of the bonding agent at about 280 °C
2. firing of the slide gate plates at about 1200 °C
3. curing after first impregnation step at 400 °C
4. curing after second impregnation step at 400 °C

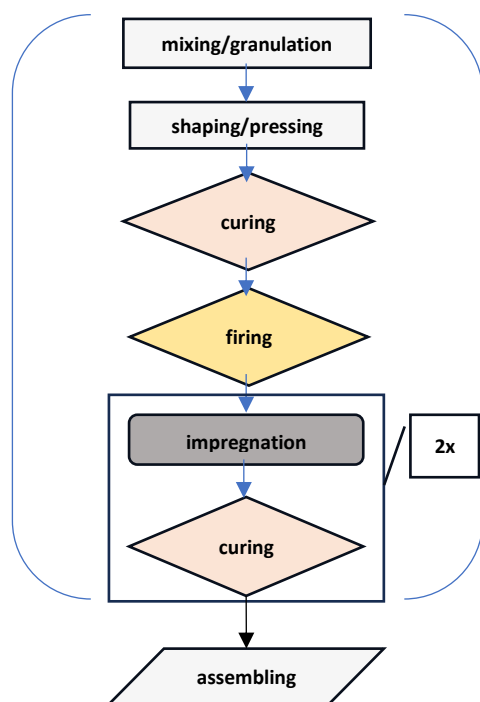
Another third of actually distributed slide gate plates are unfired and single impregnated alumina-based products. Their production process differs of course in the absence of the firing step (Fig. 4).
The processing of unfired and non-impregnated slide gate plates finally shows only one temperature treatment for the purpose of curing the carbon bond after shaping the slide gate plate bodies as displayed in Fig. 5. The curing temperature is slightly lower compared to both impregnated qualities.
Due to the lack of appropriate facilities Knöllinger collaborates with experienced European partners in the field of shaped refractories for the production of the ceramic slide gate bodies. The last step in the processing route, the assembly of the final slide gate plates, takes place at Knöllinger's plant located in Hillscheid, Germany. Assembly includes work steps as grinding, drilling, fitting in metal cans, casting of outlet nozzles etc. These steps are similar independent from the chosen processing route for the refractory bodies. Tab. 2 summarizes and compares the three described processing routes for fired and double impregnated plates, unfired and single impregnated plates and finally unfired and non-impregnated slide gate plates.


Fig. 3: processing route of alumina based, carbon bonded, fired and double impregnated slide gate plates

Tab. 2: summarized processing routes for fired + impregnated, unfired + impregnated and unfired + non-impregnated slide gate plate refractories delivered by Knöllinger

## COMPARISON OF ENVIRONMENTAL ASPECTS

Especially the differing number of thermal treatments and the use of pitch based impregnates have a significant impact on emissions of carbon dioxide related to energy consumption as well on potentially environmental harmful emissions during service and disposal of used slide gate plate refractories.

### Carbon dioxide emissions of different processing routes

Tab. 3 displays the actual carbon dioxide emissions related to production of slide gate plates following the above-described processing routes. The shown figures are determined for so-called scope I+II emissions connected to the production of fired + double impregnated (product class name "AC") and unfired + single impregnated plates ("93P", cf. Fig. 3+4, Tab. 2). As the production of unfired and non-impregnated slide gate plates ("GF") is about to get launched in Q4 of this year, the production related $CO_2$ emissions are estimated based on the verified numbers for the other two types of plates. It should be noted that the emissions associated with the assembly of the slide gate plates are not included in the figures given. Assembly includes one thermal treatment to dry-out water after wet-grinding and casting of nozzles in the same temperature range than

| | Type of slide gate plates | | |
|---|---|---|---|
| | AC | 93P | GF |
| kg $CO_2$ per ton of product | 6000 | 1800 | ≈ 350 |
| Relative emissions | 100 % | 30 % | 5-8 % |

Tab. 3: scope I+II $CO_2$-emissions related to the production of different slide gate refractories distributed by Knöllinger. Calculations based on assumptions of PAS 2050.

the curing step, namely around 250 °C. $CO_2$-emissions linked to slide gate plate assembly is assumed to be in the range of 300-350 kg $CO_2$ per ton of product. Considering this, it is expected that the total $CO_2$ emissions from the production of the unfired and non-impregnated slide gate plates will be about nine times lower compared to the fired and double impregnated plates.

### Potential for further environmentally harmful emissions

To check and compare further possible emissions of potentially harmful compounds especially during the service of slide gate plates, GC-MS-analyses of extractions made of crushed and ground "AC" and "GF" materials by hexane and methanol as solvents were conducted. These samples correspond to the materials as delivered. That means pyrolysis of the resin-based carbon bond of the "AC" sample took already place during the firing step within the production process whereas the pyrolysis of the carbon bond of the "GF" sample has not occurred yet. Other samples of these two materials were heated to 600 °C and 1200 °C in a nitrogen stream which was then guided through the same type of solvents and were analyzed by GC-MS as well. The received results are summarized in Tab. 4.

Comparing the results after extraction of the samples in the as-delivered state (column "original" in Tab. 4), it can be seen that the impregnated and fired "AC" material contains over 7000 mg/kg of

the so-called 16-PAHs (polycyclic aromatic hydrocarbons) which are classified by EPA (US Environmental Protection Agency) as priority environmental pollutants. As the "GF" sample does not show such values it can be concluded that they mainly originate from pitch impregnation. Some of these substances are partially released when the sample is heated to 600 °C, with an amount of 97 mg/kg and 30 mg/kg respectively detected in the rinsed nitrogen stream when further heated to 1200 °C.

The "GF" material shows phenol and derivates after extraction of the sample, which surely originates from the phenolic carbon bond. During degassing up to 600 °C the sample releases especially phenol by 554 mg/kg as well as benzene and bisphenol. Further heating to 1200 °C releases 116 mg/kg of benzene and 102 mg/kg of 16-PAHs. The appearance of these substances is linked to the pyrolysis of the cured phenolic resin bond as the "GF" material is not fired [1]. It can be assumed that the "AC" material shows these releases as well but already within the firing step during manufacturing. Tab. 5 summarizes the source and place of potential emissions originating from slide gate plate materials.

| | | GC-MS Analysis | | |
|---|---|---|---|---|
| | | original | 600 °C | 1200 °C |
| Benzene & derivates | AC | < 10 | < 10 | < 10 |
| | GF | < 10 | 80 | 116 |
| Phenol & derivates | AC | < 10 | < 10 | < 10 |
| | GF | 73 | 554 | < 10 |
| Bisphenol | AC | < 10 | < 10 | < 10 |
| | GF | < 10 | 74 | < 10 |
| 16-PAH's | AC | 7115 | 97 | 30 |

## CASE STUDY OF UNFIRED & NON-IMPREGNATED SLIDE GATE PLATE REFRACTORIES

First trials with Knöllinger's new "GF" materials have been conducted in a German electrical steel mill. This plant has been constantly delivered with AC qualities since 2015. Particularly, the quality in use is called "AC51". Besides being based on alumina this material also contains zirconia mullite resulting in a content of approx. 4,5% $ZrO_2$. The average service life time is 3,9 heats. In comparison, two "GF" type materials were tested under the same conditions. One quality is completely based on alumina ("GF1") whereas the second one includes zirconia mullite additions on the same level than the fired "AC51" quality ("GF2"). Both tested materials showed average service life times of approx. 3,7 to 3,8 heats. Tab. 5 summarizes the physical properties and achieved life times of all three materials. A commonly known disadvantage of only cured carbon bonded refractories is a significant loss of strength and related properties associated with pyrolysis of the phenolic resin binder [3]. This is also observed in both "GF" qualities, but in this case the degradation does not affect the service life of the slide gate

plates. Wear indicators are the widening of the casting hole and material losses on the plate surfaces next to the casting channel of slide gate plates. Fig. 6, 7 and 8 display slide gate plates with their typical appearance after having been used in the steel mill and no major differences in wear phenomena can be observed.

All plates show the same type of radial crack formation around the casting hole which are typical for thermal shock spalling as slide gate plates are not separately heated up before steel flow is initiated. The wear in the travel and working area appears to be on a similar level for all three qualities. Statistically proven statements on durability have to be drawn after a longer period of usage.

| Properties | | Slide gate plate qualities | | |
|---|---|---|---|---|
| | | AC51 | GF1 | GF2 |
| Raw material basis | | $Al_2O_3$+ZM | $Al_2O_3$ | $Al_2O_3$+ZM |

## CONCLUSIONS

The widespread use of unfired and non-impregnated slide gate plate refractories has a huge savings potential of production related $CO_2$ emissions. First calculations show nine times lower scope I+II type emissions in comparison to fired and impregnated slide gate plates representing the actual state of the art.

By not using pitch-based impregnates, the emission of potentially harmful hydrocarbons is further reduced, although important steps have been taken to reduce hazardous compounds in these materials.

First industrial trials show that the newly developed unfired and non-impregnated slide gate plates can be able to perform on the same level as fired and impregnated ones. A stable and continuous supply should be realized by the end of 2023. For cases where fired and impregnated slide gate plates cannot be easily substituted, Knöllinger's R&D activities continue to further enhance the performance of unfired and non-impregnated slide gate plate refractories.

## ABSTRACT

Alumina-carbon (Al$_2$O$_3$-C) refractory materials are widely used in the process of continuous casting of steel as flow control elements, including slide gate plates, nozzles, ladle shrouds, stoppers or submerged entry nozzles. Their task is to direct and regulate the flux of liquid steel and protect it against oxidation of the alloy additives. Decarburization at intermediate temperatures of 300-700°C, corrosion, abrasion and formation of cracks during operation are main wear factors determining the replacement of the Al$_2$O$_3$-C elements. In this work the influence of antioxidants and heat treatment temperature on the physico-chemical and strength parameters of materials was examined.

## 1. INTRODUCTION

The main advantage of Al$_2$O$_3$-C materials, predestining them to be used as flow control elements, is their high refractoriness, ability to withstand high thermal shocks, corrosion and erosion resistance. The presence of carbon in refractories lowers the contact angle of the material at the border refractory/liquid slag or steel, reducing the depth of infiltration. This in turn, causes better corrosion resistance.

Antioxidants are often used in Al$_2$O$_3$-C refractories, e.g., Si or Al. They can react directly, or indirectly, with carbon or nitrogen to form carbides and nitrides [1, 2, 3] which increase mechanical and resistance parameters of refractory materials.

Typically, Al$_2$O$_3$-C slide plates with the addition of Si, are heat treated at a temperature above 1000°C. The purpose of heat treatment is to carbonize the carbon and form a carbon bond. Carbides and other ceramic bonds are formed as a result of the thermally-activated reaction (e.g. between Si and C) and sintering process. Also, unfired Al$_2$O$_3$-C slide plates with the addition of Al on the resin bond heat-treated below 600°C are used. The refractory type is selected based on the metallurgical conditions, e.g., oxygen or calcium content in liquid steel, the presence of slag or the size of the slide gate plate. Fired materials are characterized by higher mechanical strength below 700°C, resistance to decarburization at intermediate temperatures of 300-700°C and dimensional stability. On the other hand, unfired Al$_2$O$_3$-C materials are characterized by higher corrosion resistance and increased mechanical strength above 700°C [3, 4]. The purpose of this work was to investigate the properties of Al$_2$O$_3$-C materials fired at an intermediate temperature of 600-1000°C and compare them with the properties of materials fired at higher temperatures.

## 2. MATERIALS AND METHODS

The isothermal predominance area diagrams for the Si-C-N-O and Al-C-N-O systems were determined using the FactSage 7.0 software applying *Predom* module. Al$_2$O$_3$-C refractory materials were industrially produced based on 7 different compositions, including reference material, materials with Si addition (1, 3 and 5 %) and materials with Al addition (1, 3 and 5 %), according to Tab. 1. Cylinders (35x35 mm) and beams (25x25x150 mm) were shaped at a forming pressure of 1000 kg/cm$^2$. Shapes were dried at 250°C, then fired at different temperatures of 800°C, 1000°C, 1200° and 1400°C in carbon bed to for the antioxidation protection.

Tab. 1: Starting composition of the Al$_2$O$_3$-C refractory materials

| Sample | Ref. | 1%Si | 3% Si | 5%Si | 1%Al | 3%Al | 5%Al |
|---|---|---|---|---|---|---|---|
| Tabular alumina | 86 | 86 | 86 | 86 | 86 | 86 | 86 |
| Reactive alumina | 11.6 | 11.6 | 11.6 | 11.6 | 11.6 | 11.6 | 11.6 |
| Carbon black | 2 | 2 | 2 | 2 | 2 | 2 | 2 |
| Si <0.045mm | - | 1 | 3 | 5 | - | - | - |
| Al <0.045mm | - | - | - | - | 1 | 3 | 5 |
| Novolac resin | 4.0 | 4.0 | 4.1 | 4.2 | 4.0 | 4.1 | 4.2 |

XRD diffractograms of fired materials were registered by Philips X-Ray PW 1730 diffractometer, and analyzed using PANalytical's X'pert High Score Plus software. Open porosity and bulk density were determined acc. to standard PN-EN-993-1:1998, cold crushing strength (CCS) acc. to EN-10059-1 and modulus of rapture (MOR) at room temperature acc. to EN 993-6. The JOEL JSM - JT500 LA scanning electron microscope was used for the microstructural analysis. Young's modulus (modulus of elasticity, MOE) was determined using the dynamic method by measuring the ultrasonic wave velocity with the use of ULTRATEST BP-700 PRO Ultrasonic Tester.

## 3. RESULTS AND DISCUSSION

The FactSage thermodynamic calculations for the Si-C-N-O system (Fig. 1) indicate that, after heat treatment the stable phases are SiC, SiO$_2$ and Si$_3$N$_4$. In addition, Si is the stable phase at 1400°C, while it does not occur at lower temperatures. As the temperature increases the region of SiC stability enlarges towards the CO lower partial pressure. Si$_3$N$_4$ is the stable phase within a limited range of partial pressures of CO and N$_2$.

For the Al-C-N-O system (Fig. 2), the calculations show that Al$_4$C$_3$, Al$_2$O$_3$ and AlN are the stable phases at all temperatures. As the temperature increases, the Al$_4$C$_3$ stability region enlarges towards the CO lower partial pressure. AlN is a stable phase in a limited range of partial pressures of CO and N$_2$. With increasing temperature, the stability region of AlN shifts towards the lower partial pressure of CO.

Fig. 1: Predominance diagram for Si-C-N-O system
Fig. 2: Predominance diagram for Al-C-N-O system

XRD analysis for addition of Si showed that, heat treatment at 800°C and 1000°C is insufficient to form SiC as it was detected only after firing 1200°C and 1400°C (Fig. 3).

For Al addition, $Al_4C_3$ was detected in the samples 3% and 5% Al after treatment at 800°C and 1000°C. For sample 1%Al, $Al_4C_3$ was detected only after treatment at 1200°C and 1400°C. For 1%Al and 1400°C, metallic Al was not registered, probably due to its oxidation to $Al_2O_3$. In addition, after treatment at 1400°C, graphite was detected in all antioxidants-containing samples, which was most likely formed as a result of graphitization of amorphous C derived from carbon black and/or phenol-formaldehyde resin.

Fig. 3: Diffractogram for sample 5%Si after heat treatment at 1400°C

Fig. 4: Diffractogram for sample 5%Al after heat treatment in 800°C

Results of the modulus of elasticity (Fig. 5) shows that, Si addition decreases MOE. This tendency is very clear for samples after heat treatment at 800°C and 1000°C, while for samples after treatment at 1200°C and 1400°C this effect is slighter. On the other hand, for Al addition increases MOE. This effect is most pronounced for sample 5%Al after treatment at high temperatures of 1200°C and 1400°C. Raised temperature of heat treatment increases the MOE for both additives Si and Al.

The results of flexural strength (Fig. 6) and cold crushing strength (Fig. 7) follow the same trend as the results of the MOE (Fig. 5). MOE, MOR and CCS increase with the increased heat treatment temperature and Al addition, and decrease with Si addition. However, for SiC-containing samples (for 1200°C and 1400°C) greater amount of Si increases MOR and CCS. Znaczenie wysokiego MOE i MOR

Fig. 5: Results of modulus of elasticity

Fig. 6: Results of modulus of rapture

Fig. 7: Results of cold crushing strength

During the MOR test (three-point bending test), two types of stress arise in the sample: compressive in the upper parts of the sample and tensile in its lower parts, as presented in Fig. 8. The compressive stress strength of ceramic materials, including $Al_2O_3$-C refractory materials, is several times higher than the tensile stress strength. Hence, it can be assumed that the destruction of the sample in the three-point bending test occurs as a result of the tensile stresses generated in its lower parts. In the case of the CCS test, the destruction of the sample occurs as a result of the compressive stresses increased within the material with the raised load. For ductile materials, e.g. steel, the compressive stress strength is close to the tensile stress strength. However, as mentioned earlier, in the case of brittle materials like refractory materials the compressive strength is several times higher than the bending strength.

The CCS/MOR ratio (Fig. 9) allows for a general assessment of the material brittleness. The greater the CCS/MOR ratio the higher the brittleness of the material due to its high compressive strength

463

and low tensile strength. Based on Fig. 9 it can be concluded that, we can reduce the brittleness of the material via increasing the amount of Si or Al additions. Increasing the heat treatment temperature for both additives also increases brittleness. However, for Si addition after heat treatment at 1200°C and 1400°C, the modulus of elasticity decreases, and for Al addition it happens only after treatment at 1400°C.

Fig. 8: Stresses created in the sample during bending test

Fig. 9: Ratio of cold crushing strength to modulus of rapture (CCS/MOR)

For Si addition, the open porosity (Fig. 10) increases with increasing amount of this additive, and with increasing heat treatment to 1000°C. After heating at 1200°C and 1400°C, SiC whiskers were formed in the pores of the material, reducing open porosity. The opposite tendency was observed for bulk density (Fig. 11). For Si addition, bulk density decreased with increasing Si amount and with increased raised treatment temperature, while after heat treatment at 1200°C and 1400°C we observed a slight increase in density.

For Al addition, both open porosity (Fig. 10) and bulk density (Fig. 11) decrease with the increase of the Al amount and with the increased temperature.

Fig. 10: Results of open porosity

Fig. 11: Results of bulk density

## 4. CONCLUSIONS

Formation of SiC in $Al_2O_3$-C materials requires heat treatment at minimum 1200°C, while $Al_4C_3$ generates already at 800°C. Increasing the Si amount lowers MOE, while Al addition increases MOE. The formation of both carbides (SiC and $Al_4C_3$) is highly beneficial as it increases mechanical strength (both compression and bending) compared to the reference samples without Al, Si. The ratio CCS/MOR (expressing the brittleness of the material) shows that the formation of carbide bonds allows to decrease brittleness of material. It can also be assumed that by increasing the amount of carbide bonds in the material we reduce its brittleness.

## ABSTRACT

In this paper, a kind of Al$_2$O$_3$-C refractory was prepared with plate corundum, flake graphite, alumina powder and phenolic resin as raw materials. The influence of the amount of recycled refractory (mainly composed of Al$_2$O$_3$ and C) on mechanical properties was also studied. The results showed that, with the increase of recycled refractory addition, the apparent porosity of the Al$_2$O$_3$-C refractory increased and the strength decreased sharply. When the amount of recycled materials was 30 wt%, the hot modulus of rupture of the Al$_2$O$_3$-C refractory was 8.2 MPa. Subsequent studies found that the integral strength of Al$_2$O$_3$-C refractory with 30 wt% recycled refractory could be increased ~30% by supplement solid phenolic resin. Furthermore, the hot modulus of rupture of Al$_2$O$_3$-C refractory improved by ~12% by supplementing Si powder.

## 1.INTRUCTION

The steel industry is a critical industry in refractory material consumption and also the industry with the largest amount of waste refractory[1]. The waste of a large amount of refractory which had used not only leads to the waste of refractory resources, but also brings severe environmental pollution and land resource occupation through the landfill of refractory which had used. Fully utilizing the resources of refractory which had used by steel enterprises for research and utilization can not only significantly reduce the raw material cost of refractory, but also accelerate the construction of a steel circular economy system and build a green and environmentally friendly enterprise[2].

The recovery and utilization of solid waste refractory has also been a research hotspot for scholars at home and abroad. In addition, scholars have also used waste high alumina bricks, MgO-C bricks，MgO-Al$_2$O$_3$-C bricks fly ash, and other materials for effective utilization[3-5]. Continuous casting functional refractory materials mainly consist of alumina and carbon. Because of its harsh usage environment, the raw materials used are mostly high grade, such as fused corundum, high-purity flake graphite or fused magnesia alumina spinel, etc. Moreover, functional refractory materials have a short service life, rarely exceeding 24 hours. Therefore, steel mills consume a large amount of functional refractory materials every year. The parts of functional refractory materials that do not come into contact with molten steel suffer less oxidation damage and have high recyclability. If they are directly discarded, a large amount of high-quality alumina and graphite resources will be wasted[6-7]. But there are still few reports on its recycling research

This article first investigated the effect of adding functional refractory recycled materials for continuous casting on the performance of alumina carbon refractory materials for continuous casting. The phase composition, mechanical strength, and microstructure of the samples with added recycled materials were characterized. Then, by adjusting the amount of binder added and supplementing the Si powder operation, the room temperature strength and high temperature strength of the sample with 30 wt% recycled material were reinforced, laying the foundation for subsequent industrial experiments.

## 2 EXPERIMENTAL

### 2.1 raw materials

The raw materials used in this experimental sample were:
recycled refractory materials for continuous casting (refer to Table 2 for their chemical composition), and tabular corundum particles（0.6-0.2 mm，＜0.044 mm of powder，from Yingkou , China）、Flake graphite（C≥95 wt%，＜0.15 mm, from Shandong, China）、Industrial SiC powder（SiC≥98 wt%，＜0.045 mm, from Shandong, China）、Si powder (Si＞98 wt%，＜0.074 mm, from Shandong,

China) and Solid phenolic resin powder (＜0.106 mm, from Shandong, China). Industrial alcohol is a solid phenolic resin powder solvent. The purpose of adding industrial alcohol was to dissolve solid phenolic resin powder and make it act as a binder during the mixing process. During the subsequent drying process of the mud, alcohol will evaporate and be removed, which will not affect subsequent experiments. The selected part of the recycled refractory is not contact with the molten steel. That is, the part that is not contaminated by the molten steel and slag layer. After unified classification, crushing, ball milling and screening, the recycled material particles are crushed to a size of less than 1.5 mm. The specific particle size distribution is as follows Table 1. After crushing, the particle size range of 0.2-1 mm is relatively large in the recycled refractory. The obtained chemical analysis results of the recycled refractory were shown in Table 2.

**Table 1** Screening results after crushing of recycled materials

| Particle size range | ≥1.5 mm | 1.5 mm~1 mm | 1mm~0.5mm | 0.5mm ~0.1mm | ≤0.1mm |
|---|---|---|---|---|---|
| Mass fraction (wt%) | 0 | 16.3 | 26.31 | 49.2 | 8.15 |

**Table 2** Chemical composition of recycled refractory (wt%)

| SiO$_2$ | Al$_2$O$_3$ | MgO | ZrO$_2$ | SiC | Si | C | Others |
|---|---|---|---|---|---|---|---|
| 8.90 | 56.22 | 4.90 | 3.63 | 1.00 | 1.71 | 20.58 | 2.95 |

The main components of the recycled material are Al$_2$O$_3$, C, and SiO$_2$, in addition to a small amount of ZrO$_2$, SiC, and Si. However, even though its source and composition are similar to those of the three major refractory materials for continuous casting, after high-temperature sintering above 1500 °C, new phases such as mullite, spinel, and olivine may be formed in situ in the components of the refractory materials, including SiO$_2$, Al$_2$O$_3$, MgO, and other oxides. Because the recycled refractory originally contains Al$_2$O$_3$ and C, and the particle size distribution is relatively wide. when the recycled material is introduced into the original formula A0, the content of raw material plate corundum and flake graphite in A1, A2 and A3 will also change. The specific experimental formula is shown in Table 3.

**Table 3**. Formulation of raw materials for samples (wt%)

| Raw materials | specifications | A0 | A1 | A2 | A3 |
|---|---|---|---|---|---|
| Tabular alumina | 0.6-0.2 mm | 35% | 31% | 28% | 27% |
| Tabular alumina | ＜0.044 mm | 20% | 17% | 14% | 11% |
| α-Al$_2$O$_3$ powder | 5 μm | 5% | 4% | 3% | 2% |
| Flake graphite | ＜0.15 mm | 22% | 20 | 18% | 16% |
| Solid phenolic resin | ＜0.106 mm | 10% | 10% | 10% | 10% |
| Industrial SiC powder | ＜0.045 mm | 6% | 6% | 6% | 6% |
| Si powder | ＜0.074 mm | 2% | 2% | 2% | 2% |
| Industrial alcohol (plus) | | | 6% | 6% | 6% | 6% |
| Recycled refractory | | 0% | 10% | 20% | 30% |

The sample preparation method is to mix the solid raw materials evenly in a forced countercurrent mixer, add an appropriate amount of alcohol, and then the mud is granulated at high speed for about 15 min. Subsequently, the sample was compressed and formed into 220 mm× 160 mm × 80mm square bricks under 120 MPa isostatic pressure (equipped with LDJ830/2500-300YS static press machine from AVIC Chuanxi Machinery Factory, from China). Finally, each sample was dried at 200 ° C for 12 hours and coked in carbon

465

embedded atmosphere at 1000 °C for 3 hours.

## 2.2 Characterization and testing

With reference to the Chinese National Standard GB/T 2997-2015, the apparent porosity and bulk density of samples were separately measured by the vacuum method (water as the test medium). With reference to the Chinese National Standard GB/T 5072-2008, a universal testing machine (WDW-100, China; a loading rate of 0.5 mm·min⁻¹) was used to measure the cold compressive strength of the cured samples and the coked samples. Reference to the Chinese National Standard GB/T3001-2000, the cold modulus of rupture was measured by flexural testing machine. Reference to the Chinese National Standard GB/T3002-2017, the hot modulus of rupture was measured by high temperature flexural testing machine and the samples coked in carbon embedded atmosphere at 1450 °C for 0.5 hours during the test. The refractory samples after coking at 1000 °C were crushed, ground, and sieved (200 mesh) to prepare fine powder samples that meet XRD test standards, and the phase composition was analyzed by an X-ray diffractometer (XRD, Bruker D8, Germany; a scan rate of 4 °/min, from 15° to 75°). The micromorphology of the polished and fracture surfaces of the coked samples was characterized by a scanning electron microscope (SEM, JSM6360, Japan), and their microstructure and element distribution were analyzed by an energy dispersive spectrometer (EDS, Ultim Max, England).

## 3. RESULTS AND DISCUSSION

### 3.1 Effect of adding recycled refractory on phase and particle grading

The screening statistics of mud after mixing of sample A0, A1, A2, and A3 were shown in Table 4.

**Table 4**: Results of mud sieving for sample A0, A1, A2 and A3

| Sample | ≥1.5 mm | 1.5 mm~1 mm | 1 mm~0.5 mm | 0.5mm~0.1mm | ≤0.1mm |
|--------|---------|-------------|-------------|-------------|--------|
| A0 | 0 | 4.01 | 12.05 | 82.32 | 1.62 |
| A1 | 0 | 7.26 | 22.46 | 68.06 | 2.22 |
| A2 | 0 | 8.48 | 20.89 | 66.89 | 3.77 |
| A3 | 0 | 9.29 | 23.29 | 60.66 | 6.76 |

*Fig.1 XRD patterns of the refractory samples coked at 1000 °C for 3 h*

With the amount of recycled refractory added increases, the proportion of aggregate (2-1mm) and fine powder (≤ 0.1mm) in the mud were increased. This is related to the particle size distribution of the recycled refractory itself, even though the muds undergoes high-speed rotation granulation process, some fine powder still was residue.

After coking at 1000 °C, the XRD analysis of samples A1, A2, and A3 with added recycled refractory was carried out. In order to eliminate the influence of C peak, each ample was pre-oxidized at 800 °C for decarbonization.

The XRD analysis pattern is shown in Fig 1. The main components of the three samples are $\alpha$-$Al_2O_3$, with a small amount of Si and SiC. The three samples have a large amount of amorphous glass phase in the range of 10-20 °, which is due to the presence of amorphous $SiO_2$ of the recycled refractory. With the amount of recycled refractory added increases, the increase in peak intensity of $\beta$-$Al_2O_3$ and the appearance of magnesia alumina spinel phase in A3 sample indicate

an increase in the content of Na and Mg elements in the system. The introduction of recycled refractory makes the reaction more complex in the system at high temperatures.

Through SEM analysis which was shown in Fig 2, it can be seen that the particle distribution in sample A3 with added recycled refractory is uneven, and the resin wrapping situation of sample A3 is not as good as A0. Moreover, the particle size range in A3 is large, and it is obvious that there are more fine particles and some particle surfaces are irregular. There are still impurity phases between the particles.

Fig 2 SEM images of polished surfaces of the refractory samples coked at 1000 °C for 3 h

### 3.2 Effect of adding recycled refractory on the performance of refractory

*Fig 3 Bulk density and apparent porosity of refractory samples coked at 1000 °C for 3h*

Fig 3 shows the bulk density and apparent porosity of samples A0, A1, A2, and A3 after coking at 1000 °C. The overall porosity is controlled between 16.0% and 16.5%. With the amount of recycled refractory added increases, the bulk density of the sample gradually decreases. The decrease in bulk density is due to the presence of other minerals such as $SiO_2$ and $Na_2O$ in the recycled refractory. Although the recycled material contains components with high bulk density such as MgO and $ZrO_2$, the total volume of the sample increases with the addition of recycled refractory under equal mass replacement.

The results of the amount of recycled refractory added and the mechanical strength are shown in Fig 4 and Fig 5. With the amount of recycled material added increases, the cold compressive strength (39.43 MPa, 35.19 MPa, 31.22 MPa, 24.56 MPa), cold modules of rupture (12.8 MPa, 11.7 MPa, 10.1 MPa, 8.8 MPa), and hot modules of rupture (14.1 MPa, 13.2 MPa, 11.9 MPa, 8.2 MPa) of the samples were all decreased.

The hot modules of rupture of samples A0, A1, and A2 have been improved compared to the cold modules of rupture. This may be due to the expansion of particles in the system at high temperatures, which enhances the internal structural stress. The main reason for the decrease in strength of A3 is that the recycled refractory contains many impurities, such as $SiO_2$, $Na_2O$, $K_2O$, etc. The impurity phase reduces the melting point of refractory, especially the formation of liquid phases at grain boundaries, leading to the generation of cracks. These two effects coexist, and as the amount of recycled refractory added increases, the decrease in strength caused by impurities dominates.
*Fig 4 Cold compressive strength and cold modulus of rupture of refractory samples coked at 1000 °C for 3h*

The introduction of impurities is an inevitable problem when using recycled refractory. Compared to the corundum-graphite system without recycled materials, the introduction of impurity phases increases the complexity of the components in the system. At the same time, these components are prone to react with the refractory system $Al_2O_3$, MgO, or $SiO_2$ to form a low melting point liquid phase, causing internal structural damage and thereby affecting the strength.

*Fig 5 Hot modulus of rupture of refractory samples coked at 1450 °C for 0.5 h*

When added 30 wt% recycled refractory (sample A3) in this experiment, compared with sample A0, the cold compressive strength decreased by ~37% and the cold modulus of rupture decreased by ~31%. hot modulus of rupture of A3 (8.2 MPa) has decreased by about 42% compared to A0 (14.1 MPa).

*Fig 6 SEM images and elemental distribution of polished surfaces of the refractory samples A3*

Through SEM and EDS analysis of sample A3 (refer to Fig 6). As is well known, with the increase of Na and Si content in refractory, the melting point of the system decreases sharply, and some areas are prone to the formation of low melting point phases that affect the strength. This can also explain why the high-temperature strength of A3 samples decreases more.

### 3.3 Effect of binder addition on strength of refractory sample

The addition of recycled materials will cause a decrease in the strength of the sample, and with the amount of recycled refractory added increase, the degree of weakening will also increase. The strength of refractory materials, especially high-temperature strength, is an important performance that affects the service life of refractory. The higher the high-temperature strength of the submerged entry nozzle slag line, the smaller the limit thickness of residual slag line damage. Research has shown that increasing the strength of carbon-containing refractory materials involves the addition of nanoscale additives[], nano carbon sources[], etc. Such additives are often highly effective but too expensive. The purpose of introducing

recycled refractory aim to scrap refractory for secondary utilization, mainly reflected in two aspects: environmental protection and cost reduction. Moreover, the main characteristics of continuous casting functional refractory materials are high carbon content and small particle size. On the one hand, the results in internal strength of A3 coming from the residual "carbon mesh" structure after resin curing, which is carbon bonding. The introduction of recycled materials has increased the proportion of coarse aggregate and fine powder in the formula. The difficulty of resin adhesion during material mixing and subsequent granulation processes has been increased. On the other hand, the specific surface area (roughness) and shape regularity of the particles in the raw material of the recycled refractory also different compared to conventional board corundum raw materials. It may have an impact on the bonding strength between particles. Therefore, based on sample A3, an experiment was designed to increase the amount of binder added, with the aim of improving the bonding strength between materials. Compared to A3, other samples only change the amount of resin added, without changing the amount of other raw materials added, and the increase in binder is based on A3 as a reference.

**Table 5** Supplement of solid phenolic resin in each sample

| Samples | A3 | A4 | A5 | A6 | A7 |
|---|---|---|---|---|---|
| Supplement the amount of phenolic resin | 0% | 0.5% | 1% | 1.5% | 2% |

The bulk density, mechanical properties at room temperature and hot modulus of rupture of the samples were tested. Samples A3~A7 were formed under the same conditions and tested simultaneously, rather than intentionally controlling the apparent porosity as in Experiment 1. The purpose is to minimize the impact of environmental factors on the experiment and further explore the impact of resin addition on the sample. The test results are as follows Fig 7, Fig 8 and Fig 9.

*Fig 7 Effect of phenolic resin addition on the apparent porosity and bulk density of the refractory samples*

The apparent porosity and strength of the sample first increase and then decrease with the increase of the amount of phenolic resin powder added. Bulk density decreases first and then increases.

*Fig 8 Effect of phenolic resin addition on the mechanical properties of the refractory sample at room temperature*

The results confirm the previous hypothesis that the introduction of recycled refractory has increased the difficulty of material binding. Increasing the proportion of binder, it can make the binder more fully encapsulate particles. The decrease in apparent porosity also indicates that the sample particles are more tightly packed. The increase in strength comes from the tighter carbon mesh structure generated after resin heat treatment. However, excessive addition of phenolic resin can

affect the quality of the sample. The excess of phenolic resin, resulting in resin agglomeration during the mixing process, which is equivalent to mixing resin particles in the sample. After coking, the strength of the resin agglomeration area decreases significantly due to the lack of particle fixation, making it easier to generate cracks from inside.

*Fig 9 Effect of phenolic resin addition on the hot modulus of rupture of the refractory samples*

In this experiment, sample A5 had the highest cold compressive strength, cold modulus of rupture, and hot modulus of rupture, which were 40.95 MPa, 12.8 MPa, and 12.4 MPa, respectively. Compared to sample A3, the strength of sample A5 has increased by ~30%.

## 3.4 The effect of supplementing Si powder

Si powder is a kind of commonly used additive for the industrial production of carbon-containing refractory. Previous studies have found that Si powder can improve the antioxidant and toughening effects of carbon-containing materials at high temperatures. Compared to high-end additives, it is easier to complete the conversion from laboratory to product by adding Si powder from a cost perspective. This formula contains Si powder (2 wt%), which is mainly added as an antioxidant. Therefore, under the material ratio of experimental sample A5 mentioned above, Si powder was added to it to explore the effect of Si powder addition on the high-temperature mechanical properties of the sample. Samples A5, A8, A9, and A10 were formed and tested under the same conditions.

**Table 6** Supplement amount of Si powder in each sample

| Samples | A5 | A8 | A9 | A10 |
|---------|----|----|----|-----|
| Si powder | 0% | 1% | 2% | 3% |

*Fig 10 Effect of supplement amount of Si powder on hot modulus of rupture of refractory sample*

From Fig 10, with the amount of Si powder increases, the hot modulus of rupture showed an upward trend. When the amount of Si powder is 2 wt%, the hot modulus of rupture is highest. During the heating and insulation process of Si powder at 1450 ℃, the internal Si and carbon components of the material react in situ to generate SiC, which enhances the strength of the sample. The reaction mechanism is based on formulas (4) and (5).

$$SiO_2(s)+3C(s) \rightarrow SiC(s)+2CO(g) \qquad (1)$$
$$\Delta G_{R1}=603150-331.98T+2RT\ln(P_{CO}/P_O) \qquad (2)$$
After adding 2 wt% Si powder to sample A9, the hot modulus of rupture increased to 13.8 MPa. The reason for continuing to supplement Si powder without improving its strength may be that the vacancies generated by SiC whiskers are allowed to approach saturation, while introducing more fine powder reduces the binding ability. Fig 11 shows the microstructure photos of the fracture surfaces of A5, A8, and A9 samples after the hot modulus of rupture test. There is no whisker formation between A5 grains, while shorter

whiskers are formed between A8 grains, and the length of A9 whiskers is significantly increased. The generated SiC is in the form of whiskers, which fixes the structural gaps of the matrix, suppresses crack propagation, and improves material strength. However, due to the high carbon content of the sample, particles are easily separated by graphite layers, which limits the space for whisker generation and does not significantly improve the high-temperature flexural strength. The experimental results are consistent with the previous experimental conclusions.

*Fig 11 SEM images of fracture surfaces of the refractory samples after hot modulus of rupture*

## 4. CONCLUSION

(1) Replacing raw materials with recycled materials to prepare alumina carbon refractory can cause a decrease in both cold strength and high temperature strength, and the degree of decrease increases with the addition of recycled materials. The main reasons are the irregular particles of recycled materials, large particle size distribution range and more impurities.

(2) In this experiment, increasing the amount of binder appropriately can improve the strength of alumina carbon refractory. When an additional 1wt% of solid phenolic resin is added, the strength improvement ~30%. However, excessive addition can cause a decrease in strength.

(3) After appropriate supplementation of Si powder, SiC whiskers are generated in situ in aluminum carbon refractory materials, and as the amount of Si powder supplementation increases, the amount of SiC whiskers generated increases. When the amount of Si powder added is 2wt%, the high-temperature flexural strength reaches its maximum, but the effect of excessive addition of Si powder may not be significant due to the limited vacancies that generate SiC whiskers.

# DEVELOPMENT AND IMPLEMENTATION OF HOLISTIC APPROACH TO ADDRESS CLOGGING PHENOMENA IN CONTINUOUS CASTING OF STEEL FOR VESUVIUS FLOW CONTROL CUSTOMER

Ata Fallah-Mehrjardi; Taigo Dos Santos; Andrzej Warchal; Camille Reynaert; David Dumont

VESUVIUS, Ghlin, Belgium

Fraction, size, type, and morphology of non-metallic inclusions (NMIs) in steel impact steel cleanliness i.e. steel quality (defects formation in semi-finished products) and productivity of continuous casting ( longer casting sequence for a given steel grade). Clogging in casting channels of tundish shrouds (SEN/SES/MTSP) are a complex phenomenon in Al-killed steel grades that was studied previously via characterization of industrial samples, experimental and modelling approach..

To ascertain information on the root causes of clogging phenomenon and to develop anti-clogging solutions consequently, a diagnostic approach was used in the present study to identify (1) reactions occurred in upstream & downstream processes, (2) sources of oxidative agents and (3) clogging mechanisms. To audit the casting process and build the baseline, industrial steel samples and compositions (mainly ultra-low carbon) from ladle/tundish/product and used nozzles (SEN/SES/MTSP) were recovered and analyzed iteratively.

Some steelmakers and refractory suppliers have approached the clogging problem via using solely a different SEN/SES/MTSP. This study, however, indicates the importance of applying the holistic approach to identify the contributing factors from ladle to mold/products and apply refractory solutions accordingly.

# SUBMERGED ENTRY NOZZLE PREHEATING EFFECT ON ITS PERMEABILITY

Emmanuel de Bilbao

## ABSTRACT

The submerged entry nozzle (SEN) plays a key role in continuous casting and its clogging has been discussed for a long time without converging to a real consensus about the reasons of the clogging and the effect on the steel quality. The preheating of this consumable materials is achieved thanks to air/natural gas burners placed inside the outlet ports of the nozzle. Due to the carbon content (>20%), those materials are sensitive to oxidizing atmosphere above > 500 °C. To avoid the decomposition of the graphite, the nozzle is coated with a borosilicate glass, which melts upon heating to form a viscous phase impermeable to gas to protect the graphite material from oxygen contact. However due to the abrasive flame of the burner, the protective glaze can be eroded and the core material decomposed in contact with surrounding oxygen. In this study, the effect of the preheating of the SEN on its permeability was addressed. The permeability of SEN refractory material was measured before and after preheating operations with preheating temperature ranging between 400 and 1000 °C and preheating period for 1 and 6 hours. It was found that permeability of preheated material at 400 °C was very close to not preheated material of 3-4 milli-Darcies while it increased up to 184 mD for the sample preheated at 1000 °C for 6 hours. The results confirmed air ingress through the SEN refractory material due to permeability increase may be one of the causes.

## INTRODUCTION

Submerged entry nozzle (SEN) clogging is a critical issue as it affects productivity of continuous casting process and quality of product. The causes of SEN clogging were extensively investigated and it has been now admitted clogging results in a combination of four mechanisms [1]:

- Agglomeration and sintering of deoxidation products,
- Freezing of liquid steel and build-up of solid steel
- Agglomeration of complex oxides
- Reaction products deposited in a film

The build-up of the reaction products results from the reaction between the deoxidant and i) oxygen from the steel, ii) oxygen produced by silica refractory decomposition, or iii) air flowing through nozzle porosity and driven by negative gauge pressure induced by liquid steel flow.

Very few studies focused on the air flow through nozzle refractory and the effect of the permeability. Poirier et al. observed that SEN permeability increased when the glaze coating which protects the nozzle during preheating contained defects. The authors also reported increased permeability allowed the air flow through the nozzle refractory and the oxidation of the carbon contained in the refractory, the aluminium which did not deoxidized the metal as well as the steel itself [2].

However other studies concluded that refractory permeability did play a role in nozzle clogging. For instance, Singh et al. argued accretions were found in the inner volume of the submerged part which is not in contact with air [3] and Tuttle et al. calculated the time it would take to grow the accretions observed in the lab-scale nozzle used in a casting simulator and observed it was much longer than the experimental time [4]. These latter concluded that air transport through the nozzle could not be the main raison of the clogging and permeability was not a relevant property.

The permeability role in the SEN clogging is still questionable in the case of a sound nozzle. However, if the preheating performed with natural gas burners generates hot spot in the material and local

decarburization, it can be assumed that the contribution of air ingress to clogging mechanisms becomes significant.

The preheating treatment requires to properly follow specific recommendations. In particular the temperature should not be higher than 1200 °C for the considered SEN and the nominal treatment should be at 1000 °C for 1h30. In practice these recommendations are hard to achieve and the temperature is not homogeneous in the height of the SEN, causing the glaze to be partially destroyed. Considering that permeability may have a significant impact on clogging process, the effect of the preheating of the SEN on this property was addressed.

## MATERIALS AND METHODS

### Sample preparation

Submerged entry nozzle (SEN) studied in this work was mainly made of corundum with graphite matrix. The 20 mm thick refractory body was coated outside with a glaze preventing decarburization during SEN preheating. The inner wall was protected by a liner mainly made of silica, alumina, and graphite and a thin vitreous phase-based layer.

The samples for permeability measurement were retrieved in the part of SEN in contact with air and had a diameter of 35 mm and a thickness of 25 mm (Fig. 1). The outer liner and the glaze based inner layer were removed to keep refractory body with the $SiO_2$-$Al_2O_3$-C liner.

*Fig. 1: Samples for permeability measurement retrieved in SEN part in contact with air (dashed green rectangle)*

### Preheating treatment

Samples were preheated at different temperatures, no preheating, 400 °C, 600 °C, 800 °C, and 1000 °C, and for two different times, 1 and 6 hours. For each temperature/duration couple, 3 samples were tested.

The samples were put into the furnace before heating and removed after free cooling to avoid crack formation.

### Permeability measurement

Intrinsic permeability is the property inherent to the material relating the pressure drop to the flow rate according the Darcy law. Different techniques have been developed to measure it: with gas or liquid and

in unsteady state or steady state conditions. Gas permeability measurement in steady state conditions is the technique used in standards ISO 8841:1991, DIN EN 993-4, and ASTM C577- 7 [5,6]. It consists in measuring the inlet pressure Pi, the outlet pressure Po, and the volumetric flow rate Q of the gas flowing through the sample and to derive the permeability parameters (Fig. 2).

*Fig. 2: Principle of permeability measurement in steady state conditions*

The integrated form of gas flow equation applied to the test in steady-state conditions depends on the flow regime. According to Darcy, Klinkenberg, and Forchheimer [7–9], its general form writes:

$$\frac{P_i{}^2 - P_o{}^2}{2PL} = \frac{\mu}{k_\infty \left(1 + \frac{b}{P_m}\right)} v + \frac{\rho}{k_2} v^2 \qquad (1)$$

where $L$ is the sample thickness. Contrary to the standards, the pressure drop is expressed in function of the squared pressure due to the gas compressibility. The gas velocity $v$, or flow rate, varies from the entrance to the exit because of the pressure gradient and the gas compressibility. $P$ is the absolute gas pressure for which the flow rate $v$ is evaluated, that is $P_i$ or $P_o$ for $v_i$ or $v_o$ respectively. $v$ is derived from the volumetric flow rate $Q$ per cross-sectional area of the sample perpendicular to the flow. The dynamic viscosity of the gas $\mu$ is assumed to be constant within the applied pressure range. $k_\infty$ is called the intrinsic permeability and is expected to be the permeability one would measure with liquid. The slippage factor $b$ accounts for the slippage of gas molecules and depends on both the molecular mean free path and characteristic length of pore geometry. $P_m$ is the mean pressure of $P_i$ and $P_o$.

The second right-hand side term of the equation accounts for inertial effects due to dissipation of inertial energy as fluid particles accelerate through smaller pore throats and decelerate through larger area. Although $k_2$ has the dimension of a length, it is called the non-Darcian or inertial permeability.

The standards mentioned above recommend permeability measurement in atmospheric mode, for which the exit is left at atmospheric pressure and the gas leaving the sample is thereby allowed to flow directly at this pressure. The flow rate is measured at the outlet of the sample and $P = P_o$ in equation 1. In addition, it is assumed that the mean pressure equals 1 atm. as the pressure drop is very small. However, the methods proposed by the standards do not allow for determining the intrinsic permeability and the slippage factor. It is possible to extend the standard method by applying increasing inlet pressure to get different sets of triplets ($Pi$, $Po$, $v_o$). However, the determination of the three parameters is very inaccurate when increasing inlet pressure and letting the outlet at atmospheric pressure because inertial effect may be activated and it becomes impossible to properly determine the intrinsic permeability $k_\infty$ and the slippage factor $b$.

An improved gas permeameter has been then developed to fix this issue [10]. It includes a mass flow controller put at the inlet to control the flow regime and valves put at the outlet to apply a backpressure if needed (Fig. 3). Controlling the flow regime allows to make one of the right-hand terms of equation 1 predominant with respect to the other one and to determine therefore the selected parameter i.e., the intrinsic permeability $k_\infty$ and the slippage factor $b$ or the inertial factor $k_2$. Determining the Klinkenberg factor may require to apply backpressure at the outlet to increase the measurement accuracy.

*Fig. 3: Gas permeameter developped for accurate measurement of intrinsic permeability*

## RESULTS AND DISCUSSION

The permeability measurement of the 3 not preheated samples was performed letting the outlet at atmospheric pressure as their permeability was low. The pressure drop followed a parabolic behaviour with the flow rate indicating inertial effect was significant for flow rate over 1 mm/s (red diamonds in Fig. 4).

*Fig. 4: Darcy plot of one of the three not preheated samples*

Fig. 5 plots the apparent permeability $k_a$ calculated according to equation 2 which is derived from equation 1 but not taking into account the inertial term with the reciprocal mean pressure $P_m$.

$$k_a = \frac{2P_iL}{P_i{}^2 - P_o{}^2} \cdot \mu \cdot v = k_\infty \left(1 + \frac{b}{P_m}\right) \qquad (2)$$

The green circles correspond to the 4 lowest flow rates for which the turbulent flow in the porous network was negligible while the red diamonds were derived from measurements performed in turbulent regime. Indeed, the turbulent flow rate consumes flow energy without "helping" the gas to go toward the outlet and leads to an underestimated apparent permeability. The intrinsic permeability was derived with a linear regression using the measures obtained in Darcy-Klinkenberg flow regime i.e., from the green circles. For the sample presented in the figures the intrinsic permeability was 1.2 mD. Finally, the intrinsic permeability of the three not preheated samples ranged from 0.95 to 1.65 mD.
*Fig. 5: Apparent permeability of one the three not preheated samples*

Figure Fig. 6 shows the Darcy plot for a sample preheated at 1000 °C for 6 h. At low flow rate the measures do not follow the Darcy-Klinkenberg model as the point alignment does not seem to cross the origin. It can be explained either by a diffusive regime of by gaz creep contribution. On the other hand, measurements performed with higher flow do not present a parabolic shape characteristic of a turbulent flow. Trying to fit a parabolic function representative of equation 1 gave a negative quadratic coefficient which does not make sense. The Klinkenberg plot confirms that the points at low flow rate do not obey to a Darcian flow (Fig. 7, red diamonds). Performing measurements in back pressure mode using the valves located at the outlet of the permeameter and controlling the flow rate made it possible to increase the mean pressure in the sample and to activate the Klinkenberg effect (green squares). It was possible to include measures obtained in atmospheric mode for the linear regression (green circles). The derived intrinsic permeability was 146 mD. The permeability of the two other tested sample with the same treatment was 193 and 213 mD (Tab. 1)).

Additionally, the slippage factor *b* in equation 1 account for the gas slippage on the pore wall when the characteristic pore size is close to the molecular mean free path. For given flow rate and pressure drop the higher the pore size the higher slippage factor. The slippage factor of the preheated sample (1000 °C for 6 h) was 114 kPa, almost 25 times the one of not preheated sample, 4.69 kPa. It is clear that the slippage factor increase may be explained by the pore size increase induced by the oxidation. Another point confirming the pore size increase is the activation of the turbulent flow with the not preheated sample from 1 mm/s while the almost laminar Darcy-Klinkenberg flow still predominates with the flow rate of 15 mm/s.

*Fig. 6: Darcy plot of one of the three samples preheated at 1000 °C for 6 h.*

*Fig. 7: Apparent permeability of one the three samples preheated at 1000 °C for 6 h*

*Fig. 8: Evolution of the intrinsic permeability with temperature*

Finally figure Fig. 8 shows the evolution of the intrinsic permeability with the preheating temperature for the two durations. All the values are also summarized in Tab. 1. As expected, the permeability increases with treatment temperature assuming the oxidation rate also increases with temperature. The points do not lie on a straight line although the permeability increase seems to be thermally activated. Here the increase of the permeability is due to the decarburization of the material. As the graphite flakes burn, they generate porosity which contributes to the material gas permeability. The oxidation of the carbon content is starting >500°C.

*Tab. 1: Intrinsic permeability measured on not preheated samples and heated samples from 400 °C to 1000 °C for 1 and 6 hours*

| | | $k_\infty$ (mD) | | |
|---|---|---|---|---|
| | | Sample 1 | *Sample 2* | Sample 3 |
| | Not preheated | 1.21 | 1.61 | 0.95 |
| 1 h | 400 °C | 2.69 | | |
| | 600 °C | 8.23 | 9.22 | 7.02 |
| | 800 °C | 22.7 | 17.1 | 22.2 |
| | 1000 °C | 71.6 | 46.8 | 65.7 |
| 6 h | 400 °C | 4.31 | 4.25 | 4.87 |
| | 600 °C | 12.6 | 15.9 | 15.2 |
| | 800 °C | 137 | 119 | 141 |
| | 1000 °C | 146 | 193 | 213 |

## CONCLUSIONS

The permeability of refractory body of submerged entry nozzle was measured as a function of the preheating temperature and time. It was observed that the permeability increased significantly with temperature and time due to the decarburization of the graphite content. The highest value was obtained for the test at 1000 °C for 6 h and was two orders of magnitude higher than the one of material before preheating.

This work may help to determine the contribution of air transfer in clogging process with respect to the other causes. It can be expected that actual permeability at high temperature increase and make the air transfer even more significant. Measuring accurately the permeability at high temperature is still a challenge for the future work.

# INHIBITION OF ABNORMAL DAMAGE OF CAO–ZRO$_2$–C MATERIAL FOR SUBMERGED ENTRY NOZZLES

Hironobu Miura, Wei Lin, Takayuki Matsunaga and Toshio Horiuchi

Research Center, Shinagawa Refractories Co., Ltd., Bizen-city, Japan

## ABSTRACT

The CaO-ZrO$_2$-C (CZ-C) inner linings of submerged entry nozzles were found to be damaged abnormally fast in one actual continuous slab-casting process. A significant quantity of ZrC was formed and the original graphite disappeared in the CZ-C microstructure, so the microstructure deteriorated severely. It is considered necessary to find countermeasures to inhibit ZrC formation reaction even under conditions of low CO partial pressure in order to prevent the abnormal damage of CZ-C. For this purpose, fundamental research on the effects of adding Al$_2$O$_3$ and MgO compositions into CZ-C was implemented in the present study. In a heating experiment under Ar atmosphere, the quantity of ZrC formed in the spinel (5%)-added specimen, especially in the (spinel+Al$_2$O$_3$) (5% each)-added specimen was clearly smaller than that in the conventional CZ-C material. EPMA analysis indicated that low-melting phases of Al$_2$O$_3$-CaO system were formed in the above-mentioned two specimens, coating the CZ, ZrO$_2$ and ZrC grains and simultaneously enhancing the densification of the microstructure, whereas the conventional CZ-C exhibited a microstructure in which ZrC was present in isolation between the CZ grains. On the other hand, in a molten steel-dipping experiment, both specimens maintained good alumina deposition resistance, similar to the conventional CZ-C.

## INTRODUCTION

Submerged entry nozzles are applied to introduce molten steel from the tundish into mold in the continuous casting of steel. Alumina-silica-carbon (Al$_2$O$_3$-SiO$_2$-C), having excellent resistance to both spalling and corrosion, is commonly employed as the nozzle material. However, when using Al$_2$O$_3$-SiO$_2$-C nozzles in the casting of Al-killed steel, as is well known, the phenomenon of alumina deposition on the inner wall of the nozzles, i.e, nozzle clogging often occurs.

Since the alumina deposition greatly worsens the stability of the casting operations and steel quality, many studies have been carried out on the causes and preventive measures [1-5]. The measures include the Ca-treatment of Al-killed steel, blowing argon gas through the nozzles into the molten steel and optimization of the nozzle structures and materials. As an anti-alumina deposition material, CaO-ZrO$_2$-C (CZ-C) is frequently utilized for the nozzle inner wall, focusing on the fact that CaO composition reacts with the Al$_2$O$_3$ from the molten steel to form molten phases [6]. The major component of CZ-C material is calcium zirconate CaZrO$_3$ (CZ), which has a sufficient hydration resistance.

The CZ-C nozzles usually show high performance, e.g., neither abnormal damage nor alumina deposition occur even when casting steel for more than 20 heat. However, it was found that the CaO-ZrO$_2$-C (CZ-C) inner linings are damaged abnormally fast in one actual continuous slab-casting process; specifically, the inner linings with a thickness of several millimeters are almost completely washed away after only about 2 heats cast. It has become a technical challenge to prevent the abnormal damage of CZ-C inner linings.

Since the nozzle inner linings of other materials (e.g. Al$_2$O$_3$-C, spinel-C) do not show such abnormal damage during pouring various steel grades in the same casting process, the abnormal damage of CZ-C linings can be inferred to be not solely caused by the wear due to the molten steel flow. Analyzing the microstructure of the residual CZ-C on the nozzles after use, it was observed that a significant quantity of ZrC was formed and nearly all of the original graphite disappeared, and as a result the microstructure deteriorated severely (figure 1). This microstructure was totally different from the case where no abnormal damage occurred in the inner linings of CZ-C [6].

*Fig.1: Optical microstructure of CZ-C inner lining of a nozzle used in an actual continuous slab-casting.*

This abnormal damage is considered to be closely related to the ZrC formation reaction as shown in equation (1). That is, because the reaction results in the ZrC formation and graphite disappearance and therefore the microstructural deterioration, the CZ-C inner linings are easily worn by the molten steel flow.

$$(ZrO_2)_{\text{ in CZ}}+3C(s)=ZrC(s)+2CO(g) \tag{1}$$
As equation (1) is a reaction producing CO gas, the lower the partial pressure of CO in the atmosphere relative to the equilibrium CO partial pressure of the reaction, the faster it will proceed. Therefore, the CO partial pressure in the CZ-C inner linings should be rather low in the casting process where abnormal damage has occurred in the inner linings of CZ-C.

Consequently, it is necessary to find countermeasures to inhibit the ZrC formation reaction even under the condition of extremely low CO partial pressure in order to prevent abnormal damage of CZ-C. For this purpose, fundamental research on the effects of adding Al$_2$O$_3$ and MgO compositions into the CZ-C was carried out in the present study.

## EXPERIMENTAL METHODS

Specimens included the conventional CZ-C material, spinel (MgAl$_2$O$_4$)-5% added Specimen 1, and both spinel and Al$_2$O$_3$-5% added Specimen 2 (table 1). All contained 25% graphite. The specimens were made through a process in which a mixture of the raw materials was molded by cold isostatic pressing (CIP) and then fired in a coke breeze at 1000 °C for 3 hours.

Tab. 1: Components of specimens (mass %).

| - | Conventional CZ-C | Specimen 1 | Specimen 2 |
|---|---|---|---|
| Graphite | 25 | 25 | 25 |
| CZ (CaZrO$_3$) | 75 | 70 | 65 |
| Spinel (MgAl$_2$O$_4$) | - | 5 | 5 |
| Al$_2$O$_3$ | - | - | 5 |

For the evaluation of the ZrC formation tendency at low atmospheric partial pressure of CO gas, a heating experiment in an Ar atmosphere was conducted using an electric furnace with high sealing performance, of which the heating element was graphite.

Specimens (20×20×35 mm) were set into the furnace, followed by vacuuming the furnace and introducing a high-purity Ar gas at a

flow rate of 1 L/min. Then the temperature was raised to 1560 °C at 10 °C /min and held for 3 hours. Next, the specimens were cooled rapidly in the furnace by turning off the furnace power. For the specimens after the heating experiment, the rate of change in weight was measured, and the mineral phases were identified with XRD analysis. The microstructure was also analyzed by means of EPMA.

Moreover, an experiment for evaluation of alumina deposition resistance was carried out by using a molten steel-dipping method. 22 kg of steel was melted under an Ar atmosphere in a high-frequency induction furnace, equipped with an MgO crucible, followed by adding 0.12% metal Al and stirring the molten steel. After the temperature was kept at around 1560 °C, the specimens (cuboid of 20×20 mm) were simultaneously dipped into the molten steel for 1 hour. For a comparison, a common $Al_2O_3$-$SiO_2$-C material ($SiO_2$: 20%, C: 25%) was also adopted as a dipping specimen. The alumina deposition state and microstructure of the specimens after the dipping experiment were observed. According to the experimental results so far, it has been known that ZrC does not formed in the conventional CZ-C specimen in the dipping experiment. Hence, the influence of the additives (spinel, $Al_2O_3$) on the alumina deposition resistance of CZ-C under conditions where no ZrC is generated can be investigated by this experimental method.

## RESULTS

### Evaluation of ZrC formation tendency

The apparent porosity of the specimens before the experiment (after the firing) was 14.8% (the conventional CZ-C), 14.7% (Specimen 1) and 15.1% (Specimen 2), respectively. The values were all within the normal range, and the differences among the specimens were small.

After the Ar atmosphere-heating experiment, the weight of each specimen was reduced compared to before the experiment. The rate of weight reduction of the conventional CZ-C was the largest, reaching 4.64%, followed by 4.19% for Specimen 1 and 2.10% for Specimen 2. The indexed values based on the conventional CZ-C were 100, 90 and 45, respectively (figure 2). Specimen 2 was 55% lower than the conventional.

*Fig.2: Index values of characteristics of specimens after heating experiment (under Ar at 1560 $^0$C for 3 hours).*

The XRD analysis results of the samples taken from the longitudinal middle positions of the specimens after the heating experiment revealed that ZrC was formed in each specimen, and the phases except ZrC were mainly CZ ($CaZrO_3$), graphite and $ZrO_2$(c) (figure 3). The intensity of ZrC XRD strongest peak indexed based on the conventional CZ-C was 81 for Specimen 1, and 32 for Specimen 2, which was 68% lower than the conventional (figure 2). This was consistent with the above-mentioned variation tendency in the rate of weight reduction due to the spinel and $Al_2O_3$ addition.

Moreover, analyzing the microstructures (figure 4), a deteriorated zone was found to occur in the surface side of each specimen after the heating experiment, in which a part of the original graphite disappeared and ZrC (light-colored grains) was formed.

*Fig.3: XRD patterns of specimens after heating experiment.*

*Fig.4: Optical microstructure of specimens after heating experiment.*

The deteriorated zone had a thickness of approximately 470 μm (the conventional CZ-C), 380 μm (Specimen 1) and 220 μm (Specimen 2), respectively. The index values were 100, 81 and 47 (figure 2), which was also consistent with the variation tendency in the rate of weight reduction.

On the one hand, both Specimens 1 and 2 contained 1.4% MgO composition derived from the spinel according to table 1. The reaction between MgO and carbon (MgO(s)+C(s)=Mg(g)+CO(g)) also occurred as explained later. Nevertheless, even if all the MgO (1.4%) reacts with the carbon to transform into Mg and CO gases, it only consumes 0.4% carbon, negligible compared to the initial carbon (graphite) content (25%). Thereby, the weight reduction of the specimens during the heat was primarily due to the reaction between CZ and carbon (equation (1)) even in MgO-bearing Specimens 1 and 2.

The above results for the rate of weight reduction, the XRD-peak intensity and the thickness of the deteriorated zone all imply that the quantity of ZrC formed in Specimen 1, especially in Specimen 2 was less than the conventional CZ-C; that is, the ZrC formation reaction was retarded by the spinel and $Al_2O_3$ addition.

According to EPMA analysis for the deteriorated zone (figure 5), it was found that low-melting phases of $Al_2O_3$-CaO system (around 52% $Al_2O_3$, 46% CaO) were formed in Specimens 1 and 2, which were distributed on the surface of the CZ grains and also present between the CZ grains in the form of mixing with the small $ZrO_2$ and ZrC grains; i.e., the low-melting phases coated the CZ, $ZrO_2$ and ZrC grains and simultaneously enhanced the densification of the microstructure. Conversely, the conventional CZ-C exhibited a microstructure in which ZrC was present in isolation between the CZ grains.

475

Furthermore, MgO composition was hardly detected in the deteriorated zone of Specimens 1 and 2. This suggests that the MgO-C reaction generating the Mg evaporation indeed occurred during the heating.

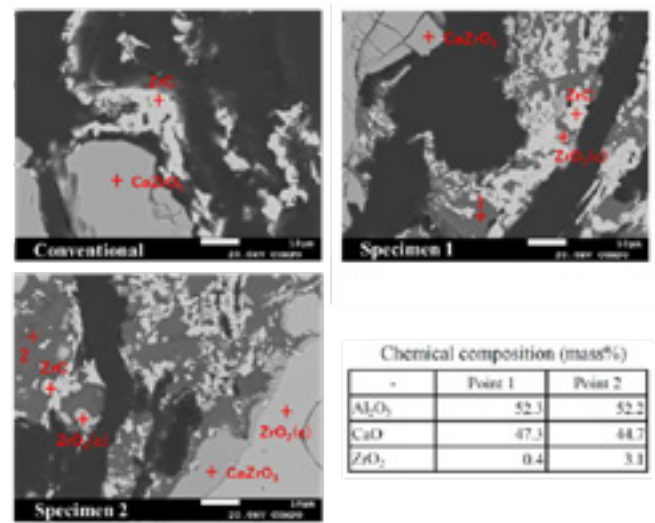

*Fig.5: EPMA analysis of deteriorated zone in specimens after heating experiment.*

On the other hand, the content of $ZrO_2$ composition (mainly $ZrO_2$ in CZ) in the specimens decreased relatively due to the addition of spinel and $Al_2O_3$ (table 1). The indexed $ZrO_2$ contents of the specimens were 100, 93 and 86, respectively. Accordingly, the $ZrO_2$ content decreased by only 14% at the maximum (Specimen 2), significantly smaller than the variation extent of the weight reduction, the ZrC XRD intensity and the thickness of the deteriorated zone described before. Therefore, the main reason for the inhibition of the ZrC formation by the spinel and $Al_2O_3$ addition is not the decrease of the $ZrO_2$ content, but the formation of the low melting point phases.

**Evaluation of alumina deposition resistance**

An adhesion layer (brown) with a maximum thickness of approximately 2 mm was observed on the surface of cross-section of the $Al_2O_3$-$SiO_2$-C specimen (as a comparative specimen) after the dipping experiment (figure 6). According to EPMA analysis, it was an $Al_2O_3$ system with over 80% $Al_2O_3$.

In contrast, almost no adhesion layer was formed on the conventional CZ-C, Specimens 1 and 2. They also did not display any corrosion. As with the conventional CZ-C, no ZrC was formed in Specimens 1 and 2 (see figure 7).

Consequently, under the condition that ZrC is not formed, Specimens 1 and 2 will exhibit a high alumina deposition resistance without corrosion, similar to the conventional CZ-C. In other words, spinel and $Al_2O_3$, within the amount of this experimental addition range, do not lower the alumina deposition resistance or corrosion resistance of CZ-C.

*Fig.6: Cross-section of specimens after molten steel-dipping experiment.*

*Fig.7: Optical microstructure of specimens after molten steel-dipping experiment.*

**DISCUSSION**

The CZ raw material included a small amount of $ZrO_2(c)$ besides the CZ. The ZrC produced from the $ZrO_2(c)$ should be extremely low. ZrC formation reactions between CZ and carbon can be expressed as equations (2)-(4) in detail (equation (2) is effectively the same as equation (1)).

The reaction of equation (2) occurs between the CZ and carbon grains in contact with each other, while equations (3) and (4) occur between the CZ and carbon grains that are not in contact.

$$CaZrO_3(s)+3C(s)=ZrC(s)+CaO(s)+2CO(g) \quad (2)$$
$$CaZrO_3(s)+4CO(g)=ZrC(s)+CaO(s)+3CO_2(g) \quad (3)$$
$$CO_2(g)+C(s)=2CO(g) \quad (4)$$
The reactions of equations (3) and (4) proceed in a chain, of which the total reaction takes the same form as equation (2). The standard Gibbs free energy change ($\triangle G^0$) of the reaction of equation (2) was calculated according to the reported standard formation Gibbs free energies of $ZrO_2$ [8], ZrC [8] and $CaZrO_3$ [9], as shown in the following equation.

$$\triangle G^0 = 674,000-318.44T, \quad J/mol \quad (5)$$

The relationship between the equilibrium CO partial pressure and temperature for the reaction of equation (2) obtained from equation (5) is illustrated in figure 8. When the partial pressure of CO in an actual atmosphere is lower than the equilibrium CO partial pressure, the reaction of equation (2) or equations (3) and (4) will proceed to the right, i.e., ZrC is generated.

*Fig.8: Equilibrium CO partial pressure of ZrC formation reactions as a function of temperature.*

From figure 8, it can be seen that the equilibrium CO partial pressure increases with the rising temperature, reaching 0.05 atm at the experiment temperature 1560 °C (1833K). As the Ar gas was blown into the furnace at a relatively high rate (1 L/min), the CO partial pressure around the specimens should have been significantly lower than 0.05 atm, and the ZrC formation may have started during temperature rising.

The phase of $Al_2O_3$ 52%, CaO 46% in Specimens 1 and 2 (see figure 5) has a melting point of approximately 1455 °C according to the $Al_2O_3$-CaO phase diagram, 95 °C lower than the experiment temperature. This indicates that a molten phase of $Al_2O_3$-CaO system began to form during temperature rising and eventually existed stably. It is believed that the molten phase played a role in suppressing ZrC formation primarily by the following mechanism.

A part of the molten phase coats the CZ grains, blocking the contact of the CZ with the carbon and CO gas; the rest exists between the CZ grains in the form of a mixture with the small $ZrO_2$ and ZrC grains, improving the compactness of the CZ-C microstructure and thus hindering the diffusion of CO gas from the inside, thereby raising the CO partial pressure in the CZ-C.

The reason why the ZrC formation could not be completely prevented by adding the $Al_2O_3$ and MgO composition is inferred to be that sufficient time is required for the formation of appropriate amount of molten phase. The low amount of ZrC formed in Specimen 2 may be because of the short time required to form a suitable molten phase. Detailed investigation on this aspect is a future topic.

Regarding the effect of MgO composition, it is believed that contact between the CZ and carbon grains was hindered and the CO partial pressure was increased due to the MgO-C reaction, which also suppressed the ZrC formation reaction to some extent [7].

On the other hand, the reason why ZrC did not form in the CZ-C specimens in the molten steel-dipping experiment is considered to be that the diffusion of CO gas was slow due to the low flow of the molten steel under the experimental condition, allowing a high CO partial pressure in the specimens.

In actual casting, when the flow of molten steel through the SEN inner lining is fast (figure 9), the CO gas diffuses and dissolves quickly into the molten steel (equation (6)), therefore the partial pressure of CO inside the CZ-C becomes low, leading to the easy formation of ZrC, similar to the case of Ar atmosphere-heating in this study.

$$CO(g)=\underline{C}+\underline{O} \qquad (6)$$

In fact, the molten steel throughput in the continuous slab-casting process where the abnormal damage occurred in the CZ-C inner linings was several times higher than the casting processes where no abnormal damage occurred in the CZ-C inner linings.

The results of this basic investigation will be helpful in finding measures to prevent the abnormal damage of CZ-C material that occurs in actual steel casting. Under practical casting conditions, the material of Specimen 2 has the potential to significantly inhibit the ZrC formation reaction and so prevent the abnormal damage, and meanwhile, exhibit high alumina deposition resistance.

Additionally, the equilibrium CO partial pressure for the formation reaction of ZrC from $ZrO_2$ is higher than from CZ (see figure 8). For example, they are 0.34 and 0.05 atm at 1560 °C (1833 K), respectively. This suggests that it is also necessary not to use CZ raw materials containing too much $ZrO_2(c)$ for the inhibition of ZrC formation.

## SUMMARY

Submerged entry nozzles with the inner linings of $CaO-ZrO_2$-C (CZ-C) material are frequently utilized to prevent alumina deposition. However, it was found that the CZ-C inner linings with a thickness of several millimeters are almost completely damaged after casting only about 2 heats in one actual continuous slab-casting process. The investigation of the microstructure of the CZ-C inner linings remaining in the used nozzles revealed that a significant quantity of ZrC was formed and the original graphite disappeared, as a result its microstructure deteriorated severely.

*Fig.9: Schematic diagram of CO gas movement from CZ-C into molten steel flow.*

It was considered necessary to find countermeasures to inhibit the ZrC formation reaction even under conditions of low CO partial pressure in order to prevent abnormal CZ-C damage. For this purpose, fundamental research on the effects of adding $Al_2O_3$ and MgO compositions into the CZ-C was implemented in the present study.

In a heating experiment under Ar atmosphere, the quantity of ZrC formed in the spinel (5%)-added specimen, especially in the (spinel+$Al_2O_3$) (5% each)-added specimen was clearly smaller than that in the conventional CZ-C material. For example, the XRD peak intensity index of ZrC was 81 for spinel-added specimen and 32 for spinel+$Al_2O_3$-added specimen, relative to 100 for the conventional CZ-C material.

EPMA analysis indicated that low-melting phases of $Al_2O_3$-CaO system were formed in the above-mentioned two specimens, coating the CZ, $ZrO_2$ and ZrC grains and enhancing the densification of the microstructure, whereas the conventional CZ-C exhibited a microstructure in which ZrC was present in isolation between CZ grains.

On the other hand, in a molten steel-dipping experiment, both specimens maintained a high alumina deposition resistance, similar to the conventional CZ-C.

## ABSTRACT

One of the causes of nozzle clogging during continuous casting of molten steel is interfacial chemical reaction between the refractory and the molten steel. Several researches have been conducted on the interfacial reaction product. However, evaluation of the interfacial chemical reaction has been insufficient. Without evaluation of the interfacial reaction, it is difficult to find out the refractory material capable of reducing the nozzle clogging. Therefore, in the present study, the interfacial chemical reaction between the refractory and molten steel was assessed in various ways: volume of the gas released from the refractory, evolution of steel components during reaction between the refractory and molten steel, thickness of the interfacial reaction product. Also, various nozzle refractories composed of different constituents were employed: alumina-silica-C base, $SiO_2$-less, lime-zirconia-C base, C-less, and oxide-less refractories. Based on the evaluation results, the refractory material capable of reducing the nozzle clogging was suggested, which can also contribute to the design direction of the nozzle material. It was found that the oxide-less refractory was efficient to reduce clogging, followed by $SiO_2$-less refractory.

## 1. Introduction

The submerged entry nozzle (SEN) is a critical component in the continuous casting process of molten metal. It serves as a conduit for the smooth flow of liquid metal from the ladle into the mold. However, one of the persistent challenges in this process is the clogging of the SEN, which can significantly impact the productivity, quality, and stability of the casting operation [1-3].

Clogging of the SEN can occur due to various factors, including suspended materials in the molten steel, reactions between the refractory and molten steel, temperature reduction, and atmospheric contamination [4]. These clogs restrict the flow of molten metal, leading to disruptions in the casting process and necessitating frequent maintenance and downtime.

Addressing the issue of SEN clogging is crucial for the efficient and reliable operation of continuous casting systems. Over the years, researchers and industry practitioners have explored different methods and techniques to mitigate or prevent clogging. This paper focuses on presenting an innovative anti-clogging material for submerged entry nozzles.

In this study, various methods were employed to evaluate the interfacial chemical reactions between refractory materials and molten steel, including the amount of gas emitted from the refractory, the image of samples after the reaction between the refractory and molten steel. Additionally, various refractory compositions, such as alumina-silica-carbon (AGS), $SiO_2$-less (AG), lime-zirconia-carbon (CSG), C-less (CL), and oxide-free (ALBN) refractories, were utilized as nozzle refractories.

Based on the evaluation results, refractories capable of reducing nozzle clogging were proposed, which can also contribute to the design direction of nozzle materials. It was found that oxide-free refractories were efficient in reducing clogging, followed by refractories without SiO2.

## 2. Clogging mechanism: SEN Inner Wall Reoxidation as a Result of Carbothermic Reaction

In the case of low carbon (C) aluminum-killed steel, the formation mechanism of network alumina in the submerged entry nozzle (SEN) can be described as follows [5]:

*Fig. 1: Reaction mechanism causing the early-stage clog deposit growth: low C Al-killed Steel [5]*

During the continuous casting process, carbothermic reactions occur within the SEN refractory, leading to the emission of carbon monoxide (CO) gas. This CO gas propagates through the interconnected pores present in the refractory material.

At the interface between the refractory and the liquid steel, the CO gas reacts with aluminum dissolved in the steel. This oxidation reaction results in the formation of alumina ($Al_2O_3$). The newly formed alumina adheres to the surface of the SEN, creating a network-like structure. This network alumina acts as a nucleation site for further alumina deposition. Simultaneously, alumina inclusions suspended in the liquid steel can also adhere to the existing network alumina. This accumulation of alumina inclusions on the network alumina is referred to as "build-up" alumina.

The presence of network alumina and build-up alumina can significantly affect the flow of molten steel through the SEN, leading to reduced flow area and potential clogging issues.

Understanding the network alumina formation mechanism is crucial for managing nozzle clogging in low carbon aluminum-killed steel. By implementing strategies to control the generation and deposition of alumina, such as refractory material selection, slag management, and control of oxygen levels in the steel, it is possible to mitigate clogging and ensure a smooth continuous casting process.

## 3. Evaluation of Gas Emissions from Refractory Materials

Previous studies have reported that the reaction between $SiO_2$ and C in the refractory materials leads to the release of CO(g) and SiO(g) [7-8]. However, it is observed that the formation of CO(g) and SiO(g) through Reaction (3.1) resulting from the reaction between $SiO_2$ and C is less spontaneous compared to the formation of CO(g) and SiC(s) through Reaction (3.2).

$$SiO_2(s) + C(s) = SiO(g) + CO(g) \qquad (3.1)$$
$$SiO_2(s) + 3C(s) = SiC(g) + 2CO(g) \qquad (3.2)$$
This indicates that only CO(g) is emitted from the refractory materials. Hence, there are discrepancies among different literature

sources regarding the gaseous emissions from refractory materials. Therefore, this study aims to verify the actual gas emissions from refractory materials through experimental validation based on thermodynamic calculations. Details of the experiental setup and test results can be found elsewhere [6].

## 3-1. Test Specimens and Testing Method
To enhance the reactivity of the refractory material at high temperatures, the refractory powder was formed into pellets (1 g, 4 pieces). The refractory material used in the experiments is shown in Table 3.1.

**Table 3.1: The refractory materials used for the submerged nozzle**

| Wt% | Oxide-based | | | | Non-Oxide | |
|---|---|---|---|---|---|---|
| | AGS | AG | CL | CSG | Wt% | ALBN |
| $SiO_2$ | 14.2 | 2.5 | 13.8 | 5.7 | AlN | 41.9 |
| $Al_2O_3$ | 54.8 | 64.8 | 78.5 | 1.8 | AlON | 29.5 |
| C | 28.8 | 27.4 | 5.5 | 22.9 | BN | 28.6 |
| $ZrO_2$ | - | - | - | 45.5 | | |
| CaO | - | - | - | 23.5 | | |

The high-temperature stability evaluation experiments of the refractory materials were conducted within an induction furnace, and the gas emissions from the refractory material were monitored using a quadrupole mass spectrometer (QMS) (Fig. 3.1). The experiments were carried out under controlled atmospheres by injecting purified Ar gas. Once the target temperature of 1600 °C was reached, the refractory materials were maintained at the temperature for 30 minutes, to induce high-temperature reactions of the refractory materials. Afterward, the power to the induction furnace was turned off, and the reactions were terminated. The volume of the emitted gases from the refractory material could be calculated.

*Fig. 3.1 Schematic diagram of the experimental setup for detecting the gases emitted from the refractory pellet using a quadrupole mass spectrometer (QMS) [6].*

## 3-2. Experimental Results and Discussion
### 3-2-1. Mass Spectrometer Analysis Results
The gases emitted from all refractory materials were analyzed using the mass analyzer, and the results are presented in Fig. 3.2. For the oxide-based refractory materials, both the $N_2$ and $O_2$ flow rates decreased before 80 minutes of reaction time, but after 80 minutes, only the $N_2$ flow rate increased rapidly. A similar phenomenon was observed for the non-oxide-based refractory materials after 60 minutes. This indicates the emission of gases from the refractory

materials, and the emitted gases differ depending on whether it is an oxide-based or non-oxide-based material.

For the oxide-based refractory materials, only CO was emitted as a gas. The reaction between $SiO_2$ and C in the refractory material leads to the generation of CO. In the non-oxide-based refractory materials, since there is no $SiO_2$ and C, the emitted gas was $N_2$. As AlON, a component of the refractory material, is unstable at low temperatures, it decomposes into $Al_2O_3$ and AlN, resulting in the generation of $N_2$ [7].

The gases emitted from the refractory material were released into the induction furnace, initiating the interfacial reactions between the refractory material and the molten metal. The reactivity of the refractory material was evaluated based on the volume of the emitted gases, as a larger gas volume indicates a higher reactivity with the molten metal. In the case of non-oxide-based materials, as CO is not emitted, they exhibit the best refractory stability. Within the oxide-based materials, the lowest volume of CO emitted was observed in AG, where $SiO_2$ is reduced. This indicates that AG has the highest refractory stability, followed by CL, CSG, and AGS (Table 3.2).

*Fig. 3.2. Confirmation of gases emitted from the refractory pellet: (a) AGS, (b) AG, (c) CL, (d) CSG, (e) ALBN ($N_2$: initial nitrogen in the crucible, CO: gas emitted from the refractory, $N_2^*$: gas emitted from the refractory). In (a) to (d), CO is emitted from the refractory around 1200 °C, while in (e), $N_2$ is emitted around 1000 °C.*

**Table 3.2: The Volume of gas emitted from 4g of refractory powder**

| ml | Oxide-based | | | | Non-Oxide |
|---|---|---|---|---|---|
| | AGS | AG | CL | CSG | ALBN |
| CO | 308 | 43.2 | 121.2 | 218 | |
| N2 | - | - | - | - | 22 |

### 3-2-2. Predicted CO Generation
Based on the mass analyzer experimental results, it was confirmed that the AG refractory material, in which $SiO_2$ was reduced, emitted the least volume of CO. However, it is generally expected that the CL refractory material, in which C is reduced, would emit the least volume of CO. Therefore, the mass of CO that can be emitted from the refractory material was calculated based on the reaction equation (Reaction (3.2)), where CO is generated. The purpose was to investigate the reason why $SiO_2$-reduced AG refractory material emits the least volume of CO, comparing it with the experimental results. The calculated masses of CO are presented in Table 3.3.

**Table 3.3: The mass of CO emitted from 100g of refractory material**

| g | Oxide-based | | | | Non-Oxide |
|---|---|---|---|---|---|
| | AGS | AG | CL | CSG | ALBN |
| CO | 13.5 | 2.3 | 12.8 | 5.3 | - |

Consistent with the mass analyzer experimental results, AG, with reduced $SiO_2$, exhibited the lowest mass of CO emitted from the refractory material. Fig. 3.3 represents the wt% and mole% of $SiO_2$ and C in the oxide-based refractory materials. Although CL had the lowest wt% of C, when converted to mole%, it still contained sufficient C to react with $SiO_2$ and emit CO. However, in the case of AG, the mole% of $SiO_2$ available for reaction with C was low. Therefore, to reduce the emission of CO from the refractory material, it is effective to decrease the wt% of $SiO_2$ rather than C, which aligns with the results of the refractory material reactivity.

**Fig. 3.3.** *SiO$_2$ and C wt % and mole % in oxide-based refractories: (a) AGS, (b) AG, (c) CL, (d) CSG (green area corresponds to Al$_2$O$_3$, orange area corresponds to CaO, ZrO$_2$ as the main components).*

### 3-3. Test Results

The emission of gas species from refractory materials was investigated using quadrupole mass spectrometer. It was observed that CO(g) is emitted from oxide-based refractory materials, while $N_2$(g) is emitted from non-oxide-based refractory materials. The volume of CO emitted from the refractory material was used to evaluate its stability. It was found that non-oxide-based refractory materials exhibited superior stability compared to oxide-based materials, and among the oxide-based materials, AG with reduced SiO2 showed the best performance.

Overall, this study provides insights into the gas emissions from refractory materials and their relation to the thermodynamic properties and composition of the materials. The findings contribute to the understanding and evaluation of refractory material performance and can be valuable in the development and selection of refractory materials for high-temperature applications.

### 4. Evaluation of Reactivity at the Interface between Refractory Materials and Molten Steel

Research on the interfacial reaction between refractories and molten steel has been continuously conducted. However, most of the studies have focused on the deposits formed by interfacial reactions. It is difficult to identify refractory materials that can improve the clogging phenomenon in nozzles based solely on studies of deposits. Therefore, in this study, various commercially available refractory materials were immersed in molten steel during the casting process to evaluate their refractory reactivity. Based on the results of refractory reactivity, refractory materials that can

reduce nozzle clogging were proposed. Details of the experiental setup and test results can be found elsewhere [8].

### 4-1. Experimental Method

In actual operations, during continuous casting, molten steel flows at a constant velocity and reacts with the immersed nozzle. To simulate this phenomenon, a rotational immersion experiment called the Finger Rotating Method (FRM) was conducted to mimic the reaction between refractory materials and molten steel. The refractory materials used in the experiment and the composition of the molten steel are presented in Table 3.1 and Table 4.1, respectively.

To prepare the molten steel, 600 g of molten iron was poured into an $Al_2O_3$ crucible. The refractory material samples for immersion were prepared in a bar-type shape (10 ×10 ×160 mm). After reaching the target temperature (1565 °C), the additives (Al) were added at 10-minute intervals. Immediately after immersion, the refractory material was stirred at a speed of 100 rpm, which is similar to the speed at which molten steel passes through the inner wall of the nozzle during continuous casting [9]. The reaction time between the refractory material and molten steel was set at 30 minutes. Afterwards, the refractory material was separated from the stirrer and collected.

SEM analysis was conducted to examine the reaction product from the refractory materials. During SEM imaging, backscattered electron (BSE) mode was used to clearly distinguish different phases based on their composition. Energy-dispersive X-ray spectroscopy (EDS) mapping analysis was conducted for elemental analysis.

**Table 4.1 Target composition of molten steel used in refractory/molten steel interface reaction experiments.**

| Type | | Fe | Al |
|---|---|---|---|

### 4-2. Test Results

The visual appearance of the refractory materials, both oxide-based and non-oxide-based, after immersion in the molten steel, is shown in Fig. 4.1. In both cases, a gray-colored deposit was observed in the immersed region. Previous literature reports have attributed the gray deposit formed on the refractory surface after immersion to $Al_2O_3$, a product of the reaction between the refractory material and the molten steel [12]. To confirm this, the morphology and composition of the deposit were examined through SEM analysis, and the results are presented in Fig. 4.2 in case of AGS and ALBN refractories.

In the non-oxide-based refractory materials, $Al_2O_3$ was also formed as a reaction product. However, the morphology of the deposits differed from that observed in the oxide-based refractory materials. While polygonal $Al_2O_3$ deposits were formed in the oxide-based refractory materials, spherical $Al_2O_3$ deposits were observed in the non-oxide-based refractory materials. Previous studies have reported that the morphology of the deposits is determined by the underlying mechanisms of their formation.

Polygonal deposits are formed as a result of interfacial reactions between the refractory material and the molten steel, while spherical deposits are attributed to residual desulfurization agents [5]. In oxide-based refractories, the generation of oxidizing gas leads to the formation of polygonal-shaped $Al_2O_3$ deposits as reaction products. However, non-oxide-based refractory materials do not produce oxidizing gases. Therefore, the spherical-shaped $Al_2O_3$ deposits observed in the non-oxide-based refractory materials are considered to be residual desulfurization agents. The absence of CO formation in the non-oxide-based refractory

materials further supports the observation of the deposit morphology.

**Fig. 4.1** *Shape of refractories after refractory/molten steel interface reaction at 1565°C for 30 minutes with Al content of 300 ppm in the molten steel: (a) AGS, (b) AG, (c) CL, (d) CSG, (e) ALBN.*

**Fig. 4.2** *Formation of deposits after refractory/molten steel interface reaction at 1565°C for 30 minutes with Al content of 300 ppm in the molten steel: (a) AGS and (b) ALBN. Deposits in (a) consist of polygonal $Al_2O_3$, while in (e, spherical $Al_2O_3$ is formed as a reaction product [8].*

## 5. Field Test

Based on the previous laboratory results, a field test was conducted to confirm the anti-clogging effect of non-oxide-based refractories. A comparison was made between the existing product with a calcium zirconate liner and an improved product with a non-oxide-based liner (Fig. 5.1). The test was conducted using a 20Ch H-beam caster, and the results are as follows.

**Fig. 5.1** *Schematic diagram of the products used in field test. (a) Calcium Zirconate Liner SEN, (b) ALBN Liner SEN*

**Fig. 5.2** *Field Test Results (a) calcium zirconate liner SEN, (b) ALBN liner SEN*

In the existing SEN with the calcium zirconate liner, it was observed that there was an anti-clogging effect due to the formation of low-melting compounds during the casting process. However, In the long-term casting, the liner was consumed, leading to a decrease in refractory lining life and the occurrence of refractory wear. And another problem with calcium zirconate liner includes poor steel quality resulting from zirconia washed into the steel flow.

On the other hand, the newly developed non-oxide-based liner, demonstrated consistent results with its anticipated performance. It not only exhibited an anti-clogging effect, preventing the build-up of adhered materials, but also showed minimal refractory wear. Therefore, it is expected to enhance stability during extended casting process.

Furthermore, in order to validate the operational stability of non-oxide refractories, a large-scale slab caster test is currently scheduled. The results will be reported in future publications for reference and consideration.

## CONCLUSIONS

Among various factors that cause nozzle clogging, we focus on the reactions between refractory materials and molten steel to observe the phenomenon of nozzle clogging. Both commercially available oxide-based refractories and newly developed non-oxide-based refractories were utilized to identify refractory materials. The interface reactions between refractories and molten steel involve an initial interfacial reaction followed by the attachment of suspended materials. The reactivity of the refractories was evaluated through two experiments.

Firstly, gas emissions from the refractories were observed using a quadrupole mass analyzer, and subsequently, the interface reactions were simulated by immersing the refractories in molten steel. In oxide-based refractories, $CO(g)$ was emitted, while $N_2(g)$ was emitted in non-oxide-based refractories. The reactivity of the refractories was evaluated based on the volume of oxidizing gases emitted from the refractories and the SEM image of the reaction products at the interface.

The non-oxide-based refractories exhibited superior stability compared to the oxide-based refractories, while within the oxide-based refractories, refractories with reduced $SiO_2$ content showed improved stability.

Furthermore, based on laboratory test results, field tests confirmed. The SEN with the developed non-oxide-based liner exhibited a lower corrosion rate caused by molten steel compared to the existing calcium zirconate liner. Nozzle clogging was not observed upon inspection of the used SEN. It was confirmed that the product has an anti-clogging effect.

Therefore, to maximize the anti-clogging functionality by reducing the interface reactions between refractories and molten steel, non-oxide-based refractories should be used in non-oxide environments, while $SiO_2$-reduced refractories should be used in oxide-based environments.

**ABSTRACT**

Thin Slab Casting & Rolling (TSCR) known as compact strip mill production (CSP) is an integrated technology of casting to enhance productivity, reduce energy consumption and lower the operating cost. In this facility, thin slabs are casted at high speed and directly hot rolled into strip of required dimensions. Mold thickness in thin slab caster ranges from 50-70 mm.

In Continuous Casting, tundish is placed over mould. SEN (Submerged Entry Nozzle) is fixed at bottom of Tundish and acts as a medium for flow of liquid steel. During casting Tundish refractories play very crucial role like prevention of re-oxidation of molten steel, control flow from Tundish to Mould & Safe casting operation. Tundish refractories used in Continuous casting are Ladle Shroud, Tundish Working lining, Mono Block Stopper (MBS), SEN etc.

Continuous casting operation in thin slab mould is highly influenced by SEN Design, Material quality, Application (due to manual installation process) and operational casting parameters. SEN performance and failure directly affects the productivity of shop and have process safety implications.

This paper covers various practical aspects regarding improving SEN reliability in a particular shop to improve overall productivity & safety aspect at caster. In this study SEN bottleneck has been identified & categorized as Crack on SEN face, Neck breakage, High erosion in slag line & Metal trickling. Last 5 years data is considered. Each phenomena probable cause has been analysed & studied. Countermeasure deployment & respective results are analysed.

Post this study & various actions, this shop has set benchmark in terms of productivity in global steel industry. It also includes additional learnings related to site application, operational parameters.

**Key Words:**

Continuous Casting, Submerged Entry Nozzle, Failure Analysis, Refractory, Field Study

**INTRODUCTION:**

This paper includes study & experiences at Thin Slab Caster and Rolling mill (a new energy efficient 'Compact Strip Processing' technology). Tata Steel LD3 TSCR is a steel melting & casting shop Jamshedpur works dedicated to Flat Products.

Submerged entry nozzle (SEN) has a key role in steel plant productivity & reliable operation as any failure may lead to interruption in production, in addition to this safety may also be impacted.

SEN is a refractory tube used for transfer of molten steel from Tundish to mould. Flow lines & laminarity of flow depends on SEN design & proper installation in Tundish. Any failure in SEN will put a break in continuous casting operation, may have a potential of safety hazard at caster floor & equipment damage.

SEN is designed based on inputs of casting parameters, customer requirement, casting duration etc.

Based on investigation & field study all possible causes were analysed & based on result most prominent causes with respect to each type is briefly explained.

This study focuses on the impact of field installation operations and customer operating conditions on the performance of Tundish refractories, including SEN. Therefore, as a rule, we assume that the refractories used are of a particular quality that satisfies the customer's required specifications.

This article summarizes all countermeasures taken in SEN to reduce sequence break ratio, enhance equipment availability and enhance shop safety.

**Caster Refractories Arrangement:**

In Continuous Casting, tundish is placed over mould. SEN is fitted at bottom of Tundish. During casting Tundish refractories play very crucial role like prevention of re-oxidation of molten steel control flow from Tundish to Mould, safe casting operation. Tundish refractories which play vital role during continuous casting are Ladle Shroud, Tundish Working lining, Mono Block Stopper (MBS), Submerged Entry Nozzle SEN etc. (As shown in figure 1).

A- Tundish
B- Tundish Working Lining
C- Shroud
D- MBS
E- SEN
F- Mold
Figure 1: Schematic of Caster Refractory Arrangement

Tundish:

Its serves as buffer or intermediate vessel/ reservoir for the liquid steel during ladle change and therefore, makes sequential casting possible. The tundish is designed for optimum flow pattern such that inclusion separation into the top slag is supported.

Tundish Working lining:

Wear lining between liquid steel and permanent lining is a MgO monolithic layer. It resists erosive and corrosive attack of molten steel and slag.

Shroud:

It's role to Safely delivery of molten steel from Steel Ladle to tundish and prevention of re-oxidation of molten steel.

Mono Block Stopper (MBS):
It's role to control flow of molten steel from tundish to Mold. Safe and reliable stopper opening to allow transfer and shutting off.

Submerged Entry Nozzle (SEN):
Its role is to Safely delivery of molten steel from tundish to Mold and Prevention of re-oxidation of molten steel & allow streamline mould filling which results in smooth solidification in mould.

Split Ring (SR):
It's a part of Tundish refractories act as a key, and it helps to lock and hold the SEN with Tundish.

Well Block (WB):
It's a part of TD refractories and it holds the Split Ring within itself which in turn locks the SEN.

**SEN Material selection:**
Material selection for the SEN is highly crucial as its different zones in SEN which has a specific function & its performance depends on operational like preheating condition, mould flux etc. Based on experience and operational condition the following base material has been selected. Schematic of SEN body shown in figure 2.

Seat area: fired $ZrO_2$ ring.
To take care of mechanical strength as well as abrasion and corrosion.
Body: $Al_2O_3$-Graphite
Abrasion, corrosion and thermal spalling resistance.
Slag Line: $ZrO_2$-Graphite
High corrosion and thermal spalling resistance.
Bottom/ Port: $Al_2O_3$-Graphite
Abrasion, corrosion and thermal spalling resistance.
Figure2: Schematic of SEN Body

**SEN Failures History:**
Figure 3: SEN Failure Summary Graph

Data for only TRL Krosaki SEN failure is considered. It has been observed that while there are some variations in terms of number of SEN failure in each year, It is confirmed that it occurs at a certain frequency.
Improvement actions started from 2021-2022 & some continued till 22-23.

These failures were categorized for a focussed investigation & troubleshooting.
SEN Failure are as follows: -
1. Crack on SEN Face,
2. Neck breakage,
3. High erosion in slag line,
4. Metal trickling
Figure 4: SEN Failure Cases Categorized from FY18 to FY23

**1) Crack on SEN face-**
This type of failure generally occurs in Narrow face of SEN, A vertical crack generates from port to Slag line (Zirconia Band) of SEN. As shown in Figure 5. This failure can lead to Casting interruption, disturbed flow in mould, Mould breakout etc.
Figure 5: Crack on SEN face

Predominant probable causes for Crack on SEN are as follows:
a) Material/ Handling Issue - If any internal crack persists in SEN body during transfer of SEN may lead to crack formation in SEN during operation.
Figure 6: Stress in SEN neck area

b) Thermal Shock in SEN- SEN is made from $Al_2O_3$ Graphite must be preheated to temperature range between 1000°C and 1200°C to prevent thermal shock. Thermal shock can occur due to abnormal preheating of SEN OR more heat loss time from

483

preheating end to casting start. Preheating end to the cast start shall begin within 3 - 5 minutes to avoid instant cooling of SEN.

<u>Action taken for Crack on SEN face:</u>
a)   Stabilization of SEN preheating temperature. Earlier common line was there for compressed air supply for SEN preheating. To maintain stable pressure, a dedicated compressor air line for SEN preheating system.

b)   Real time monitoring of SEN preheating temperature. SEN preheating temperature monitoring at regular intervals to check real time condition of SEN preheating.

**2) Neck breakage**
During Casting if any SEN breakage from neck may have a potential of safety hazard at caster.

Figure 7: Breakage in SEN Neck

<u>Predominant probable cause of SEN neck breakage are as follows:</u>
a)   Excessive Stress in SEN Neck caused during fixing - Well Block and Split Ring which are main item responsible for holding & locking of SEN with Tundish. A special mortar is applied to fill the joints between Well block and Split ring, Split Ring and SEN. In Ideal condition, Well Block Split ring should be set in proper locking position to eliminate excessive stress in SEN neck (As shown in Figure 8.).

Figure 8: Standard assembly of Well Block, Split Ring and SEN

During installation if Split ring is not in proper position, Stress will increase on the neck area of SEN.

b)   Mechanical stress in SEN Neck during movement of SEN- During Tundish handling & transfer from Tundish preparation area to caster or placing of Tundish from Caster Car, there are chances of SEN interference, this may lead to generate stress in Neck of SEN.

c)   Thermal stress in SEN Neck due to thermal shock can be considered as a probable reason for crack on SEN face.

<u>Action taken for SEN Neck breakage:</u>
a)   Modification in SEN installation process turned out to be a positive one. Ensuring Split Ring & WB in proper locking position to counter stress in SEN Neck.

**3) High erosion in slag line (Zr Band)**
SEN puncture occurs due to high erosion of SEN in slag line (Zr band) As shown in figure 9.

Figure 9: High erosion/ Puncture in Slag line (ZG band) of SEN

<u>Predominant Probable Cause of abnormal ZG band erosion:</u>
a)   Biased Flow in Mould can cause abnormal Zirconia band erosion or SEN breakage from Zirconia band. Biased flow from port of SEN can disturb mould meniscus which can cause mould powder entrapment, highly corrosive in nature causing ZG Band Erosion/ breakage.

b)   Abnormal Ramping pattern followed during casting operation- Ramping of Tundish/ SEN is done to prevent excess erosion in slag line of SEN. During Ramping Tundish is lowered or raised so that Mould meniscus level is not eroding a particular band of Zirconia.

<u>Action taken for abnormal ZG band erosion:</u>
a)   SEN body & port design is optimized for smooth flow of molten steel into mould. Design changed by modification in SEN port area was done. Modified SEN port design acts as a flow separator & ensure smooth streamline flow from SEN Body. As a result, reduction of slag line erosion is achieved by improvement of molten steel flow in the mould. Apart from this, Zirconia band was also strengthened by increasing thickness as a counter to solve excessive erosion.

b)   Improvement in ramping pattern: - Tundish ramping (upward and downward) is done by actuator (as shown in figure 10), chances of band overlapping due tundish ramping error is there.

Based on Field study & data collection we were able to investigate tundish ramping error condition. Ramping band length was optimized to prevent band overlapping during tundish ramping.

Figure 10: High erosion in slag line (ZG band) due to band overlapping by Tundish ramping error

**4) Metal Trickling**

Metal trickling or SEN breakage from neck occurs during continuous casting (As shown in Figure 11).

Figure 11: Metal trickling through SEN Neck

Predominant Probable Cause of Metal trickling through SEN Neck-

a)  Application error- Joint material application process is totally dependent on human skill. If joint material mortar and ramming mass are applied in wrong process then there is chance of metal trickling between joint of SEN, Well block and Split ring. (As shown in figure 12).

Figure 12: Assembly of SEN, Well block and Split ring

Action taken for Metal trickling through SEN Neck

a)  In earlier process ramming mass was being installed in one step process (one layer), due to which Ramming material was having less compactness due to which metal penetration occurred during casting. Step wise Ramming mass application process is introduced for more compactness which does not allow metal trickle.

Figure 13: Step - Wise Layer Ramming for Proper Compactness

**CONCLUSION:**

Various SEN Failure troubles were investigated categorically through site study, data collection & analysis was carried out by data study, simulation, design & process parameters etc. Based on analysis, all possible causes were identified & counteractions were taken to minimize SEN Failure issue.

Results of countermeasures was also studied with an aim to minimize SEN Failure issues leading to unplanned sequence break, safety issues at caster, quality & productivity issues.

Emphasizing the results categorically –

Issue of Crack on SEN face was mainly due to abnormal preheating. Continuous monitoring SEN temperature can prevent from thermal shock during SEN preheating.

Issue of SEN Neck breakage- root cause was identified as improper application during SEN fixing, which was responsible for excessive stress generation, eventually leading to SEN neck breakage, the problem was eliminated by modification in SEN installation practice.

Issue of high erosion in slag line (ZG band) of SEN was mainly due to tundish ramping error & biased flow in mould. Better ramping discipline in case of high error can eliminate such issues.

Issue of Metal trickling from SEN neck is mainly due to improper installation of joint material mortar and ramming mass, this has been completely addressed by implementation of proper installation practice for SEN, well block and split ring.

## ABSTRACT

Zirconia metering nozzles play a crucial role in controlling the flow of liquid steel during continuous casting processes. The chemical composition, thermal properties, and mechanical characteristics directly impact the functionality and performance of these nozzles in steelmaking plants. This study focuses on the investigation of stabilized zirconia metering nozzles modified with magnesia and explores the effect of calcium input from CaFe additives on the surface recrystallization of these nozzles.

Industrial samples were prepared using zirconia with 99% purity and particle sizes less than 7 µm. After mixing, the samples were pressed at a pressure of 1200 Kgf/cm² and fired at a temperature of 1600°C, following a specialized heating cycle. Physical properties, including density, apparent porosity, and cold crushing strength (CCS), were determined according to DIN EN 993-1 and EN 993-5 standards. Microstructure and phase analysis were conducted using XRD, FESEM, and EDS techniques.

Optical microscopy revealed the growth of zirconia grains and an increase in the porosity size on the hot surface. FESEM and EDS analysis confirmed the occurrence of recrystallization on the hot surface, with higher concentrations of calcium (Ca) and magnesium (Mg) compared to the cold surface. The expansion during recrystallization and grain growth of ZrO directly influence the lifetime of zirconia metering nozzles.

This study provides valuable insights into the modification of stabilized zirconia metering nozzles with calcium input and its impact on surface recrystallization. The findings contribute to enhancing the understanding of casting processes and optimizing the performance and longevity of zirconia metering nozzles in steelmaking applications.

Keywords: Stabilized zirconia, metering nozzle tundish, recrystallization, casting rate

## INTRODUCTION

The continuous casting process relies on functional refractories with extended service life for optimal performance. Among these refractories, the metering nozzle system holds significant importance[1,2]. Partially stabilized zirconia (PSZ) is the primary raw material used in the production of metering nozzles due to its advantageous properties, including high thermal expansion coefficient, resistance to chemical corrosion, oxidation, and wear[3].

The similarity in radii between cations such as Mg²⁺, Ca²⁺, and Y³⁺ (common stabilizers) and Zr⁴⁺ in zirconia results in their high solubility, allowing their precipitation after rapid cooling from elevated temperatures. This unique characteristic enables the retention of the cubic phase of zirconia below its phase transformation temperature[1]. Previous studies by Primachenko et al.[1,4] and Roa and Anglada[1,5] have highlighted the correlation between damage to zirconia nozzles and the precipitation of stabilizers and slag. Furthermore, Li et al.[1,6] discovered that grain fracture contributes to the deterioration of zirconia metering nozzles.

Klaudia et al.[7] emphasized several key factors contributing to nozzle damage, including erosion from liquid steel, infiltration of molten steel and slag into the refractory material, slag composition, and rapid temperature changes[2,7]. Additionally, their research revealed the recrystallization of ZrO$_2$ grains along the hot face of zirconia nozzles, stabilized at high temperatures through the dissolution of oxides present in the slag and molten steel[7].

However, the maximum service life of metering nozzles is dependent on the grade of the steel products being cast. In this study, we investigated the cross-sectional properties of zirconia metering nozzles after 22 hours of service life in a steel plant to determine the primary mechanisms leading to nozzle damage. X-ray fluorescence (XRF), X-ray diffraction (XRD), field emission scanning electron microscopy (FESEM) with energy-dispersive X-ray spectroscopy (EDS), and optical microscopy techniques were employed to comprehensively analyze the zirconia metering nozzles.

This research provides valuable insights into the mechanisms of damage in partially stabilized zirconia metering nozzles and contributes to the understanding of their performance and service life in the continuous casting process.

## EXPERIMENTAL METHOD AND PROCESS

Zirconia of 99% purity, with a particle size diameter of less than 7 µm, was utilized in this study. The samples were prepared by mixing the zirconia powder, followed by pressing at a pressure of 1200 Kgf/cm². Subsequently, the specimens were fired at a temperature of 1600°C using a specific heating cycle.

To assess the physical properties of the prepared zirconia samples, several parameters were determined according to the DIN EN 993-1 and EN 993-5 standards. These included density, apparent porosity, and cold crushing strength (CCS).

In order to investigate the microstructure and phase analysis of the samples, X-ray diffraction (XRD), scanning electron microscopy (SEM), and energy-dispersive X-ray spectroscopy (EDS) techniques were employed.

Table 1 presents the chemical analysis of the zirconia raw materials used in the study, while Tables 2 and 3 provide the physical characteristics and chemical composition of the unused zirconia metering nozzles, respectively.

Tab. 1: Chemical analysis of zirconia raw materials

## RESULT AND DISCUSSION

Figures 1, 2, and 3 depict the optical microscopy images of the hot and cold surfaces of the sample after a service life of 22 hours in contact with liquid steel treated with CaFe cored wire additive.

*Fig.1: cross section of refractory metring nozzle*

Figure 1 illustrates two distinct zones in the corroded zirconia metering nozzles: a dark zone corresponding to the hot face and a bright zone associated with the cold face.
*Fig.2: Cross-section of the polished surface from hot face of refractory metring nozzle*

*Fig.3:Cross-section of the polished surface from cold face of refractory metring nozzle*

*Fig.4: Schematic diagram of the possible bulk density against sintering time curve for highly agglomerated ultrafine powder[8]*

The sintering of highly agglomerated ultrafine zirconia powders involves mechanisms like I- neck formation and shrinkage, II- fissure formation and growth, III- pore growth, IV-grain growth, V- pore rearrangement shrinkage, and pore entrapment. During sintering, a decrease in bulk density is observed in highly agglomerated powders due to fissure formation and pore growth. In zone I, efforts were made to achieve maximum density, but after 22 hours of service life, density reduction occurs, possibly due to fissure formation and growth. The low thermal conductivity and heat loss of PSZ contribute to grain growth on the hot face.

*Fig.5: Temperature profile of zirconia metering nozzle after one hour of casting [2].*

Based on Figure 5, the temperature in the hot face of the zirconia metering nozzles is approximately 1600°C, while in the cold face it is around 1200°C, indicating the low thermal conductivity of the nozzles. So the stage 3 in figure 4 will be started , which specifically affects the corrosion resistance of the zirconia metering nozzles in the hot face.

The composition analysis in Table 2 reveals that the main component of unused zirconia metering nozzles is 95% Zirconia. However, XRF analysis of used zirconia metering nozzles confirms a decrease in $ZrO_2$ content to 93.40%, along with the presence of other oxides such as $Fe_2O_3$, CaO, MgO, $SiO_2$, and $Al_2O_3$, as shown in Table 4.

Tab. 4: Chemical analysis of zirconia metering nozzle

| $ZrO_2$ | $Al_2O_3$ | $Fe_2O_3$ | $SiO_2$ | CaO | MgO | $TiO_2$ |
|---------|-----------|-----------|---------|------|------|---------|
| 93.40 | 1.68 | 0.18 | 0.91 | 0.61 | 2.80 | 0.07 |

The XRD analysis confirmed that the unused sample primarily consisted of monoclinic Zirconia and magnesia-stabilized zirconia (Magnesium Zirconium Oxide).
Further XRD analysis using Rietveld quantitative phase analysis revealed an increased content of stabilized Zirconia in the reacted layer (hot zone), indicating a higher concentration of stabilizer agents in the hot face. Previous research by Klaudia et al. [7] has reported that the addition of MgO and CaO stabilizes the high-temperature phase of zirconium oxide by dissolving in $ZrO_2$. This solid solution alters the internal structure of the $ZrO_2$ crystal, preserving the cubic phase at room temperature and resulting in a sample composed of both cubic and monoclinic zirconia phases [3]. Comparison of the XRD analysis between the hot and cold faces (Figures 6 and 7) showed the appearance of cubic phases and a decrease in the percentage of $ZrO_2$ monoclinic phase, indicating a recrystallization process during the service life. However, the subsequent grain growth process revealed the second stage of damage to the zirconia metering nozzles, leading to increased pore distribution and the potential penetration of other oxides.

Fig. 6: XRD analysis of hot face from refractory metering nozzle
Fig. 7: XRD analysis of cold face from refractory metering nozzle

To investigate the aforementioned mechanism, microstructure analysis using FESEM and EDS was conducted, and the results are presented in Figures 8 and 9.

In Figure 8a, the observation of grain growth and an increase in pore size is evident. Furthermore, EDS analysis confirmed the presence of oxides such as $Fe_2O_3$, CaO, MgO, $SiO_2$, and $Al_2O_3$, indicating their penetration into the hot face from the liquid steel or slag. The significant quantity of these phases in the hot face can be attributed to the formation of a liquid phase at lower temperatures, thereby promoting corrosion of the metering nozzles.

On the other hand, the microstructure study and EDS analysis of the cold face, as shown in Figure 9, did not reveal any notable damages.

*Fig. 8a:* FESEM analysis of hot face from refractory metering nozzle
8b: EDS analysis of hot face from refractory metering nozzle

*Fig. 9a:* FESEM analysis of cold face from refractory metering nozzle
9b: EDS analysis of cold face from refractory metering nozzle

It is well known that during steel casting using zirconia metering nozzles, the casting speed remains relatively constant over time. This is attributed to the formation of solid solutions and recrystallization in the hot surface, as indicated by the $ZrO_2$-MgO-CaO phase diagram.

Initially, MgO and CaO contribute to recrystallization and grain growth. However, as the casting duration progresses, the presence of high porosity allows for the penetration of $SiO_2$, $Al_2O_3$, and $Fe_2O_3$. This can lead to the formation of low melting phases and an increase in the corrosion rate. By comparing the two mechanisms at the beginning and end of casting, it can be observed that the corrosion rate remains relatively constant, which is crucial for steel manufacturing (see Figure 10).

*Fig .10: the corrosion rates in contrast with grain growth in schematically*

**CONCLUSIONS**

The investigation results of Zirconia metering nozzles after a 22-hour trial in a steel plant have demonstrated that the damage process of these nozzles is characterized by three distinct steps: grain growth, recrystallization, and destabilization and decomposition of the material.

Interestingly, grain growth and recrystallization have the potential to mitigate the corrosion rate by inducing expansion and thereby extending the operational lifespan of zirconia nozzles. This effect, however, is contingent upon the effective control of steel liquid and slag oxides penetration during the service life of the nozzles.

**Abstract**

Submerged entry nozzle (SEN) is an important functional refractory for high-efficient continuous casting. When casting high-quality steel, SEN is easy to be clogged, which will cause flow field instability, slag entrapment, adhesions, refractories falling off, etc., resulting in a significant increase in inclusions in the molten steel, deterioration of billet quality, and even interruption of continuous casting. Negative pressure in SEN will accelerate clogging. This factor is neglected in the design process of the existing Al$_2$O$_3$ clogging experimental method. Therefore, based on the SEN negative pressure, this paper innovatively designed an Al$_2$O$_3$ clogging experimental method under near working conditions, and verified its feasibility. Compared with the existing experimental methods, this new experiment method stimulates the working conditions, ensures the stable source, content, and size of Al$_2$O$_3$ inclusions around specimen. The composition and morphology of the clogging on the specimen obtained by the new simulating experimental method are the same as those on the inner wall of the SEN obtained by the factory. The new method was used to optimize the anti-clogging liner, and it was determined that the calcium stabilized ZrO$_2$ lining present good anti-clogging effects.

Keywords: SEN, clogging, Al$_2$O$_3$, negative pressure, experimental method

## 1 Introduction

SEN is an important functional refractory for high-efficient continuous casting, cooperating with mold fluxes to prevent molten steel oxidation, control the flow field and temperature field of molten steel in the mold, ensure slab quality and continuous casting process stability [1–3]. When casting high-quality steel, SEN is easy to be clogged, which will cause flow field instability, slag entrapment, adhesions, refractories falling off, etc., resulting in a significant increase in inclusions in the molten steel, deterioration of billet quality, and even interruption of continuous casting [4,5]. Therefore, it is imperative to anti SEN clogging.

SEN inner wall is generally Al$_2$O$_3$-C material, decarbonization will occur after contact with molten steel. The roughness of the SEN inner wall increases significantly after decarburization, which accelerates the adhesion of inclusions on its surface and eventually causes rapid clogging of the SEN. In order to prevent the SEN clogging, a variety of lining materials have been developed, which have good anti-clogging effect on some steel castings, but the universality is poor. The main reason is that there is a large deviation between the conditions of existing inclusions clogging experiment and the actual working conditions. Therefore, it is necessary to innovate the inclusions clogging experimental method. Researchers show that there is negative pressure in SEN during continuous casting [6-8]. Under the action of pressure difference, the external air or the oxidizing gas produced by the carbothermal reduction reaction may be transmitted to the SEN-molten steel interface, oxidizing the [Al] in the molten steel, resulting in SEN clogging. Therefore, the continuous oxidation of molten steel caused by negative pressure is an important reason for SEN clogging. However, the researchers ignored the role of negative pressure in Al$_2$O$_3$ clogging experiment.

From what has been discussed above, in this paper, new Al$_2$O$_3$ clogging experimental method under near working conditions based on negative pressure principle is designed and verified by high temperature simulation experiment. Then, the designed new Al$_2$O$_3$ clogging experimental method is used to optimize the anti-clogging lining materials.

## 2 Experiment

### 2.1 Design ideas

In this section, the innovative Al$_2$O$_3$ clogging experimental method under near working conditions is designed. Under the action of pressure difference, the external air will be sucked into the SEN (as shown in **Fig. 1a**). However, this situation cannot be achieved under laboratory conditions. In order to achieve the same effect, an equivalent experiment is designed here (as shown in **Fig. 1b**). A certain pressure of air is continuously introduced into the specimen. **Fig. 2** shows the shortcomings of the existing experimental methods and the advantages of the new method.

### 2.2 Specimen preparation

The raw materials used in this experiment are shown in **Table 1**, experimental formulations of Al$_2$O$_3$-C specimen and, anti-clogging lining materials are shown in **Table 2** and **3**. The specimens was prepared, firstly, mixture was prepared by mixing raw materials in Erich intensive mixer; secondly, the volatile matter of mixture was regulated by drying in electric drying oven (60 °C for ≈12 h); thirdly, crucible specimens (inner diameter is 25 mm; outer diameters is 40 mm; height is 350 mm) were obtained by isotactic pressing at 120 MPa; fourthly, the specimens were dried (at 120 °C for 12 h, at 180 °C for 6 h); finally, specimens were heat-treated under the carbon embedded condition (at 850 °C for 6 h).

### 2.3 Experimental device and process

The schematic diagram of Al$_2$O$_3$ clogging experimental method under near working conditions was shown in **Fig. 3**. The new experimental method was verified by high temperature simulation experiment. Firstly, the steel ingot was melted under argon protection. Then, the preheated specimens at 1100 ºC were slowly immersed in the molten steel. After the temperature was stabilized at 1550 ºC, the Al wire (0.20 wt % of total molten steel%) was fed into the molten steel. Subsequently, air was injected into or extracted from inside the specimens under the given pressure (−15000, 0, 15000 and 30000 Pa). Finally, the specimens were brought out of the molten steel after 10 min and the Al$_2$O$_3$ cloggings on the surface of the specimens were observed.

## 2.4 Characterization

Fracture and polished section morphology of specimens were observed by field-emission scanning electron microscopy (FE-SEM, JEOL JSM-700F) with an energy-dispersive X-ray spectroscopy (EDS).

## 3 Results and discussion

### 3.2 Verification of experimental method

Macrophotographs of specimens under different air pressures are shown in **Fig. 4**. It can be seen that when the air pressure is 0 Pa, a small amount of Al$_2$O$_3$ cloggings on the surface of the specimen (as shown in Fig. 8b). The main reasons are as follows: ① when the specimen was immersed in molten steel, due to the drastic temperature change (to 1550 °C), the air in the specimen would expand rapidly and diffuse to the specimen-molten steel interface, which will oxidize the metal [Al] near the specimen to form Al$_2$O$_3$ inclusions; ② decarburization of the molten steel increased the surface roughness of the specimen, which increases the contact area between the specimen and the Al$_2$O$_3$ inclusions.

When the air pressure is -15000 Pa, there was almost no $Al_2O_3$ cloggings on the surface of the specimen (as shown in **Fig. 4a**). The main reason is that most of the air inside the specimen is extracted, and the residual air cannot reach the specimen-molten interface, resulting in almost no $Al_2O_3$ cloggings near the specimen (as shown in **Fig. 5a**).

**Fig. 3** Schematic diagram of $Al_2O_3$ clogging experimental method under near working conditions

**Fig. 4** Macrophotographs of specimens under different air pressures: (a) -15000 Pa, (b) 0 Pa, (c) 15000 Pa, and (d) 30000 Pa

When the internal air pressure of the specimen is 15000 Pa and 30000 Pa, there are more $Al_2O_3$ cloggings on the surface of the specimens, and the higher the pressure is, the more the thickness of the cloggings is (as shown in **Fig. 4c** and **d**). Because under the action of pressure difference, air will continuously reach the specimen-molten steel interface (as shown in **Fig. 5b**) and oxidize Al in the molten steel to form a large number of $Al_2O_3$ inclusions. This shows that the new experimental method realizes the idea of $Al_2O_3$ clogging and can be used for the development of SEN anti-clogging lining materials.

**Fig. 5** Clogging mechanism of specimens: (a) extracting air from inside the specimen (-15000 Pa); (b) injecting air into specimens (15000, 30000Pa)

When the internal pressure of the specimen is 30000 Pa, the fracture morphology of the cloggings is shown in **Fig. 6**. It can be seen that the cloggings are composed of $\alpha$-$Al_2O_3$ and $\beta$-$Al_2O_3$, and they are staggered distribution. The microstructure of the cloggings was shown in **Fig. 7**. It can be seen that the cloggings was mainly composed of $\alpha$-$Al_2O_3$, $\beta$-$Al_2O_3$, and cold steel, which is basically consistent with the microstructure of cloggings on the specimens obtain by $Al_2O_3$ clogging experimental method under near work conditions.

**Fig. 6** Fracture morphology of cloggings on $Al_2O_3$-C specimen when the inner pressure in specimen is 30000 Pa: (a) cross section fracture at the red line mark of specimen; (b,c) enlargement diagram of red box area in Fig. 11a

**Fig. 7** Fracture morphology of cloggings on SEN used by a domestic company: (a) macrophotograph of cross section of SEN; (b) enlargement diagram of red box area in Fig. 12a

**3.3 Application of experimental method**

**Fig. 8** is the macrophotographs of the specimens after the experiment (four materials are compounded on the same sample). It can be seen that there are more cloggings on the $Al_2O_3$-C specimen surface than those on the lining specimen surface, indicating that the graphite-free lining presents a better effect on preventing $Al_2O_3$ clogging. In addition, there are more cold steel on the surface of $MgAl_2O_4$ and $Al_2O_3$-$SiO_2$ lining materials. The cold steel on the $MgAl_2O_4$ material surface is distributed in clusters, and the cold steel on the $Al_2O_3$-$SiO_2$ material surface is uniformly dispersed. This shows that the anti-clogging effect of $MgAl_2O_4$ and $Al_2O_3$-$SiO_2$ materials are poor.
**Fig. 8** Clogging state of different lining materials

**Fig. 9** Microstructure of cloggings on the specimens surface: (a) Al₂O₃-C; (b) ZrO₂; (c) MgAl₂O₄; (d) Al₂O₃; (e) Al₂O₃-SiO₂

The microstructure of the above specimens were analyzed, and the results were shown in **Fig. 9**. It can be seen that the thickness of the cloggings on the lining specimen surface is much smaller than that on the Al₂O₃-C specimen surface. The thickness of the cloggings on the ZrO₂ material surface is the smallest (0.2mm), which is 1/5 of that on the Al₂O₃-C specimen surface, 2/5 of that on the MgAl₂O₄

material surface, and 1/2 of that on the surface of Al₂O₃ material and Al₂O₃-SiO₂ material. In addition, it can be seen that there is no Fe in the cloggings on the ZrO₂ material surface, which indicates that ZrO₂ material does not react with molten steel. Therefore, choosing ZrO₂ as SEN lining can improve the anti-clogging ability of SEN.

**4 Conclusions**

In this paper, an Al₂O₃ clogging experimental method under near working conditions was innovatively designed and verified. Then the optimization of anti-clogging lining material is studied by using this new method. The research conclusions are as follows:

(1) The new Al₂O₃ clogging experimental method simulates the actual working conditions, which ensures the stable source, content, and size of Al₂O₃ inclusions around specimen and makes the experimental results more reliable. It provides strong support for make up the shortcomings of the existing experimental method and further research and development of new anti-clogging SEN lining material.

(2) Fused calcium stabilized zirconia (ZrO₂) has poor reactivity with Al₂O₃ inclusions, non-wetting with molten steel, and possess excellent anti-nodulation properties.

# THE DEVELOPMENT OF THE THERMAL INSULATION COATING

Wataru Koide, Shigeru Morimoto, Noriaki Yamauchi, Masahiro Shinato, and Keisuke Kachi

TYK Corporation, Gifu, Japan

## ABSTRACT

The refractories for continuous casting such as submerged entry nozzle (SEN) are often preheated before casting.

To keep SEN temperature, it applies an insulation on.

In the past, RCF (Refractory Ceramic Fiber) used to be generally applied as an insulation, but due to concerns about its health effects, the shift to AES (Alkaline Earth Silicate) is progressing worldwide.

It has also been developed that the coating material does not contain fibers as an insulation. Fiber-type insulation sheets have a prickly feel on the skin, so non-fiber-type insulation coatings are preferred sometimes.

This non-fiber insulation coating has another effect that prevent the antioxidant glaze melt from the molten steel splashes during casting.

However, instead of high heat retention, the heat insulation inhibits heat transfer from the outer surface of the nozzle, which is a factor in inhibiting preheating in a short time.

In order to solve these issues, it's developed that the non-fiber insulation material that improves to make shorter the preheating time and keep the heat retention after preheating.

## INTRODUCTION

In general, SEN are preheated before using to reduce the risk of thermal spalling and the insulation is applied on the SEN to keep the preheating temperature.

RCF fiber used to be most usual insulation fiber, but due to concerns about its health effects, the shift to AES fiber is progressing worldwide.

On the other hand, non-fiber type insulation material has been developed for long time. It's preferred sometimes compared with fiber type insulation.

As one of issue, non-fiber type insulations is slightly higher thermal conductivity than fiber type insulations.

In this study, by adding carbon to the conventional heat insulating material, we have developed a heat insulating material that maintains the heat insulating effect after temperature rise while improving the heating rate and the cooling rate.

## EXPERIMENTAL METHODS

### Test sample

The refractory sample is used alumina-graphite, which is generally used the nozzle for the continuous casting, and applied the glaze on the surface. Tab. 1 shows the chemical composition of the refractory samples used in this test, and the thermal insulation coating materials. Sample A has no insulation on the refractory sample. 3 other samples are applied 3 types of insulation on each sample. Sample B is applied AES fiber sheet by inorganic adhesive and keep drying in the atmosphere for 24 hours. Sample C is applied the non-fiber insulation material (Insulation 1 on Tab. 1), which is conventional. Sample D is applied the new non-insulation material (Insulation 2 on Tab. 1). Sample C and Sample D are applied the insulation materials by spraying and keep drying at 100°C for 8hours, after drying in the atmosphere for 4 hours. Insulation 2 is added Carbon to Insulation 1.

Tab. 1: Chemical composition

| | | Alumina-graphite | Insulation 1 | Insulation 2 |
|---|---|---|---|---|
| Chemical composition / mass% | C | 32 | 5 | 20 |
| | $Al_2O_3$ | 66 | 65 | 55 |
| | $SiO_2$ | - | 26 | 21 |

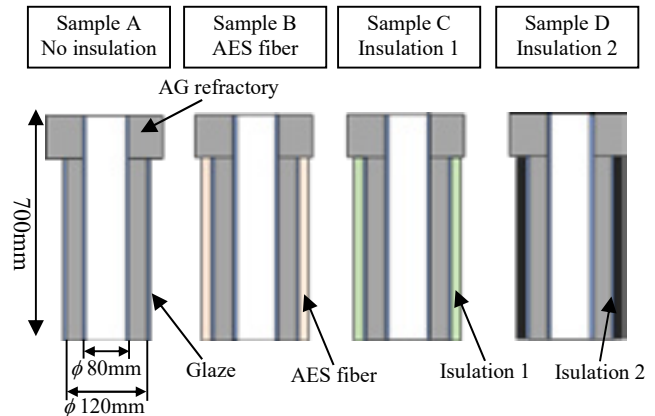

*Fig. 1: Appearance of each sample.*

### Test procedure

Fig. 2 shows the appearance of heating test. The sample put in the furnace, heat up to 1200°C and keep for 2hours. After that, the sample is brought out from furnace and keep in the atmosphere. While the testing, it is monitored the temperature. The K type thermocouple is inserted like Fig. 3 to measure the temperature of the sample.

*Fig. 2: Appearance of heating test.*

*Fig. 3: Temperature measurement.*

## RESULTS

### The appearance of non-fiber insulation

Fig 4 shows the appearance of non-fiber insulation coating.

The color of Insulation 1 is white before heating. The color is due to $Al_2O_3$ and $SiO_2$. The color of Insulation 1 is changed to ocher after heating.

The color of Insulation 2 is black before heating. It is due to carbon. The color is changed to ocher same as Insulation 1 after heating. After carbon oxidizes and vaporizes in heating, by leaving behind $Al_2O_3$ and $SiO_2$, the color of insulation 2 is changed ocher.

| Insulation 1 (Conventional) | | Insulation 2 (Carbon added) | |
|---|---|---|---|
| Before heating | After heating @ 1200°C | Before heating | After heating @ 1200°C |
| White | Ocher | Black | Ocher |

Fig. 4: The appearance of non-fiber insulation.

### The comparison of heating rate

At first, it's compared the heating rate of each sample while heating.

Tab.2 shows the result about the temperature of each sample for each 10 min while heating. Fig.5 shows the graph about the temperature of each sample for each 1min while heating.

The temperature of Sample B after heating for 10 minutes was more than 150°C lower than that of Sample A. The insulation sheet would make slow the heating rate.

On the other hand, the gap of the temperature after 10 minutes between Sample A and Sample C was less than 150°C, and between Sample A and Sample D was less than 100°C.

From these results, it was confirmed that the non-fiber insulation material has a higher temperature rise property than the AES fiber insulation sheet. And also, the addition of carbon raw material can further improve the temperature heating property.

Tab. 2: Temperature of each sample while heating.

| Heating time / min | Sample A | Sample B | Sample C | Sample D |
|---|---|---|---|---|
| 10 | 878 | 714 | 750 | 793 |
| 20 | 1090 | 990 | 1020 | 1050 |
| 30 | 1177 | 1109 | 1127 | 1145 |
| 40 | 1201 | 1158 | 1168 | 1187 |

Fig. 5: Temperature of each sample while heating.

### The comparison of cooling rate

There is the comparison of cooling rate after the refractory temperature reach at 1200°C and keep for 2 hours.

Tab.3 shows the result about the temperature of each sample for each 10 min while cooling. Fig.6 shows the graph about the temperature of each sample for each 1min while cooling.

The temperature of Sample B after cooling for 10 minutes was approximately 200°C higher than that of Sample A. It's confirmed the AES fiber sheet has high thermal insulation.

The temperature of Sample C after cooling for 10 minutes was approximately 150°C higher than that of Sample A. It means the insulation material is lower insulating than the fiber sheet.

The temperature of Sample D after cooling for 10 minutes was approximately 350°C higher than that of Sample A. Sample D shows the highest insulation performance in 4 samples.

Tab. 3: Temperature of each sample while cooling.

| Cooling time / min | Sample A | Sample B | Sample C | Sample D |
|---|---|---|---|---|
| 5 | 618 | 792 | 768 | 958 |
| 10 | 485 | 685 | 639 | 837 |
| 20 | 324 | 536 | 476 | 666 |
| 30 | 214 | 435 | 384 | 538 |

Fig. 6: Temperature of each sample while cooling.

495

**CONSIDERASIONS**

It's expected that the addition of carbon would improve the heating rate. As the result in "The comparison of heating rate", the temperature rising of Sample D (the insulation material including carbon) is slightly faster than that of Sample B (AES fiber) and Sample C (the conventional insulation material).

On the other hand, as mentioned in "The comparison of cooling rate", the temperature rising of Sample D is much slower than that Sample C.

At first, it is thought that the added carbon, which is high thermal conductivity, improved the heating rate of the insulation material during heating. When the sample was heated above a certain temperature, the carbon oxidized and vaporized, creating a large number of pores in the heat insulating material.

Tab.4 shows the physical properties of insulation material before and after heating.

Sample making method
- Mixed insulation material and dried at 100°C (Before heating)
- Heated above sample at 1200°C for 2 hours (After heating)

Tab. 4: The physical properties of insulation

|  | Insulation 1 (Conventional) | | Insulation 2 (Carbon added) | |
|---|---|---|---|---|
|  | Before heating | After heating | Before heating | After heating |
| Apparent porosity / % | 38.4 | 39.0 | 47.3 | 56.0 |
| Bulk density / g·cm⁻³ | 1.66 | 1.79 | 1.13 | 1.22 |
| Modulus of rupture / MPa | 2.9 | 6.8 | 1.0 | 2.8 |

The bulk density and modulus of rupture of Insulation 1 increased after heating, and the apparent porosity of one almost unchanged. It is considered the reason that the volatile matter content vaporizes during heating and the some of materials in insulation sinters.

On the other hand, not only the bulk density and modulus of rupture of Insulation 2 increased after heating, but also apparent porosity of one increased. It is thought the reason that the pore in insulation increases by carbon oxidizing and vaporizing during heating.

Fig.7 shows the observation results by Microscope for insulation materials before and after heating.

Insulation 1 was no significant difference between before and after heating. it was observed that the number of pores for Insulation 2 after heating increased compared to before heating. It is presumed that these pores were formed after the carbon disappeared as described above.

By adding carbon to insulation material, it was improved the heating rate at the start of heating, and by disappearing carbon during heating, it has higher heat insulation than the conventional, great improving the heat retention property of the refractory temperature after heating.

*Fig. 7: Microscope observation results.*

**CONCLUSIONS**

The non-fiber insulation coating, which have been developed so far, have been inferior to the AES insulation fiber in terms of thermal insulation.

In this development, by adding carbon, which is high thermal conductivity, to the insulation material, it was possible to ensure the heating rate during heating. In addition, by carbon vaporizing, the thermal insulation properties during cooling after heating can be improved compared to the conventional insulation material, and the thermal insulation performance exceeds that of the AES insulation sheet.

It is expected to improve the heat insulation (the resistance of the heat removal) of the refractory after preheating, without increasing the energy cost for preheating the nozzle.

As issue of the future, the workability of the insulation material application is worse than the conventional one. Moreover, it could be possible that the insulation coating peels off from the refractory due to weaker strength of the insulation material. Therefore, in order to maintain stable performance, selection of the optimum additive amount will be a future issue.

## ABSTRACT

The increasing demands in iron and steel industry with regard to longer casting times and speeds as well as improved steel qualities require the constant further development and investigation of existing material systems. Zirconia is one of the most promising functional refractory materials in continuous steel casting and is mainly employed in areas with high thermal and chemical stresses such as the slag line and the nose of monoblock stoppers or the inlet area of submerged entry nozzles. The key for the application of zirconia based ceramics in such harsh application areas is a profound understanding of its thermomechanical and thermochemical properties that are mainly influenced by the type and the amount of stabilizer, the grain size as well as the thermal conditions during sintering and operation. Within the present contribution coarse grained (up to 5 mm) zirconia self-flowing castables based on a yttria stabilized zirconia co-stabilized by magnesia are developed and bars as well a model monoblock stoppers are cast. The mechanical and thermo-mechanical properties are evaluated after sintering at 1650 °C. The influence of different stabilizer variants as well as the contribution of the binder to the phase evolution of the zirconia during sintering and operation and thus the influence on the thermo-mechanical properties is investigated with the aid of EDS- and X-ray diffraction measurements.

## INTRODUCTION

In the continuous casting of steel zirconia refractories are employed in areas with high thermal and chemical stresses such as the slag line and the nose of monoblock stoppers or the inlet area of submerged entry nozzles since they offer excellent corrosion and erosion resistance and a unique combination of strength, toughness, hardness and thermal shock resistance [1]. Up to date and depending on the required steel quality carbon-bonded zirconia materials are employed among others because they offer an excellent thermal shock performance. Nevertheless, their application will be more limited in the future since they do not meet the quality requirements of low and ultra-low carbon steels due to dissolution processes [2]. In the present study a fuse cast yttria stabilized (2.46 wt.%) zirconia co-stabilized by 1.44 wt.% magnesia is introduced. The use of carbon as binder is consciously avoided for the above mentioned reasons. A good thermal shock resistance of the co-stabilized zirconia with residual strengths of >5 MPa, even after recurring thermal shock, is addressed by employing coarse grains (up to 5 mm) and tailoring a high metastable tetragonal phase proportion. Therefore, the impact of calcium magnesium aluminate cement (CMA) as hydraulic binder [3, 4] as well as of a hydratable alumina binder on the phase evolution during sintering is investigated. The development of self-flowing castables is presented not only for test specimen but also for application-oriented components. The physical and thermo-mechanical properties are evaluated. The microstructure as well as the phase compositions of the sintered materials are investigated with the aid of SEM and X-ray diffraction.

## MATERIALS AND METHODS

In the present study a fuse cast yttria stabilized zirconia co-stabilized with magnesia was employed. As binder 3-9 wt.% CMA72 provided by Imerys S.A. with a mean particle size of 15 µm was used. As an alternative binder, 1 wt.% Alphabond 300 (Almatis, Germany), hydratable alumina binder was used [5, 6]. Peramin AL 200 (Imerys S.A.) [4] was used as a dispersing agent for the CMA containing castables. For the castables prepared with Alphabond 300 as binder, ADW and ADS [7] were used as dispersants and for adjusting the setting behavior. The investigated self-flowing castables with the compositions given in Tab. 1 were designed according to the grain size distribution model of Dinger and Funk [8-10] with a distribution modulus of 0.28. Casting of the self-flowing masses was done in steel molds with the dimensions 25 x 25 x 150 mm³. Furthermore, the most promising composition was chosen to cast model monoblock stopper with a diameter of 40 mm and a length of 340 mm. All samples were demolded after 24 h and then dried stepwise up to 110 °C. Sintering was conducted at 1650 °C in oxidizing atmosphere with a heating rate of 1 K/min with a dwell time of 120 min at maximum temperature. For composition Z991AB an additional dwell of 60 min at 500 °C during heating was done.

The initial co-stabilized zirconia powder exhibits a partial stabilization since reflexes for all three phases were identified. The quantification using Rietveld refinement yields 56 % monoclinic, 16 % tetragonal and 27 % cubic phase. The sintering of the cast samples was conducted at 1650 °C in the phase field of the tetragonal solid solution (for yttria stabilized) and tetragonal/cubic solid solution (for magnesia stabilized). The results of the x-ray analysis after sintering are summarized in Tab. 2.

Fig. 1 displays the microstructure of the composition Z94CMA6 after sintering, showing that an adequate densification of the matrix

took place. Grain boundaries, pores are visible as well as spinel agglomerates with sizes of up to 50 µm.

*Fig. 1: SEM micrograph (BSE mode) of the co-stabilized zirconia sintered at 1650 °C*

*Fig. 2: SEM micrograph (BSE mode) of composition Z94CMA6 sintered at 1650 °C with marked positions 1-10 of EDS point analyses.*

*Fig. 3: SEM micrograph (BSE mode) of composition Z94CMA6 sintered at 1650 °C with marked positions 11-16 of EDS point analyses.*

Detailed EDS analyses were carried out in order to investigate the interactions between zirconia and the binders. Fig. 2 and Fig. 3 displayed a polished cross-section of the sample Z94CMA6. The results of the EDS scans for the marked positions are summarized in Tab. 3 and Tab. 4.

Four different areas of the microstructure were investigated in detail. The EDS point analyses 2, 3, 5, 9 reveal a depletion of the fine zirconia matrix by magnesia. The co-stabilized powder in initial state contained 1.44 wt.% MgO; it decreased during sintering to 0.7 wt.%. In the fine zirconia matrix, a CaO-content of 2.4 wt.% was determined via EDS point analysis. During sintering calcium ions (present in the CMA binder) diffuse into the zirconia grains and lead to a stabilization of the zirconia. According to the phase diagram, this stabilization takes place in the phase field of tetragonal and tetragonal/cubic solid solution modification [11]. Close to the grain boundaries of the large zirconia grains (EDS scans 1, 7, 8) also a depletion by magnesia was registered. In addition to that, small precipitates are formed close to the grain boundaries of large (>1 mm) zirconia grains. These have also been identified as magnesium aluminate spinel. At distances >15 µm from the grain boundary the initial chemical composition of the co-stabilized zirconia was measured. The EDS point analyses 11-15 clearly identify magnesium aluminate spinel that was formed during sintering.

Fig. 4 shows the microstructure of the composition Z99AB1 with 1 wt.% Alphabond 300. It appears less densified as compared to the composition Z94CMA6 with 6 wt.% CMA. The open porosity was determined to be 17.4 % and the pores appear elongated with a span of up to 50 µm. Fig. 4 also contains position of EDS point analyses and the results are summarized in Tab. 5 and Tab. 6. In the EDS point analyses 1- 5 as well as 6-10, taken in the center or at the boundaries of large zirconia grains, a strong deviation in the chemical compositions with regard to magnesia content can be recognized, indicating the diffusion of magnesia and thus a severe destabilization. This was confirmed by x-ray analysis, where the monoclinic phase content was determined to be 84 %. In addition to that spinel was formed during sintering (EDS positions 11 and 12). Furthermore, smallest spinel precipitates (≤300 nm) start to grow within the zirconia grains.

Tab. 7 summarizes the physical and mechanical properties of the co-stabilized zirconia castables. The linear shrinkage was small in all of the compositions. Thus, the formation of large stresses during sintering (responsible for crack formation) was prevented. This is one basic requirement for the fabrication of large-scale components.

Tab. 7: Physical, mechanical and thermomechanical properties of the castables after sintering at 1650 °C

| | Z99 AB1 | Z97 CMA3 | Z94 CMA6 | Z91 CMA9 |

| Young´s Modulus after TS (GPa) | 9.5 ± 0.4 | 21.5 ± 2.0 | 30.9 ± 0.0 | 12.5 ± 0.6 |

The open porosity of the castables was determined between 16.8 to 17.7 % and thus typical values for self-flowing castables were obtained [12]. The porosities for the compositions Z94CMA6 and Z91CMA9 with 6 or 9 wt.% CMA are lower as compared to the other compositions. This might be the result of the noticeable spinel formation during sintering, which was shown in Tab. 2. It was recognized that the spinel "grows" into the pores. The lowest flexural strength was determined for composition Z99AB1 with 8.5 MPa. During sintering a severe destabilization of the co-stabilized zirconia was registered and the monoclinic phase content significantly increased to 84 %. During sintering, upon cooling the phase transformation tetragonal to monoclinic is accompanied by a volume expansion of 3-5 % resulting in the damage of the microstructure and thus deteriorates the mechanical properties. This is also reflected in the remaining strength after thermal shock testing where a loss in strength of 47 % was registered. Composition Z94CMA6 had the highest flexural strength with 14.8 MPa. The calcia contained in the CMA cement stabilized the tetragonal zirconia phase during

sintering. Thus, a significant decrease in monoclinic phase was registered, see Tab. 2. This means, that on the one hand the tetragonal to monoclinic phase transformation upon cooling is inhibited and on the other hand that the tetragonal grains may undergo (depending on their size) a martensitic phase transformation during mechanical loading. Despite the high tetragonal phase content of 61 %, the composition Z91CMA9 has the lowest flexural strength in the group of CMA containing castables. In the x-ray analysis it was shown that a severe spinel formation (18 %) took place during sintering. The spinel grains grow to sizes >50 μm and thus weakened the zirconia matrix deteriorating the mechanical as well as thermo-mechanical properties. The compositions Z97CMA3 and Z94CMA6 show a very good thermal shock performance with losses in strength of only 24 % and 37 % after one thermal shock testing cycle.

In order to evaluate the thermal shock performance in an application-oriented manner, the composition Z94CMA6 was thermally cycled for 5 times and the remaining strength was determined after one, three and five thermal shock tests. The results are summarized in Fig. 5. As expected, the loss in strength is most pronounced after the first thermal shock. A remaining strength of 9.3 ± 1.0 MPa was determined after the first thermal shock. In the further tests, the loss in strength is less pronounced since the microstructure is characterized by a distinct micro-crack network (from transformation of tetragonal to monoclinic phase and due to spinel formation during sintering). In addition to that, the tetragonal zirconia phase is able to transform stress-assisted (martensitic) into monoclinic state. This leads to closure of cracks and prevents further crack propagation. After the third thermal shock a loss in strength of 27 % and after the fifth thermal shock a loss in strength of 20 % was determined. The remaining strength after five thermal shocks was measured to be 5.5 ± 1.5 MPa, which is a good value for coarse zirconia refractories.

*Fig. 5: Flexural strength after thermal shock testing, composition Z94CMA6 with 6 wt.% CMA*

In the final part of this study, larger application-oriented components have been developed, e.g. for casting experiments in a steel casting simulator (Systec, Germany) [12-14]. Model monoblock stopper with a length of 340 mm and a diameter of 40 mm were successfully cast, see Fig. 6. For the preparation of the self-flowing castables the same compositions as shown in Tab. 1 were used without further modification. The mixing routine was also identical, but the casting itself had to be modified. Small portions of the self-flowing mass were filled into the stopper mold that consisted of two parts. During the filling of the mold, short breaks for the de-airing of the self-flowing mass were made. Demolding took place after 24 h. After drying the stopper was sintered on an alumina bed (2 mm) in a lying position with a heating rate of 1 K/min to 1650 °C and a dwell at maximum temperature of 120 min. Due to the small shrinkage during sintering as well as due to the tailored phase composition of the co-stabilized zirconia a defect-free stopper was successfully fabricated. In further studies the stopper/testing bars will be investigated in the above mentioned steel casting simulator.

*Fig. 6: Defect-free stopper rod prepared with coarse grained co-stabilized zirconia.*

## CONCLUSIONS

Within this paper a yttria stabilized zirconia co-stabilized by magnesia has been introduced for the preparation of coarse-grained self-flowing castables. The co-stabilized zirconia was composed of 56 % monoclinic, 16 % tetragonal and 27 % cubic phase. Traces of alumina and ytterbium silicate were also detected. The addition of calcium magnesium aluminate (CMA) cement as binder led to a stabilization of the tetragonal zirconia phase during sintering due to the replacement of magnesia as stabilizer by calcia. After sintering the tetragonal phase content was determined to be in the range of 45 and 61 % depending on the CMA content. With the aid of EDS measurements, it was shown that the stabilization of the zirconia involved all the different zirconia particle sizes. In large zirconia particles (up to 5 mm) the initial chemical composition was detected at distances of 15-20 μm from the grain boundary. The monoclinic phase content decreased significantly in all of the CMA containing compositions. In contrast to this, the compositions prepared with hydratable alumina binder showed a severe destabilization with a monoclinic phase content of 84 % after sintering. In all compositions the chemical reactions between magnesia (lost as stabilizer) with alumina (from binder) and the subsequent formation of magnesium aluminate spinel was recognized.

All of the prepared samples had a very small shrinkage during sintering, thus enabling the preparation of larger components. The flexural strength was the highest in compositions Z94CMA6 and Z97CMA3 with 14.8 ± 1.8 MPa and 12.6 ± 1.6, respectively. The flexural strengths of the compositions Z99AB1 and Z91CMA9 were low, due to the high monoclinic phase content and the high spinel content, respectively. For the composition Z94CMA6 the thermal shock performance was further evaluated by quenching the samples 5 times. As expected, the loss in strength was most pronounced after the first thermal shock test. A remaining strength of 9.3 ± 1.0 MPa was determined. The loss in strength was less pronounced in the further thermal shocks. A remaining strength after five thermal shocks of 5.5 ± 1.5 MPa was determined.

Finally, large application-oriented components were developed for casting experiments in a steel casting simulator (Systec, Germany). After a minor modification of the casting routine, model monoblock stopper with a length of 340 mm and a diameter of 40 mm were successfully cast and defect-free stoppers were obtained after sintering. In future work these stoppers will be tested in real-term conditions in the above mentioned steel casting simulator.

## ABSTRACT

Different $Al_2O_3$-based materials were investigated as base materials for the extrusion of cellular filter components for the continuous casting of steel melts. The final filter component should be implemented at the tundish bottom. It has to withstand thermal shock and oxidation during preheating and at the first melt contact. Additionally, it has to survive the corrosive attack and mechanical stresses at high temperatures during the continuous casting process over several melt batches and a duration of several hours. Thus, the fine $Al_2O_3$ basis was modified regarding three major factors: Adding a coarser alumina fraction, adding a carbonaceous fraction and adding $ZrO_2$. The resulting eight combinations were mixed with methylene cellulose to form plastic mixes and extruded into bar-shaped samples. The samples were investigated regarding their shrinkage behaviour, density, porosity, mechanical strength and thermal shock behaviour. The oxidic material with the most promising property profile was $Al_2O_3$-$ZrO_2$ with 200 µm grain. The carbon-bonded material with the most promising property profile was $Al_2O_3$-$ZrO_2$-C with 200 µm grain. Both materials were successfully applied to generate large-scale filter tube prototypes.

## INTRODUCTION

Ensuring steel cleanliness is of ever-increasing importance with regard to increasing efficiency, performance and safety while reducing carbon footprint, scrap rates and the waste of energy and raw material [1]. When all technologies of modern steelmaking including advanced secondary metallurgy, the use of high-performance refractories, clever plant, ladle and tundish design as well as state-of-the-art process control systems, are utilized to full potential, steel melt filtration can provide a further way to remove remaining non-metallic inclusions shortly before the casting process.

While melt filtration is state of the art in batch processes, e.g. in foundries, it is quite challenging in continuous casting. The high duration of casting sequences and the amount of steel melt passing through filters increases the risk of filter blockage or failure substantially. Wetzig et al. [2,3] investigated the immersion of exchangeable foam filter systems in an industrial tundish in order to tackle these challenges. The immersion process allows for flexible removal and replacement of the filters after a defined casting time. In this way, filter blockage or failure and a premature termination of the casting process is avoided. Of course, this method is only possible if the tundish design allows for it. Some systems include covers, instruments or generally limited space above the tundish. In this case, classic fixed implementation of filters into the tundish prior to casting is the only possibility.

In this case, the following conditions have to be considered:

1. Preheating of the system prior to casting (oxidation, thermal shock)
2. Casting duration (high temperature creep, corrosion, erosion)
3. Filter position and tundish design (mechanical stresses depending on pressure and flow conditions)
4. Steel melt composition and temperature (corrosion, thermal shock)

The expected conditions should determine a) the applied filter type and b) the applied filter material. The target application in the present case was a filter tube at the bottom of the tundish, directly above the outlet to the moulds. The system is preheated with gas burners and then cast on directly with melt including first slag contact. After that the filter has to withstand constant melt flow and ferro-static pressure at temperatures greater than 1500°C for several hours. Due to the filter positioning and the severe conditions, foam filters were deemed too fragile and thus too risky. As an alternative, an extruded cellular chaotic structure like presented by Essock et al. [4] was proposed. Essock et al. extruded SiC "spaghetti" filters and successfully applied them in iron casting. A structure on this basis with comparatively dense and strong filter struts was also considered most suitable for the present investigation.

For the selection of the most suitable filter material, a fine alumina-based material (A) was modified using a combination 3 main factors:

- adding $Al_2O_3$ with < 200 µm grain size ($^b$),
- adding monoclinic $ZrO_2$ (Z) and
- adding carbonaceous material (C)

The 8 resulting compositions were analysed on their shrinkage, density, porosity, mechanical strength and thermal shock resistance. The materials with the most suitable property profile were applied to manufacture a filter prototype.

## EXPERIMENTAL

Table 1 shows the base composition the investigated compositions. The alumina portion of compositions including a second alumina faction was optimized based on a Dinger-Funk model using q = 0.2 as exponent. The material was dry-mixed together with 2 wt.% methyl cellulose derivative in an intensive mixer for 5 minutes. Afterwards, 0.3 wt.% of dispersing agent was added and water was introduced in a stepwise manner while mixing until the approximate consistency of a reference extrusion mix was achieved (see Fig. 1a). The final material was mixed for another 5 minutes. Since water may evaporate during mixing, a sample of each mix was analysed on their actual humidity in a moisture analyser. It ranged between 12.6 wt.% ($^b$AZ) and 19.7 wt.% (AZC) depending on the individual mix. The mixes were stored in air-tight plastic bags for 24 hours in order to let the methyl cellulose soak.

Tab. 1: Extrusion material compositions.

|  | A | $^b$A | AZ | $^b$AZ | AC | $^b$AC | AZC | $^b$AZC |
|---|---|---|---|---|---|---|---|---|
| Raw material composition in wt.% | | | | | | | | |
| $Al_2O_3$ (< 20 µm) | 100 | 17 | 80 | 5 | 70 | 33 | 56 | 26 |
| $Al_2O_3$ (< 200 µm) | - | 83 | - | 75 | - | 37 | - | 30 |
| $ZrO_2$ | - | - | 20 | 20 | - | - | 14 | 14 |
| Pitch binder | - | - | - | - | 20 | 20 | 20 | 20 |
| Graphite | - | - | - | - | 10 | 10 | 10 | 10 |

After the soaking time, the mixes were extruded into strands of approximately 300 mm length using a piston extruder (see Fig. 1b) with a rectangular nozzle of the dimension 4 x 5 mm². The strands were marked with a stamp in 50 mm distance sections to allow for the determination of the shrinkage after drying and the subsequent separation of bar-shaped samples.

After drying for 24 hours at room temperature, the dimensions and mass of 30 random bar-shaped samples per composition were measured to determine the geometric density, dry shrinkage and parameters for mechanical testing on 3-point bending strength

(CMOR). The mechanical testing was performed using a mechanical testing machine TIRA test 2420.

*Fig. 1: Sample preparation; a) Extrusion mix in intensive mixer; b) Piston extruder; firing preparation of bar-shaped carbon-bonded samples in pet-coke bed (c) and oxidic samples (d).*

The rest of the oxidic samples was fired for 5 hours at 1600 °C and the rest of the carbonaceous samples was fired in coke bed (reducing atmosphere) for 3 hours at 800 °C (Figure 1c-d). The measurement of the mass and dimensions, the determination of the geometric density and the shrinkage as well as the CMOR measurement of 30 random samples were again performed after firing. Furthermore, 10 samples of each composition were tested on their open porosity and raw density using the Archimedes principle. To disclose also the closed porosity, the true density of each material was also analysed by means of a helium pycnometer.

Finally, 30 more fired samples of each material were subjected to thermal shock in water (25 °C) from a temperature of 1000 °C. The CMOR of the shocked samples was measured to determine the residual strength of each material as a proxy for the thermal shock resistance.

The data was then analysed in comparison to find the most suitable materials in order to manufacture first filter prototypes.

## RESULTS AND DISCUSSION

All materials were extrudable without major issues regarding surface quality, tearing or deformation. However, there was some deformation after drying depending on the amount of water used. In this regard, the coarser oxide materials [b]A and [b]AZ were of advantage, whereas fine, carbon-bonded materials show more deformation after firing.

This directly correlated with the linear dry shrinkage of the investigated materials which ranged from about 1 to 2 % for [b]A and [b]AZ and was about 3 to 4 % for other materials.

Geometric density after drying was about 1.5 g/cm³ and very similar for carbon-bonded materials. For oxidic materials, the lower water demand of [b]A and [b]AZ, led to roughly 15-20% higher density implying lower porosity compared to their finer counterparts A and AZ.

The dry CMOR of most materials was in the range of 8 to 11 MPa. Materials [b]A and [b]AZ, which were preferred regarding their dry shrinkage showed much lower dry CMOR of about 5 MPa. This mainly originated from higher roughness and the coarser microstructure. This effect was not observed for the coarse carbon-bonded materials [b]AC and [b]AZC which suggests that the dry CMOR was dominated by the binding matrix, in this case carbonaceous material.

After firing, most materials shrank another 3 to 5 % with [b]A showing the lowest shrinkage in the test. The fine oxidic materials A and AZ both shrank over 17% in length after firing. This high

shrinkage already eliminates these materials for use as base materials of large-scale filter components as the expected degree of deformation and residual stress is critical.

Of course, the high shrinkage comes with high densification which made materials A and AZ the compositions with the highest geometric density after firing. For the fired materials, the density and porosity were investigated more comprehensively using the Archimedes principle in combination with helium pycnometry. In carbon-bonded materials, the carbonaceous matrix dominated the effect on the microstructure resulting in similar total porosity ranging from 44 to 50 % with negligible closed porosity. Coarse oxidic materials [b]A and [b]AZ had slightly lower porosity of about 35 % which was entirely open. Fine oxidic materials A and AZ had the lowest total porosity of 11 to 12 % with a majority of pores closed. In terms of corrosion, this would be favourable if the shrinkage behaviour of the fine materials were not so critical. Considering the similarity of the other materials in the study, the porosity was not a major selection point.

The CMOR after firing again showed that all carbon-bonded materials were rather similar ranging from 18 to 20 MPa. Zirconia-containing materials showed slightly lower CMOR than their zirconia-free counterparts. This originated from microcracks in the microstructure of the material introduced by the monoclinic zirconia and its phase transitions during firing. Naturally, the CMOR of fine materials was much higher with 149 MPa for AZ and 162 MPa for A compared to coarse materials (25 and 38 MPa). However, the most critical property for the intended application as filter material was the residual strength after thermal shock. Fine materials A and AZ only retained about 20 % of their CMOR after shocking. Material [b]A with 27% residual strength provided no major improvement of the thermal shock performance. All other materials retained above 35% of their CMOR after shocking with coarser materials outperforming slightly. [b]AZC showed the highest residual strength in the test with 46 %. Material [b]AZ retained 39 % of its strength making it the highest performing oxidic material in the test.

In summary, the critical shrinkage and low thermal shock resistance disqualified the materials A and AZ from further consideration. The carbon-bonded materials all performed similar, so due to its slightly higher residual strength, [b]AZC was chosen as carbon-bonded filter material. However, due to oxidation during the preheating, coatings will be necessary to apply the material in the final application for industrial continuous casting of steel. Hence, composition [b]AZ was chosen as most suitable oxidic alternative due to its low shrinkage and favourable thermal shock behaviour.

*Fig. 2: Filter prototypes using materials a) [b]AZC and b) [b]AZ [5]*

Both materials were used to extrude hollow cylindric filter prototypes with the height of 160 mm and a mean outer diameter of 200 mm. The geometry had a slight cone shape to allow for easy demoulding. The wall thickness of the cellular filter walls amounted to 30 mm. The manufacturing was performed by extruding a continuous strand into a constantly rotated cone-shaped polymer mould with a core in the middle. The rotation speed of the mould was chosen slightly slower than the extrusion speed to allow for a random swerving and stacking of the strand. The extrusion

was continued until the mould was filled. Figure 2 shows the resulting filter prototypes for both materials [5].

The prototypes showed no major cracks or deformation after drying. The strand contact points were strongly connected due to the strong cohesion of the cellulose in wet state. Due to its higher density and thus higher own weight, the [b]AZ cellular structure was slightly densified especially in the lower parts of the component. The lower-density carbon-bonded material [b]AZC allowed for a much more open pore structure. A next step to improve the open-celled structure will be to automate and control the movement of the strand and the mould to optimize the stacking process for maximum porosity and strand support. The shown filter prototypes will furthermore be tested in contact with molten steel.

## CONCLUSIONS

The material design has a major impact on the extrusion process, processing prior to firing and the component integrity and properties after firing. The most critical characteristics were the firing shrinkage, which made materials A and AZ unsuitable for upscaling as well as the residual strength after thermal shock based on which the materials [b]AZC and [b]AZ were preferable. Both materials were successfully applied to manufacture first filter prototypes for implementation at the tundish bottom in industrial continuous casting. The testing in contact with molten steel, the computer-controlled extrusion of ordered cellular structures as well as the investigation of even more coarse-grained materials will be next steps in the investigation.

# DEVELOPMENT OF VIBROCAST ALUMINA−SPINEL INNER NOZZLES FOR VACUUM INGOT CASTING

Ph. D. Valeriy V. Martynenko*, Ph. D. Iryna G. Shulyk, Ph. D. Pavlo O. Kushchenko, Lyudmyla N. Zolotukhina

Ukrainian Research Institute of Refractories named after A.S. Berezhnoy, Kharkiv, Ukraine

## ABSTRACT

During the steelmaking process the steel must be degassed for removal gases from liquid. One type of vacuum degassing processes is stream degassing practice, in particular ladle to ingot mould degassing. Inner nozzles used in this method must have increased performance characteristics, because must be able to pass up to 500 MT of liquid steel at a rate of up to 10 MT/min. The refractory most suitable for such conditions is an alumina-spinel material based on fused alumina and magnesia-alumina spinel. The influence of grain composition of the coarse-grained batch on the properties of alumina-spinel vibrocast mass (moisture, flowing during vibration) and on the properties of unfired and fired at 1580 °C vibrocast samples has been studied. The optimum grain composition of vibrocast alumina-spinel mass and its moisture, which ensure the achievement of the highest properties of products, were determined. The industrial tests in service at one of metallurgical enterprises of Ukraine developed inner nozzles established that they provide non-stop casting of steel from 240 to 450 MT at temperature 1580-1650 °C and are characterized by high corrosion resistance (have insignificant wear of steel casting channel, which does not exceed ~ 3-5 mm). Petrographic studies of the inner nozzle sample after service have shown that, due to the contact of molten steel with refractory, a band of spinel up to ~ 0.2 mm wide is formed in it, which restrains the penetration of molten metal in the nozzle structure and prevents its wear, thereby increasing its corrosion resistance.

## INTRODUCTION

One of the methods for improving the metal quality during casting is vacuum metallurgy, which makes it possible to effectively fight harmful impurities to produce high-quality alloyed grades of steel. During the steelmaking process the steel must be degassed for removal gases from liquid. One type of vacuum degassing processes is stream degassing practice, in particular ladle to ingot mould degassing. Inner nozzles used in this method must have increased performance characteristics, because must be able to pass up to 500 MT of liquid steel at a rate of up to 10 MT/min. In world practice, the production of high-quality ladle refractories is based on the use of high-purity materials and, first of all, magnesia-alumina spinel (MA spinel), which has such properties as high corrosion resistance and high-temperature strength along with high refractoriness [1-3]. The refractory most suitable for such conditions is an alumina-spinel material based on fused alumina and magnesia-alumina spinel. In addition, an essential factor in the resistance of refractories in service to various aggressive reagents, along with their chemical and mineral composition, is the structure, the main characteristic of which is porosity (or density).

A large complex of works on production of plugs for steel casting in steel ladles, including the use of MA spinel, has been carried out by the Institute [4–7]. These studies were used as the basis for the development of vibrocast alumina-spinel inner nozzles for vacuum casting steel for ladles to ingot mould degassing. Developed inner nozzle is used in the processing of carbon-alloyed steel at its temperature in the steel ladle of 1580-1650 ºC. It is designed to form a jet of metal, regulate the rate of continuous casting, which reaches 450 MT of steel with metal flow rate through the channel of 10 MT/min. Residual pressure in the vacuum chamber during casting is not more than 2 mbar, the channel diameter wear of the inner nozzle should not be more than 5 mm. The design of the inner nozzle is shown in figure 1.

Fig. 1. Design of inner nozzle.

## EXPERIMENTAL PART

The following raw materials were used:
– fused alumina produced by Ukrainian Research Institute of Refractories named after A.S. Berezhnoy;
– fused MA spinel produced by Ukrainian Research Institute of Refractories named after A.S. Berezhnoy;
– alumina grade of "Salox M-S1 (ALO-Ex34)" (presented mainly α-$Al_2O_3$);
– powdery quartz;
– dispersing additives Castament FS-10 and FW-10.

The chemical composition of raw materials is given in Table 1.

Tab. 1. The chemical composition of raw materials

| Content, % wt. | Chemical composition of | | | |
|---|---|---|---|---|
| | fused alumina | fused MA spinel | alumina grade of "Salox M-S1 (ALO-Ex34)" | powdery quartz |
| L.O.I. | 0.04 | – | 0.02 | 0.13 |
| $SiO_2$ | 0.05 | 0.45 | 0.10 | 99.36 |
| $Al_2O_3$ | 99.50 | 85.61 | 99.70 | 0.42 |
| $TiO_2$ | <0.02 | – | 0.01 | – |
| $Fe_2O_3$ | 0.05 | 0.26 | 0.02 | 0.04 |
| CaO | 0.02 | 0.87 | 0.03 | 0.02 |
| MgO | 0.04 | 12.6 | 0.02 | 0.02 |
| $Na_2O$ | 0.32 | – | 0.13 | – |

As follows from the data in table 1, the initial raw materials were characterized by high content of main components and contained a small amount of impurities.

Fused alumina with a maximum grain size of 5 mm at a certain ratio of fractions 5-2, 2-1, 1-0.5, < 0.5 mm was used as a coarse-grained component of the batch. To obtain the matrix fused MA spinel and alumina were grained separately in a vibrating mill, and then these components were mixed with powdery quartz.

The particle size of finely dispersed materials is given in table 2.

Tab. 2. The particle size of finely dispersed materials.

| Material name | Particle size, μm | | Particle size content ≤ 10 μm, % |
|---|---|---|---|
| | Maximum | Prevailing | |
| Alumina grade of "Salox M-S1 (ALO-Ex34)" | 20 | < 4-8 | 90-92 |
| Fused MA spinel | 60 | <4-15 | 60 (≤ 4 μm ~ 25 %) |
| Powdery quartz | 130 | <4-30 | — |

The coarse-grained component was mixed with the fine-grained part of batch, in which dispersing additives were previously introduced, moistened with tap water. The moisture content of

grainy masses for vibrocasting was determined according to DSTU EN ISO 1927-3:2018. The actual moisture of batch was 4.1-4.4 %. The flowing of freshly prepared coarse-grained masses of alumina-spinel composition under vibration was carried out according to DSTU EN ISO 1927-4:2018.

Determination of the main properties of green samples was carried out on samples in the form of a cube with an edge size of 40 mm, fired ones at 1580 º C - on samples-cubes with an edge size of 40 mm, cut out of bricks with size 230x115x40 mm and manufactured by vibro-casting with the vibration amplitude of shake table 0.5 mm and frequency of 50 Hz, using removable plaster molds reinforced with metal. The green samples after mold disassembly were kept in natural conditions of the shop premises for 24 hours, and then dried in a desiccator at 110 ºC for 3 days. After drying, bricks were fired in a batch gas-flame oven at 1580 ºC with isothermal holding at this temperature for 8 hours.

Chemical composition of the materials was determined by chemical analysis according to the current standards of Ukraine.

Particle size of the fine-grained materials was determined under the MIN-8 microscope using an ocular micrometer. Petrographic study of samples microstructure was carried out under the microscope MIN-8 in immersion preparations in transmitted polarized light and on polished anshliffe in reflected light under the microscope Nu-2E. [1]

Open porosity and apparent density of fired samples were determined according to DSTU ISO 5017:2014, the cold crushing strength - according to DSTU ISO 10059-1:2018.

Linear dimensions change of samples during firing was determined as the ratio of linear dimensions difference before and after firing to their linear size before firing and expressed as a percentage.

To study the effect of the grain composition of coarse-grained component, four compositions were made (table 3).

Tab. 3. The composition of the studied vibrocasting MA samples, % wt.

| № of compo sition | Coarse fractions of fused alumina, mm | | | | Matrix: MA spinel, alumina, quartz |
|---|---|---|---|---|---|
| | 5-2 mm | 2-1 mm | 1-0,5 mm | < 0,5mm | |
| 1 | 30 | 10 | 10 | 15 | 35 |
| 2 | 25 | 10 | 10 | 20 | 35 |
| 3 | 20 | 10 | 10 | 25 | 35 |
| 4 | 15 | 10 | 10 | 30 | 35 |

**RESULTS AND DISCUSSION**
The properties of alumina-spinel masses and green vibrocast samples after drying at 110 °C are given in table 4.

Tab. 4. The properties of alumina-spinel masses and green vibrocast samples after drying at 110 °C

| Property name | № of composition | | | |
|---|---|---|---|---|
| | 1 | 2 | 3 | 4 |
| Moisture, % | 4.1 | 4.2 | 4.3 | 4.4 |
| Flowing, % | 85.0 | 90.0 | 100.0 | 100.0 |
| Properties of samples after drying at 110 °C: | | | | |
| - apparent density, g/cm$^3$ | 3.17 | 3.18 | 3.19 | 3.20 |
| - cold crushing strength, N/mm$^2$ | 6.8 | 7.0 | 7.8 | 8.6 |

The properties of vibrocast samples after firing at 1580 °C are shown in table 5.

Tab. 5. The properties of samples after firing at 1580 °C

| Property name | № of composition | | | |
|---|---|---|---|---|
| | 1 | 2 | 3 | 4 |
| Linear shrinkage, % | 0.9 | 0.8 | 0.9 | 0.9 |
| Open porosity, % | 15.0 | 14.7 | 14.5 | 14.3 |
| Apparent density, g/cm$^3$ | 3.28 | 3.30 | 3.31 | 3.33 |
| Cold crushing strength, N/mm$^2$ | 245 | 324 | 340 | 365 |

As is known [8], the porosity of refractory products resulting from various molding methods depends not only on the pressure and molding conditions, but is also determined by the ratio of grain sizes, i.e. the grain composition of batch. The data analysis shown in table 4 shows that changing the grain size distribution of fractions 5-2 mm and < 0.5 mm according to the row: 30 → 25 → 20 → 15 % and 15 → 20 → 25 → 30 %, while maintaining the constant grain size distribution of fractions 2-0.5 mm, leads to an increase in the mass flowing under vibration from 85 to 100 % with the moisture of these masses equal to 4.1-4.4 %. Thus the apparent density of unfired samples and cold crushing strength increase from 3.17 to 3.20 g/cm$^3$ and from 6.8 to 8.6 N/mm$^2$, respectively.

In the process of high-temperature firing at 1580 ºC all samples are sintered and their structure is compacted, this is evidenced by their property values; but the pattern of apparent density growth from 3.28 to 3.33 g/cm$^3$, as well as cold crushing strength from 245 to 365 N/mm$^2$, and open porosity reduction of vibrocast samples from 15.0 to 14.3 % remains the same, that is as decrease of grain fraction of 5-2 mm in the row: 30 → 25→20→15 % and increasing of the grains content of fraction < 0,5 mm in the row: 15 → 20 → 25 → 30 % at preservation of a constant content of grain fraction of 2-0,5 mm in the coarse-grained component of batch.

The samples made from the batch with coarse-grained component of the established optimum grain composition: 5-2 mm - 15 %, 2-0.5 mm - 20 %, < 0.5 mm - 30 % are characterized by the highest properties (open porosity 14.3 %, apparent density 3.33 g/cm$^3$, cold crushing strength 365 N/mm$^2$). This ratio of grains in the coarse-grained component of batch provides the most optimal packing in the vibrocasting process and contributes to the formation of a dense refractory structure.

Taking into account the obtained results of researches and with the purpose of industrial tests in the service in Institute a vibrocast alumina-spinel inner nozzles were produced, which are characterized by high property indicators: content, wt. %: Al$_2$O$_3$ - 96.0, MgO - 1.5, SiO$_2$ - 0.6; open porosity 14.0-14.5 %; apparent density 3.32-3.35 g/cm$^3$; cold crushing strength 320-360 N/mm$^2$.

The industrial tests in service at one of metallurgical enterprises of Ukraine these inner nozzles in vacuum casting of steel from tundishes established that they provide non-stop casting of steel from 240 to 450 MT at temperature 1580-1650 °C and have high corrosion resistance - the steel casting channel wear is insignificant (does not exceed ~ 3-5 mm).

Petrographic studies of the inner nozzle sample after service have established that under the influence of high temperature and molten steel in it formed three zones: the least changed, transitional and reactionary.

The least changed zone structure of the inner nozzle sample practically does not differ from its structure before the tests. It consists of angular-shaped grains of fused alumina filler and fine-dispersed binder, which is represented by crystals of magnesia-alumina spinel and sintered α-Al$_2$O$_3$.

The transitional zone with a width of ~ 0.6-1.0 mm tightly contacts the least changed one. This contact is clearly expressed and relatively even, differs from the least changed zone microstructure by a more compacted microstructure due to its sintering.

On the contact of the transitional zone with the reactionary zone under a microscope a band up to ~ 0.2 mm wide is observed, which mainly consists of a dense cluster of spinel crystals < 8 microns in size, close to isometric or elongated shape, and in a small amount

505

[1] Carried out by T. G. Tyshyna.

of sintered α-Al$_2$O$_3$, cemented by films and irregularly shaped glass-phase precipitates. This band has different widths and contains metallic inclusions.

The contact zone microstructure of the transitional and reactionary zones is shown in figure 2.

Fig. 2. The contact zone microstructure of the transitional and reactionary zones of the inner nozzle sample:
I – reactionary zones; II – spinel band; III - transitional zone;
1 – fused alumina; 2 - sintered α-Al$_2$O$_3$; 3 – MA spinel; 4 - metallic inclusions; 5 - pores.

The reactionary zone of the inner nozzle sample consists of single residual grains of fused alumina filler with traces of corrosion and a crystalline mass of idiomorphic elongated-prismatic crystals of sintered α-Al$_2$O$_3$ sized ~ 10-15 μm, cemented by a glass binder. In the reactionary zone, metallic inclusions up to ~ 0.5-0.6 mm in size are present, rounded and irregular in shape due to the filling of pores with molten metal.

Thus, the petrographic studies of the inner nozzle sample after service have established that due to the contact of molten steel with refractory, the spinel band up to ~ 0.2 mm wide is formed in it, which restrains the penetration of molten metal through pores and microcracks in the inner nozzle structure and prevents its wear, thereby increasing its corrosion resistance.

As a result of the research the technology of vibrocast alumina-spinel inner nozzles for vacuum casting steel from tundish ladles to ingot mould degassing was developed.

## CONCLUSIONS

The technology of inner nozzles for tundish ladles to ingot mould degassing has been developed. It is established that the highest property indicators (open porosity 14.3 %, apparent density 3.33 g/cm$^3$ and cold crushing strength 365 N/mm$^2$) are characterized by vibrocast samples made of batch with the coarse-grained component of established optimum grain composition.

For industrial tests a inner nozzles was made with the following properties: content, wt. %: SiO$_2$ - 0.6, Al$_2$O$_3$ - 96.2, MgO - 1.49, CaO - 0.19; open porosity - 15.2 %; apparent density - 3.30 g/cm$^3$; cold crushing strength - 174 N/mm$^2$.

Tests of the alumina-spinel inner nozzles during vacuum casting of steel showed that they provide non-stop casting of 240 to 450 MT of steel at a temperature of 1580-1650 °C in the tundish ladle. Wear of steel casting channel diameter did not exceed 3-5 mm.

Petrographic studies of the inner nozzles after service have established the formation of spinel "band" of up to 0.2 mm wide in the refractory at the contact with the molten steel, which restrains the melt penetration into the refractory and causes its insignificant wear.

## ABSTRACT

In ladle preparation, Slide Gate refractory changing is a time taking & exhaustive process as it involves changing of refractories like Upper Nozzle, Slide Plate & Lower Nozzle. Changing of these refractories is human exhaustive process as these are heavy in weight and executed in heat & dusty environment and the entire process is done manually in every steel plant of India.

Refractory arrangement in slide gate system is in such a way that firstly upper nozzle is fixed in ladle well block (it is part of ladle lining) then slide plate and lower nozzle. One of the highly exhaustive processes is changing and fixing of upper nozzle, its weight is around 17 Kgs and after applying mortar its weight increases to 25-30 Kgs and operator has to lift and fix manually. The upper nozzle fixing process requires more time, human effort leading to fatigue to operators and sometimes delay in preparation of ladle. This is a controlled and precise operation; deviations can lead to failure. To eliminate these problems a mechanized manipulator was designed to reduce human effort, better ergonomics and to make the process easier and operator friendly. This mechanized manipulator consists of some mechanical & pneumatic components which allows operator to lift and handle such heavy load without any effort. The manipulator is provided with a pneumatic suspension system which carries the load of refractory which helps in lifting and fixing of nozzle with all degree of freedom. This system works completely with pneumatic, with this system operator has to give only 1-2 kgs of force for lifting 25-30 kgs of load as complete load is being nullified by the pneumatic suspension system. A special type of gripper was also provided to grip the refractory components without damaging it. This type of solution can serve to solve various weight handling issues in heat & dusty environment across steel industry.

## INTRODUCTION

In steel making, various process are being carried out from primary steelmaking to final casting shown in fig.1 and in this process liquid steel is transferred by steel ladle. First ladle is sent for to BOF (Basic oxygen furnace) for tapping, then the processed liquid steel is poured into the ladle and then ladle is sent for secondary refining station and then casting shown in fig.2

Fig. 1 Steel making process.

Fig. 2 Steel casting process.

where the casting is done by opening of ladle slide gate machine which is mounted underneath of steel ladle and actuated with the help of hydraulic cylinder. After operating of slide gate machine, the bore of slide plate inside the machine gets matched and casting starts. In the whole process of steelmaking ladle slide gate plays a very crucial role for casting of steel smoothly.

Ladle slide gate machine shown in fig.3 consist of various consumable refractories like slide plate, upper nozzle, lower nozzle. After casting is completed, ladle is sent to preparation area also known as ladle tilters to make the slide gate ready by cleaning the hole and changing the slide gate refractories based on operational requirements. The entire process of slide gate preparation and refractory changing is done manually almost in every steel plant in India and across the world.

Fig. 3 Slide gate machine assembly.

## EXISTING CHALLENGES IN FIXING UPPER NOZZLE

During preparation of slide gate, its refractories upper nozzle, slide plates & lower nozzle is changed depending upon its life. These refractories are heavy in weight, specially upper nozzle. It weighs around 17 kgs and refractory arrangement in slide gate system is in such a way that first upper nozzle is fixed into well block (it's a part of ladle lining) and before fixing upper nozzle into well block, a thick mortar coating is applied to the outer surface of upper nozzle as a joint material between upper nozzle and well block and it is lifted by the help of jig for fixing into well block shown in fig.4.

Fig. 4 Manual Upper nozzle fixing process.

507

In total its weight reachs upto 30 kgs approx. then slide plates and lower nozzle is fixed which is later tightened by mechanical force.

## ASSOCIATED PROBLEMS

*Fatigue to Operators* - The entire process is done manually like lifting & fixing heavy weight and done in heat & dusty environent which makes the process more human exhaustive as its done multiple times (normally 10-12 in a day).

*Chances of Error* – As its done manually and the process requires precision in upper nozzle fixing, any deviation could lead to leakage of liquid steel.

*Delay in preparation*- Due to manual preparation and sometimes human error, preparation gets delayed and delay in slide gate prepration directly effects the shop production as delay in ladle supply causes productivity loss.

Challenge was taken to develop a mechanized system to solve the problem with manual process and to make the operator work easier.

## AVAILABLE OPTIONS

*Robotic System*- This system includes advanced robots and the entire process is done fully automatically with robots as shown in fig.5.

Fig. 5 Robot for slide gate preparation.

Only few steelmakers outside India has installed the system which is still under development stage. As this include advanced systems, requires high maintenance & more space for installation.

## SEMI-MECHANIZED MANIPULATOR

The objective of this design was to make a manipulator which will easily lift the heavy weight of refractories and will work in a challenging environment, i.e. heat & dusty area.

Manipulators weight lifting concept is based on pneumatic suspension system, this type of lifting devices are normally used in automotive industries but using same in steel industry was a bit challenging due to its working environment (Hot & dusty). Using pneumatic suspension concept, a semi-mechanized manipulator fully pneumatic based system was designed as shown in fig.6.

This Manipulator mainly consist of vertical pillar, primary arm, secondary arm, pneumatic suspension, clutch, gripper and other parts.

*Vertical Pillar*- Provide strength and holds the load of system it is mounted in the tilter platform.

*Arms*- Provide degree of freedom and movement to system so that upper nozzle can be moved within the range.

*Pneumatic suspension* - Lifts and balance the load with pneumatic cylinder operator only need to give 1-2 Kgs of force to lift 25-30 Kgs of load. This pneumatic suspension can lift upto 100 Kgs of load.

*Clutch*- Provides rotary provision for upper nozzle with the help of incorporated jig with very simple clutch mechanism.

*Gripper*- Grips the upper nozzle from inside by pneumatic force without damaging and works in High temperature.

The whole system (Pneumatic suspension & gripper) works with pneumatic line with minimum required pressure of 5 bars. Operator only needs to guide the upper nozzle for fixing & applying Mortar as load of upper nozzle is being nullified by the pneumatic suspension. For applying mortar rotary provision is also provided in the jig.

Fig. 6 TRLK Semi-mechanized manipulator.

## CONCLUSION

Effort required is now reduced by 96% with precise control. Process has become more standard now as load is lifted by the system, operator just needs to guide and push the jig into well block in order to fix upper nozzle which also take less time. With this semi-mechanized system process has became smoother & safer. It can be customized easliy and can be used as lifting & handling applications (upto 100 Kgs of load) across steel plant and other industries.

# MODIFICATIONS IN LADLE SLIDE GATE SYSTEM FOR IMPROVING SAFETY & PRODUCTIVITY

Gaurav Pandey, Gautam Choudhury, Ujjwal Kumar, Deepak Kumar, Manishankar Mukherjee,
Shubhashish Paul, Sunanda Sengupta, Hiroshi Nagata, P.B. Panda
TRL Krosaki Refractories Ltd. Jharsuguda (Odisha), India

## ABSTRACT

In steel melting shop, teeming ladle is used for treatment & transfer of liquid steel for various operations. Finally at caster, liquid steel is shaped into semi-finished product through continuous casting process. Ladle slide gate (LSG) is fixed underneath the teeming ladle, it is a mechanical assembly having some refractory components. Function of LSG is to control the discharge of liquid steel from ladle to tundish.

Post casting at Caster machine, teeming ladle is transported to Ladle preparation area where various operations such as consumable refractory replacement is performed, this is a time intensive process. Any delay in ladle preparation, leads to direct productivity loss. This operation is performed in ladle running condition so safe operation is a concern.

This paper covers modifications in LSG & introduction of products used in LSG for safety & productive benefits.

A Backsplash cover was developed, it's a sacrificial component which saves LSG machine from damage & eliminates long ladle preparation time.

Modification in cylinder fixing area to ensure LSG cylinder removal in close condition only. With this there is no chance of LSG open position during tapping operation.

A mortar collecting tool was developed for use during ladle nozzle (LN) changing operation, this is installed in advance to ensure easy cleaning of excess mortar. This reduces ladle preparation time & effort.

A LN GO - NO GO gauge is developed as LN checking is crucial job as it indicates suitability to usage for further heats. With simple GO – NO GO gauge, it easy & quick checking.

## INTRODUCTION

Ladle slide gate machine which is mounted underneath of teeming ladle with the help of hydraulic cylinder. After operating of slide gate machine, the bore of the slide plates inside the machine gets matched and casting starts. In the whole process of steelmaking ladle slide gate plays a very crucial role for casting of steel smoothly. Ladle slide gate machine shown in (figure1) consist of various consumable refractories like Slide Plate, Ladle nozzle, Collector Nozzle and Mortar which is changed after certain life.

*Fig. 1: Slide gate refractory arrangement.*

After casting is completed then ladle is sent to preparation area to make the slide gate ready by cleaning the hole and changing the slide gate refractories if required. For this hydraulic cylinder is required to operate the slide gate which is fixed in preparation stand. It is attached in machine and after preparation it is detached. Some modifications and various tools were developed for easy and safe operation of slide gate.

## BACKSPLASH PROTECTION COVER

At caster ladle shroud is fixed in collector nozzle of slide gate to guide the flow of liquid steel from ladle to tundish and prevent steel from reoxidation. But due to improper fixing of ladle shroud or some other operational reasons backsplash occurs at caster.

During backsplash liquid steel penetrates in the slide gate machine causing damage to machine parts which leads to various problems.

1. Damage of machine parts increase of spare cost.
2. Increase in maintenance time at preparation area causing delay in supply of ladle and loss of production.
3. Unplanned ladle outage for changing slide gate causes shortage of ladle and loss of production.
4. Sometimes due to severe backsplashes machine sliding stuck at caster which causes uncontrolled discharge of liquid steel and it's a process safety hazard.

To prevent these issues and metal penetration in machine due to backsplash a backsplash protection cover was designed using some mechanical parts. This backsplash protection cover is fixed in the machine around collector nozzle using some screws. This cover itself gets damaged in case of backsplash and won't allow metal to penetrate into the machine as shown in (figure. 2).

*Fig. 2: Backsplash at Caster with & without backsplash protection cover.*

Post implementation of Backsplash protection cover damage of machine parts were reduced and unplanned ladle outage cases were reduced by 40%.

## ENSURING EJECTION OF HYDRAULIC CYLINDER IN CLOSE POSITION OF SLIDE GATE

Slide gate after casting comes to preparation area for refractory change/bore cleaning etc. jobs. During preparation hydraulic cylinder is used to operate and sliding of machine which is disengaged from machine after the job is completed.

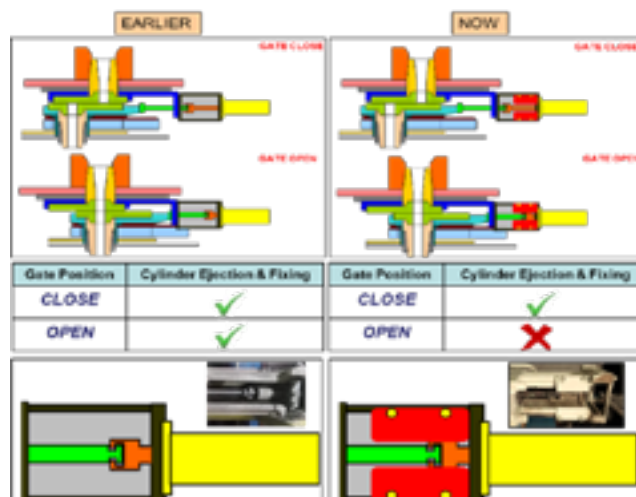

*Fig. 3: Fixing of stopper plate in LSG machine to ensure ejection of hydraulic cylinder in close position.*

If hydraulic cylinder is ejected in open position of slide gate than there are chances of drainage from slide gate during tapping from BOF, at one of the customer site this incident happened.

To prevent this mishappening, modification in slide gate machine was done, a stopper plate was fixed in the cylinder bracket of machine to ensure ejection of hydraulic cylinder in close position of slide gate as shown in (figure 3).

## MORTAR COLLECTING TOOL

Slide gate system has Ladle Nozzle which is fixed in the well block of ladle and mortar is used as a joint material. To ensure proper mortar in the joint excess mortar is applied intentionally over the ladle nozzle and fixing some excess mortar comes back and gets spread over the slide plate setting area as shown in (figure 4).

Fig. 4: Excess mortar after nozzle fixing.

If this spread mortar is not cleaned properly than it could lead to improper setting of slide plate resulting cracking ad failure between slide plate as shown in (figure 5). Also, this increases preparation time as cleaning mortar takes 2-3 mins of time.

Fig. 5: Effect of excess mortar on slide plate.

To encounter these issues a mechanical template was designed which is fixed in the plate setting area before fixing of ladle into well block so that the excess mortar coming out of well block instead of getting spread over the plate setting area gets collecting in this template as shown in (figure 6).

Fig. 6: Excess mortar condition with mortar collecting tool.

With implementation of this mortar collecting tool cleaning of excess mortar became easy and helped in reducing the preparation time.

## LADLE NOZZLE CONDITION CHECKING

Damage/erosion happens during the usage of side gate refractories, and it is important to keep checking the condition of refractory to prevent from failure or abnormality. One of the key checking is done at running condition of refractory is bore erosion of ladle nozzle as it goes for multiple heats. Earlier checking of ladle nozzle bore erosion was done with calliper & measuring tape. but it has some negative branches like.

1. Longer exposer to heat as it is performed multiple times
2. Chances of error in measurement

To overcome these challenges a GO NOGO gauge was designed considering erosion pattern and potential of ladle nozzle for further heats. With the help of gauge checking process and judgement became easy, operator only needs to insert the gauge in the bore of ladle nozzle and can make judgement as shown in (figure 7).

Fig. 7: Checking of Ladle Nozzle bore previous (with caliper and tape) VS now (with GO NOGO Gauge).

## CONCLUSION

Even a small change can make a big impact. Slide gate preparation is very crucial job a little deviation can lead to a big failure as it plays with $1600^0C$ liquid steel. Slide gate preparation still in India and many parts of the world is done manually due to its criticality and various checkpoints. It is important to make and design the process more user-friendly for better safety and safe operation.

With backsplash protection cover safety at caster was improved and helped in reducing preparation time and unplanned ladle outage.

With modification in slide gate to ensure ejection of hydraulic cylinder in close position the process was fool proofed, operator can't send ladle for tapping in open position of slide gate by mistake also.

With mortar collecting tool excess mortar cleaning became easy as excess mortar is now being collected in mortar collecting tool instead of spreading over plate setting area.

With ladle nozzle GO NOGO gauge checking of bore erosion very easy and safe also exposer to heat was reduced.

With all these ideas, process safety of slide gate was improved and improved productivity by reducing preparation time. This also helped in standardizing of checking and inspection process at slide gate preparation area by development of tools and gauges.

With slight modification in design applicability of these ideas are possible for different shops.

# DEVELOPMENT OF OLIVINE BASED PRECAST CASTABLE FOR TUNDISH WEIR AND DAM

Shang-ru, Yeh, Ping-chum, Liu, Henry, Chen.
Good Furnace Refractory Industrial Co., Ltd, New Taipei City, Taiwan, R.O.C

## ABSTRACT

Forsterite, also known as olivine, is a natural wide ore and can be used as material directly for refractory. Its potential to produce refractory castable is possible. For the environment friendly and operation requirement of China Steel Corp., Kaohsiung, Forsterite based precast castable for tundish weir and dam must be developed and studied. Experiment results show that introducing alumina cement as a hardening accelerator or alumina lactate as an anti-hydration additive or both of them can reduce the HMOR of olivine based precast castable for tundish weir and dam. Slag erosion test indicates that the slag resistance of olivine based precast castable is better then that of high alumina low cement precast castable. Moreover, the slag resistance of olivine based precast castable containing olivine powder in matrix is worse than that of olivine based precast castable without olivine powder. Field test results demonstrate that less olivine aggregates content in Tundish weir and dam fulfills the continuous steel operation at the customer site in Kaohsiung.

## INTRODUCUION

Forsterite, also known as olivine, is a natural wide ore and can be used as material directly for refractory [1]. By the limited literature review, its potential to produce refractory castable is possible [2]. Moreover, for the environment friendly and operation requirement of China Steel Corp., Kaohsiung, Forsterite based precast castable for tundish weir and dam must be developed and studied. Otherwise, Forsterite is also a kind of basic refractory raw material. Refractory made by forsterite may help to produce clean steel while continuing operation [3]. Furthermore, refractory made by forsterite may reduce the risk of hydration damage of basic refractory. According to the requirement from R & D of China Steel Corp. in 2019, Good Furnace Refractory Industrial Co., Ltd. had an opportunity to develop olivine based monolithic refractory for tundish. The following is a simplified presentation of the whole development from the laboratory to the application at custom site.

## Materials and Experiments

■Materials

There are four testing recipes compositing by olivine aggregates and fines, dead burn magnesia (DBM), sea water magnesia, microsilica fume, specialty Mag, and silicon carbide powder. And silicon carbide powder, olivine and dead burn magnesia are from mainland China. Sea water magnesia is from Japan. Microsilica fume, specialty M are sold by Elkem and alumina cement is provided by Almatis. These four testing recipes are shown as follow in Table 1.

Table 1 Formula developed for tundish weir and dam precast

|  | A | B | C | D |
|---|---|---|---|---|
| Olivine aggregates | O | O | O | O |
| DBM 1-0 mm | × | × | O | O |
| DBM 100F |  | × | × | O |
| DBM powder |  | O | × | O |
| Sea water MgO flour |  | O | O | × |
| Microsilica fume | 8% | 5.5% | 8% | 6% |
| Olivine 200F | O |  | × | × |
| Specialty M | O | O | O | O |
| Alumina cement | O | × | × | × |

× means no using in formula.

■Sample preparation and Testing methods

Testing samples composited in Table 1 are adding and mixing appropriate amount of water, casting in a $40 \times 40 \times 160$ mm mould. Samples are removed from the mould, dried in 110°C for 24 hours and then detected their properties shown in Table 2.

Table 2 Testing mothed in this work

| Property | Standard |
|---|---|
| Bulk density (BD) | JIR R 2205 |
| Apparent porosity (AP) | JIS R 2205 |
| Modulus of rapture (MOR) | JIS R 2553 |
| Cold crush strength (CCS) | JIS R 2553 |
| Permanent liner change (PLC) | JIS R 2554 |
| Hot modulus of rapture (HMOR) | GB/T 3002 |
| Slag erosion | Crucible |

## RESULTS AND DISCUSSION

■Evaluation in laboratory

Table 3 presents the physical properties of every formula shown in Table 1 after 1500°C × 3 hrs firing and their HMOR results under 1500°C is also shown in the same table. According to Table 3, only BD and AP of recipe D are better than Currently but the mechanical properties of all olivine based formula, including A, B, C, and D, is worse than Currently due to the difference between the sintering property of olivine with dead burnt magnesia (no cement bonding) and high alumina material with high alumina cement.

Table 3 Physical properties after 1500°C firing and HMOR at 1500°C

|  | A | B | C | D | Currently* |
|---|---|---|---|---|---|
| BD, g/cm³ | 2.34 | 2.46 | 2.49 | 2.71 | 2.55 |
| AP, % | 28.5 | 24.6 | 24.5 | 17.1 | 18 |
| PLC, % | +0.41 | -0.47 | -0.25 | +0.06 | +0.5 |
| MOR, MPa | 9.0 | 6.5 | 8.0 | 4.9 | 15 |
| CCS, MPa | 46 | 32 | 43 | 38 | 85 |
| HMOR, MPa | 1.3 | 3.3 | 3.6 | 1.9 | 1.8 |

*Currently means the original alumina weir and dam recipe using at custom site currently

Figure 1 is the slag erosion test results of original high alumina weir and dam recipe using at custom site currently and developed recipe A. Apparently, figure 1 indicates that recipe B is much better than original high alumina recipe. Therefore, recipe B was decided to carry out the field test at custom site.

(A)       (B)
*Fig. 1: Comparison of slag erosion by crucible method (A) original high alumina recipe and (B) olivine based recipe B.*

Figure 2 is the slag erosion test results of Recipe B, C, D but A not including because HMOR of Recipe A is lower than the original high alumina weir and dam recipe. By the experience, HMOR of tundish weir and dam lower than 1.4 MPa means the risk of fracture by molten steel or slag during the continuous casting

511

operation, so we decide not to carry out the slag erosion test of Recipe A. From figure 2, small area of slag erosion can be observed both in the crucible cross section of recipe B and C but only slightly slag penetration exists in the crucible cross section of recipe D.

(A)                                  (B)

(C)
*Fig. 2: Comparison of slag erosion by crucible method (A) olivine based recipe B, (B) olivine based recipe C, and (C) olivine based recipe D.*

■Field test at custom site

Before the field test at custom site, all recipes pass the quality examination executed by China Steel Corp. Figure 3 shows the field test result of recipe B.

*Fig.  3: Field test at custom site of Recipe B*

From figure 3, it's clear that weir and dam made by recipe B was eroded by slag and nothing remained after continuous operation.

By discussion after knowing the trail result, recipe C was introduced to try. Comparing with recipe B, there is no DBM powder content but sea water magnesia flour replaced in recipe C. Figure 4 indicates that weir and dam made by recipe C is better than those made by recipe B after continuous operation. Unfortunately, from figure 4, there was one weir fabricated by recipe C eroded through by tundish slag.

*Fig. 4 Field test result of Recipe C*

Learning the result and experience from recipe B and C, to use higher quality of magnesia powder, avoid olivine 1 mm, and less microsilica fume are the keys to develop olivine based weir and dam precast well. Therefore, recipe D, containing DBM97 1-0 mm and powder, was the last chance for the field test at China Steel Corp. Figure 5 presents that weir and dam fabricated by recipe D are fulfill with the operation condition at custom site and remain whole block after 5 cycles of continuous casting of steel.

*Fig 5: Field test result of recipe D at custom site*

## CONCLUSIONS

Tundish weir and dam precast castable using olivine was developed and field test investigated at custom site. Results show as follows.

1. By using olivine coarse aggregates, 1-0 mm dead burn magnesia 97, dead burn magnesia 97 fines, and less microsilica fume, it is the better way to make the performance of olivine based tundish weir and dam suitable adapted well for the continuous casting operation at custom site.
2. Using some olivine fine aggregate and 200F in olivine based weir and dam pre cast give higher HMOR. But higher HMOR for olivine based does not give good slag or molten steel resistance for that at field test.
3. To achieve good tundish slag erosion resistance for olivine based tundish weir and dam precast during the continuous casting operation, it is important to not only choose good quality of dead burn magnesia fines in the matrix part of olivine based precast but also avoid to use olivine fine aggregate in coarse part.

# CARBON BONDED RODS FOR MEASUREMENT OF MOLTEN STEEL VELOCITY AT THE MENISCUS LEVEL IN THE CONTINUOUS CASTER MOULD: FROM THE LAB TO THE PLANT TRIALS

Bruno Luchini[1]; Tony Wetzig[2]; Vasileious Roungos[2]; Marc Neumann[2]; Steve Verdier[1]; Pieter Put[1]; Laurens Jan Pille[1]; Christos G. Aneziris[2]; Sido Sinnema[1]

[1]Tata Steel Nederland, R&D, IJmuiden, Netherlands; [2]IKFVW/TU Bergakademie Freiberg, Freiberg, Germany

During continuous casting of steel, monitoring the velocity and direction of the melt flow is a crucial step for the process control. One of the methods used to perform such measurement is the so-called "rod deflection method". Refractory rods are mounted in a rotational pivot equipped with a potentiometer. The rods are then inserted into the copper mould and deflected in response to the molten steel flow. By monitoring their deflection, the flow pattern and velocity can be obtained in the region close to the meniscus. Due to the very harsh conditions such as high temperature, extremely reactive mould powder material and high melt velocity, selecting refractory materials able survive this scenario is a challenging task. In this study, TSN and IKFVW discuss the conceptual process and the testing procedures used to select and produce the carbon-bonded refractory rods used in the rod deflection device.

# PUREBLOX 1400, HOW TRB TAKE UP THE ENERGY SAVING CHALLENGE WHILE USING SAFER PRODUCTS

Simon CHIARTANO*, Martial BARRET, Stéphane DUHAMEL, Benoît VANDENBON
TRB, Nesles, France.

## ABSTRACT

Currently, many heat treatment furnaces are made up of insulating linings composed of refractory ceramic fibers (RCF). This technology withstands temperatures theoretically up to 1400°C. However, the fibers that constitute this product are classified Carcinogenic, Mutagenic, or toxic to Reproduction (CMR) [1]. Two alternative technologies can be used today: polycrystalline fiber and high temperature bio fiber. The first one has a very high cost, the second does not withstand temperatures exceeding 1150°C, under certain favorable conditions.

Our approach was global to find a new solution with the same specifications in term of resistance and thermal performance but with a non-classified safer product: the Pureblox 1400.

## MATERIAL & METHODS

Context was the replacement of RCF which are often used in heat treatment furnace and unfortunately harmful for lungs because CMR classified. This study explores every step of a new product development, from design to manufacturing including mechanical and thermal behaviour calculated by simulation and checked by measurement, laboratory test and final installation at our customers.

## SIMULATION

Simulation was used to evaluate the energy balance and optimize insulation and material choice.

Figure 1: Temperature comparison in a reheating furnace – RCF design (l) Pureblox new design (r)

Figure 1 shows thermal profile on both RCF and Pureblox design. Results are very similar which validate the new design. Same conclusion can be made on energy balance with the heat flux magnitude comparison on Figure 2.

Figure 2: Heat flux magnitude comparison on both RCF and Pureblox design in a reheating furnace

## PRODUCT DEVELOPMENT

Specific laboratory tests including thermal conductivity and specific heat were also made to find the best formulation for this new material. See Table 1.

| Pureblox 1400 property | Value | Unity |
|---|---|---|
| Density | 830 | kg/m³ |
| Thermal conductivity[1] | 0.38 | W/m.K |
| Specific heat[2] | 1060 | J/kg.K |
| CCS[3] | 2 | MPa |

Table 1 : Pureblox 1400 material properties

## MEASUREMENT

On site measurement was implemented. First, IR Camera was used to measure temperature of external walls. Full mapping of the shell temperature is a powerful tool to estimate the global exchange of the furnace as shown on Figure 3. It also allows to compare one solution to another.

Figure 3: Thermographic view of a reheating forge furnace made of Pureblox 1400

A specific and tailor-made instrumentation was carried out with thermocouples located at different depth and position of a furnace made of Pureblox 1400, see Figure 4. Temperatures were recorded at every material interface, during several months of utilization, results are given on Figure 5.

---

[1] At 800°C
[2] At 1000°C
[3] After firing at 1200°C

Figure 4: Instrumentation system of a reheating forge furnace made of Pureblox 1400

Figure 5: Temperature measurement inside the refractory lining of a reheating forge furnace made of Pureblox 1400

All these measurements are useful to evaluate accurately the true performance of our solution on site and check both simulation and laboratory results.

**DESIGN**

After few years of development and tests, our new Pueblox 1400 solution is ready to be installed at our customers: it is made of an advanced low-density material in precast shape (see Figure 6) and insulating back layers.

Figure 6: Pureblox 1400 precast shape

Precast shape is a huge advantage in term of assembly time: installation become faster and easier rather than other products (bricks, modules, …). The solution can be installed on both walls (Figure 7) and roof (Figure 8).

Figure 7: Pureblox 1400 precast shapes wall installation

Figure 8: Pureblox 1400 precast shapes roof installation

**CONCLUSIONS**

With a thickness equivalent to current installation, the solution developed by TRB with the PUREBLOX 1400 product offers a cumulative thermal insulation equivalent to CMR classified ceramic fibers using a safer product for the health of operators and withstands temperatures up to 1400°C.

This new solution is already implemented in 3 different customer furnaces and give excellent results as shown on Figure 9.

# THE INFLUENCE OF ALUMINA TYPE ON CORROSION RESISTANCE OF SMART AL$_2$O$_3$–MGO MONOLITHIC REFRACTORIES USED IN CRUCIBLE INDUCTION FURNACES

M. Bavand Vandchali[1], S. M. M. Tabatabaie Hedashi[1,2],
1. Almas Alborz Refractories Co., Tehran, Iran.
2. Material Science and Engineering Department, Faculty of Engineering, IKIU, Iran.

**ABSTRACT**

In the present paper, the influence of alumina type (white fused (WFA) and tabular (TA)) on corrosion behavior of two commercial DVM linings has been investigated based on the post-mortem analysis. The microstructural analysis results show that the nature, amount and rate of in-situ spinel formation is different according to the alumina type. Higher expansion amount in TA-based DVM is accompanied to higher crack formation in the hot face of refractory lining and extensive molten metal penetration and microstructural spalling, although corrosion is low. Al$_2$O$_3$-rich spinel structure has been detected in the matrix of both refractory that mainly enhance corrosion resistance in due to formation of complex spinel structure via accommodation of corrosive ions from slag in steelmaking process. As well as, according to microstructural evolution of grains corrosion, a continuous layer from CA$_6$ and CA$_2$ crystals forms around the alumina grains, WFA and TA, that decrease its corrosion rate due to indirect corrosion behavior.

## 1. INTRODUCTION

During the steelmaking process in crucible induction furnace (CIF), refractory lining is exposed to different aggressive condition and corroded by corrosive liquid molten steel and slag at high temperatures (1620-1700°C). Also, the further metallurgical demand due to above wear mechanism has resulted in the development of high-quality refractory lining to withstand the hard conditions of the furnace and create very safe environment for steelmakers. Due to steelmakers requirements choosing the right refractories for a given malting or holding application is very important and depends on many parameters such as melting temperature, holding time, volume, inductive stirring, additive & alloying agents, etc. As smart refractories, the Al$_2$O$_3$-MgO dry vibrating mixes (DVM) development has brought a significant evolution in the history of refractories as lining of modern CIF. The techno-commercial benefits of spinel bonded DVM refractories compare to traditional silica based ramming mixes showed significant service life and despite the high price, it is very economical due to its patching capability. DVM refractories mainly composed of Al$_2$O$_3$ and MgO addition in special grain sizes in the matrix, which results in-situ spinel formation at steel melting temperature. Also, the major advantage of these DVM is that they are installed in the dry form by compaction via vibration/ramming without any binders that need water for the formation of a green strength. A sufficient green strength is realized by an optimized particle size distribution and high strength in the front layer developed by an initial sintering step due to formation of in-situ spinel (MgAl$_2$O$_4$) phase via reaction of Al$_2$O$_3$ and MgO in the matrix. It has been well clarified that the basic challenge in the designing of DVM refractories is the kinetic and amount of in-situ spinel phase formation in the front layer (hot face) to resist against early corrosion, but also to remain unchanged layer at the back of the furnace refractory lining (cold face) for safety purposes. Ideally, a trisection of the lining develops with a contact zone between lining and coil of furnace that keeps its safety function during the whole furnace lifetime (Fig. 1).

-Very strong sintered layer with spinel bonded matrix should be formed on the hot face of refractory lining to resist against corrosive slag and molten metal.

-The succeeding semi-sintered layer with little in-situ spinel formation and higher porosity is a low sintered part of the furnace refractory lining and the unchanged layer of the DVM is a mechanically compacted mass without any ceramic bond.

-The existence of unchanged layer is important at the end of the furnace campaign as this is required in order to press the furnace out.

*Fig. 1: schematic of multi-layer concept of DVM lining in CIF.*

According to alumina based monolithic refractories designing, the different types of alumina such as tabular alumina (TA), fused alumina (WFA, GFA, BFA) and bauxite can be used. The difference in the structure, properties and reactivity of different types of alumina will change the final properties of the refractory and as a result its performance. The purpose of this paper is to outline the differences between TA based (TA sample) and WFA based (WF sample) DVM refractories as working lining of CIF and show their influence on the performance and corrosion behavior.

## 2. EXPERIMENTA PROCEDURE

In evolution of alumina type influence on the performance of the CIF refractory lining, the appearance of the furnace after a specified numbers of heat in similar metallurgical condition and also *post-mortem* scanning electron microscope (by FESEM technique) examination of corroded samples taken from lining of furnace were investigated. The samples were selected from top 1/3 of the furnace where the slag attack, thermal shock stresses and mechanical wear were predominant, usually.

The sample of refractory lining obtained from a 10mt CIF and DVM refractory of the lining was provided by Almas Alborz Refractories Co., the specific brand being coded as DiamoRam Al-Sp18-T (TA-based) and DiamoRam Al-Sp18-W (WF-based). With this lining the furnace was used to melt numerous heats of steel until the furnace demanded repair and patching due to refractory lining wear. Table 1. described the structure of the studied lining material from 10mt CIF.

*Tab. 1: CIF characteristics and structure of the linings breakout.*

| DVM Refractory Brand | DiamoRam Al-Sp 18-T | DiamoRam Al-Sp 18-W |
|---|---|---|
| Steel type | Carbon Steel | |
| Tapping temperature | 1650-1680 | |

| Numbers of patching | 2 | 3 |

## 3. RESULT AND DISCUSSION

### 3.1. Lining appearance

The appearance of the refractory wear lining of the furnace with two different linings, TA and WF, after 60 heats is shown. Unlike the TA lining, which has many island expansion cracks on the surface of the hot face, the WF lining has a smooth surface without any cracks. (Fig. 2). This phenomenon can be attributed to the difference in structural characteristics, reactivity and expansion behavior of in-situ spinel phase formation between MgO with TA and WFA in the matrix of refractory lining. This is due to higher thermal reactivity of TA with fine MgO compared to WFA and fine MgO particles. Also, the results showed that the expansion rate after firing at 1600°C in TA sample is approximately 1.5 times that of the WF sample and thus the corresponding strength in TA lining reduced significantly and cracks formed on the lining.

*Fig. 2: Furnace refractory lining after 50 heats.*

The picture of representative pieces from TA and WF linings used in post-mortem analysis is shown in Fig. 3. As seen, completely different appearance is observed in two samples. Despite the presence of different layers formed by the hot face of the refractory lining, the structure of each layer is different. (Table 1.). Also, a dense sinter layer is formed on the hot surface of the TA sample and the slag penetration in the TA sample is lower compared to WF sample. The notable point is the lack of continuity between the layers in the TA sample, which will cause the structural difference between sinter layer compared to the semi-sinter and unchanged layers. As a result, due to the thermal shocks and increasing tap to tap times, the possibility of cracks formation and thermal spalling increases.

*Fig.3: Microscopical overview from.*

### 3.2. Microstructural evaluation by FESEM

According to the microstructural evolution of two TA-based and WFA-based samples after firing at high temperature at 1600°C (not shown here), the nature of in-situ formed spinel, i.e., MgO-rich, $Al_2O_3$-rich or stoichiometric spinel in the matrix of DVM refractories related to the $Al_2O_3$/MgO ratio, size, amount and spinalization behavior of alumina type. On the basis of two mentioned DVM formulations, only the type of alumina changed and thus the nature of spinel is same. But the speed and amount of spinel formation can be different. This fact is clearly visible in the appearance of the samples and difference in the thickness of sintered layer on the hot face.

*Fig. 4: Slag penetration and spinel crystal separation.*

According to the in-situ formed spinel in the matrix and on the surface of alumina aggregates and its reaction with the slag composition, different phases according slag composition formed during corrosion process. Elemental analysis by EDX were done on the different phases in contrast that help to distinguished reaction phases. Higher magnification from reaction area shown in Fig. 4.
*Fig.5: Spinel formation on the surface of alumina aggregate and reaction with slag.*

The reaction of spinel matrix with slag shows the penetration of slag liquid phase into the spinel crystals that contain impurities such as Si, Ca and Ti. In this case, the reaction between the penetrated liquid slag and impurities in the spinel grains boundaries forms different calcium aluminates and calcium titanate phases. The formation of these phases, some of which are liquid at that temperature with low viscosities, separate the spinel crystals and moves them into the slag.

As well as, according to solid state reaction mechanism on the basis of Wagner theory, lower size and amount of MgO grains compare to alumina particles, causes the spinel phase to form on the surface and around of alumina particles. Therefore, TA-based sample show higher penetration and corrosion resistance compare to WFA-based sample due to higher spinel formation. Higher spinel formation in the matrix create denser structure and also enhance matrix capability to accommodation of $Fe^{+2}$ and $Mn^{+2}$ ions from corrosive slag and formation of dense complex spinel structure (Mg, Fe, Mn)(Al, Fe)$_2$O$_4$ (Fig. 5).

It is well known that the aggregates phase has a significant influence on the extend and mechanism of liquid slag corrosion on refractories. Therefore, the corrosion behavior of aggregates is usually important in order to evaluate the corrosion mechanism of refractories. As well as, spinel formation on the surface of alumina aggregates and create an indirect corrosion, other phases with different contrast in BSE micrograph also found near to hot face of refractory/slag as reaction products. This means $Al_2O_3$ aggregates and spinel layer formed on $Al_2O_3$ surface react with the refractory lining and new phases occur upon dissolution of $Al_2O_3$. As shown, a larger number of columnar crystals ($CA_6$ and $CA_2$ and calcium titanium phase (CT) confirmed by EDS results (Fig. 4.)), were completely formed on the surface of $Al_2O_3$ aggregate in contact with slag, and the growth direction of these phases is perpendicular to the surface of $Al_2O_3$. Therefore, different phases formed consecutively as a result of the reaction between the liquid slag and matrix and aggregates. It seems, when $Al_2O_3$ aggregates are exposed to the liquid slag, high melting calcium aluminate phases such as $CA_6$ and $CA_2$ (according to the $CaO$-$Al_2O_3$) phase diagram) precipitated. As a result, the proposed corrosion mechanism for $Al_2O_3$ is can be explained as a dissolution-precipitation process inside a liquid phase with formation of $CA_6$ layer. Therefore, the $Al_2O_3$ aggregate remained for the reaction with slag was reduced, resulting in the formation of a second layer of $CA_2$. Thus, the $Al_2O_3$ aggregate remained for the reaction with slag was reduced, resulting in the formation of a second layer of $CA_2$.

As reported according to thermodynamic data, different reactions involving the corrosion of the $Al_2O_3$ aggregates and the values of free energy of formation associated with each of them are described in Eqs. (1) and (2), respectively:

$$6Al_2O_{3(l)}+CaO_{(l)} \longrightarrow CaO.6Al_2O_{3(s)} \quad \Delta G° = -261.1 \text{ kJ/mol} \quad (1)$$
$$2Al_2O_{3(l)}+CaO_{(l)} \longrightarrow CaO.2Al_2O_{3(s)} \quad \Delta G° = -152.2 \text{ kJ/mol} \quad (2)$$
Both above reactions are possible, as their $\Delta G°$ values are negative. When comparing reaction (1) (precipitation of $CA_6$) and Eq. (2) (precipitation of $CA_2$), it is concluded that the former presents a lower $\Delta G°$ value than the latter and, therefore, it is the preferential product observed in the micrograph (Fig. 5).

As the slag attack and reaction increases, or in other words, as $CA_6$ dissolves within the slag, a continuous layer of $CA_2$ forms. In the following, as CaO concentration increases due to the slag attack, CA and $CA_2$ phases form. Given that the melting temperatures of them are below 1650°C, they dissolve in the slag at CIF working temperature. After the $CA_2$ layer, spinel crystals formed discretely, which could be due to the reaction between MgO and $Al_2O_3$ and the slag's enrichment of magnesia and alumina inside the slag.

## 4. CONCLUSIONS

1. The island cracks formation on the surface of TA-based DVM lining of CIF is the mainly create due to lower thermal shock resistance, thermal and structural properties of tabular alumina compare to fused alumina.

2. A dense spinel structure in the matrix of TA-based DVM decrease penetration depth of liquid slag into lining.

3. Corrosion of alumina aggregates and matrix accompanied to formation of calcium aluminate phase and is same in TA-based and WFA-based DVM lining.

## ABSTRACT

Silica ($SiO_2$) dry vibrating mixes with sintering additive boric acid ($H_3BO_3$) or diboron trioxide / Boron oxide ($B_2O_3$) are the standard refractory lining products used for crucible induction furnaces (CIF) in the iron foundries worldwide. The sintering agents are used to control the reaction with $SiO_2$ that forms a melt phase on the surface of the grains, which protect the refractory lining, reduces infiltration and extend the campaign life of the lining. Though, the sintering agents have shown a high performance of the refractory lining life, they are classified as reproductive toxicity "1B" to humans, present challenging health effects and environmental disposal problems. Currently, delivered products are labeled with 1B and regulatory institutions are proposing a further reduction in concentration of less than 0.3 % $B_2O_3$ in all products. This paper presents recent developments on a novel sintering agent combination for $SiO_2$ refractory lining products. The sintering additive is not classified by legislation and is envisaged to minimized health risks to humans and the environment. For a better evaluation of the suitability of the novel sintering agent for binding the $SiO_2$ matrix, a chemical and mineralogical analysis was performed with lining samples hammered from the furnace. Field applications revealed equivalent performance comparable to current sintering agents.

## 1.0 INTRODUCTION

The most common and well know sintering agents for binding $SiO_2$ dry vibrating mixes (DVM) used in lining the hot face of crucible induction furnaces (CIF) for melting recycled copper, iron and their alloys are boric acid ($H_3BO_3$) or boron oxide ($B_2O_3$) or frits and/or phosphate. In some special cases, additives such as chrome oxide and/or carbon are added to improve the slag resistance of the lining wall or the anti-wetting effect respectively. The $SiO_2$ content in the mixture varies from 94 – 99 % and the rest constitutes the sintering agents, converters and stabilitators. When mix and thermally heat treated, based on the additive ionic state, they can either interchange with the silicon ion in the crystal structure or stay unreacted within its interstitials/cavities. This alters the $SiO_2$ crystal structure and lower its melting point with the formation of a melt/sintered phase according to Fig. 1, suitable for resisting slag and liquid metal infiltration [1, 2].

*Fig. 1: Reaction mechanism showing the influence of the network builders, converters and stabilizers on the quartz crystal structure* [2, 3]

The suitability and functionality of the sintering agent is based on certain properties. It should have a low melting temperature ($H_3BO_3$:170 °C, $B_2O_3$: 450 °C, phosphate: >200 °C, frits: >700 °C) couple with a high temperature stability up to 1700 °C. A desirable high expansion, softening and less sealing effects are reported during high temperature service life for frits or phosphate compared to low temperature consolidation and lower expansion when $B_2O_3$ or $H_3BO_3$ were used [1]. The suitable additives are currently classified as toxic material category 1B and are listed as substance of very high concern by REACH (Registration; Evaluation, Authorization and Restriction of Chemicals) and ECHA (European Chemicals Agency) with a maximum permitted concentration of C≥5.5 % for $H_3BO_3$ and C≥3.1 % for $B_2O_3$. Recently, in Europe a new legislation to label all products containing pure boron oxide concentration of C≥0.3 % $B_2O_3$ was adopted [4]. Some Asian countries have signed a regulation adopting a maximum concentration level of 0.3 % $B_2O_3$ in all $SiO_2$ products.

Novel $SiO_2$ products without pure $H_3BO_3$ and/or $B_2O_3$ bears a real potential for minimization of health and environmental hazards. The goal of this work is to develop a dry vibrating $SiO_2$ refractory product with a novel sintering agent that does not contain pure $H_3BO_3$ and $B_2O_3$. It is expected to have similar performance comparable to the $H_3BO_3$ and $B_2O_3$ sintering agents, which could possibly be use as an alternative in case of regulation enforcement in future.

### 1.1 Experimental and material processing routes

Silica raw materials of varying particle sizes were mixed separately with three different sintering agents [phosphate from Chemische Fabrik Budenheim KG; glass frit from Reimbold & Strick; and/or DFP high temperature combination binder (HTB)]. Obtained results are compared to the standard $SiO_2$-$B_2O_3$ concept as follows [2].

1. $SiO_2$ + Phosphate concept denoted as **SiO₂-P**
2. $SiO_2$ + Glass frit concept denoted as **SiO₂-GF**
3. $SiO_2$ + DFP „HTB"combination concept denoted as **SiO₂-HTB**
4. $SiO_2$ + $B_2O_3$ standard concept denoted as **SiO₂-B₂O₃**

Mixture 1 to 4 were homogenized separately, and cylindrical shapes of 50 X 50 mm were compacted from each system. The samples were subjected to a heat treatment with a constant heating rate of 5 K min$^{-1}$ to maximum temperature between 1200 °C and 1600 °C. Sawn cross-sections of some samples are represented in Fig. 2. The sintered samples were characterized in terms of physical properties and compared with the $SiO_2$-$B_2O_3$ concept. Industrial trials were carried out with iron foundries melting recycled cast and ductile iron. In this short overview, selected laboratory physical properties of the best results (Fig. 2 and Tab. 1), results of the industrial trials (Fig. 3) including the mineralogical analysis in Fig. 4 and Tab. 2 are presented.

## 2.0 RESULTS AND SUMMARY

### 2.1 Density, cold crushing strength and open porosity

In Tab. 1, the results of the cold crushing strength (CCS), bulk density, open porosity and permanent linear change (PLC) values for the $SiO_2$-HTB and $SiO_2$-$B_2O_3$ system are compared. The CCS values for both systems increase due to sintering and densification. The $SiO_2$-$B_2O_3$ system shows a higher strength and less porosity for sintered samples at 1600 °C. A possible reason is the start of early densification in the $SiO_2$-$B_2O_3$ system. The low strength value for the $SiO_2$-HTB sample sintered at 1200 °C is related to its high initial start melting temperature and late densification, which was observed to start at >700 °C compared to 450 °C for the $SiO_2$-$B_2O_3$ system [1].

### 2.2 Results and observation of the pushout crucibles

Fig. 3 represent the pushout crucibles and breakout lining samples from the different furnaces with some collected data listed. More wearing, erosion, less heat numbers and deep sintering were observed in the $SiO_2$-P and $SiO_2$-GF systems compared to the $SiO_2$-HTB system. In Fig. 3 (upper-left), it was observed that, above 1500 °C, the $SiO_2$-P system showed very high amount of blown-out melted surface view, suspected to originate from low melting eutectic aluminum phosphate formation with intensified erosion and infiltration compared to the other sintering agents [2]. Though, the $SiO_2$-GF achieved more heat numbers than the $SiO_2$-P system, its sintered and fritted layer showed less density, and the loose layer

was completely hardened after 100 heats (Fig. 3, top-right). This was suspected to be caused by the alkali ($Na^+$, $K^+$, $Ca^{2+}$) content of the glass frit, that is voluminous and capable of softening and forming low eutectic melting phases, weakening the lining microstructure at temperatures >1500 °C [1, 3]. Comparable sintered, fritted, and loose zones with higher heat numbers were observed with the $SiO_2$-HTB system similar to the $SiO_2$-$B_2O_3$ system. In Fig. 3 and Fig. 4, the $SiO_2$-HTB and $SiO_2$-$B_2O_3$ systems showed no infiltration observed beyond the sintered zones.

*Fig. 2: Matrix view of the cross-section of the sintered samples at 1400 °C and 1600 °C for 5 hrs*

Tab. 1: Physical properties of the $SiO_2$-HTB and $SiO_2$-$B_2O_3$ system

| Temperature [°C] | 1200 | | 1400 | | 1600 | |
|---|---|---|---|---|---|---|
| System | $SiO_2$-HTB | $SiO_2$-$B_2O_3$ | $SiO_2$-HTB | $SiO_2$-$B_2O_3$ | $SiO_2$-HTB | $SiO_2$-$B_2O_3$ |
| CCS [MPa] | 8 | 17 | 10 | 16 | 20 | 27 |
| Density [g/cm³] | 1,92 | 1,96 | 1,87 | 1,95 | 1,83 | 1,81 |
| OP [%] | 21 | 20 | 22 | 18 | 18 | 15 |
| PLC [%] | 0,6 | 0,3 | 1,7 | 0,2 | 3,1 | 3,6 |

## 2.3 Chemical and mineral analysis of the lining samples

Breakout lining cross sections, SEM micrographs and EDX spot analysis for the $SiO_2$-HTB and $SiO_2$-$B_2O_3$ crucible samples are shown in Fig. 4, with corresponding mineral analyses in Tab. 2. The infiltration zones A and C of both systems

consist of slag and silica with dentritic crystallites of fayalite observed. In addition, CuO was analyzed in the infiltration zone of the $SiO_2$-$B_2O_3$ system (Tab. 1), suspected to be an impurity from the used scrap. Moving into zones B and D, the matrix densification is improved and shows a reduction in the impurities observed. The quartzite is totally cristobalized, showing cloudy structures with typical crack structures of the quartz at the beginning of transformation to tridymite/cristobalite. The glassy matrix with rest quartzite and large transformed grains are observed typically in B and D [4,5]. The matrix is made up of tridymite and cristobalite with some mullitization traces observed along the boundaries or in-between the tridymite and quartzite grain boundaries, which is suspected to have improved the strength of the $SiO_2$ product.

Tab. 2: Qualitative mineral analysis of the zones

| Samples | Zone | Major phase | Minor phase | Trace |
|---|---|---|---|---|
| $SiO_2$-HTB | Infiltration | Cristobalite | Tridymite, Fayalite, Amorphous, | Quartz |
| | Sinter | Quartz | Cristobalite, Mullite, amorphous | Tridymit |
| $SiO_2$-$B_2O_3$ | Infiltration | Tridymite | Cristobalite, Fayalite, Cu | Quartz |
| | Sinter | Quartz | Cristobalite, amorphous | Tridymit |

## 3.0 Summary

The introduction of the DFP "HTB" combination binder into the $SiO_2$ crystal, resulted in a reinforcement and stabilization of the $SiO_2$ structure with similar wear and heat numbers achieved comparable to the pure $SiO_2$-$B_2O_3$ system. Low melting eutectics and alkali content reduces the refractoriness of the $SiO_2$-P and $SiO_2$-GF system respectively. Until date, 20 iron foundries melting cast and ductile iron with medium and line frequency furnaces, having capacity of 1-16t have carried out successful trials with the novel sintering agent with greater than 85 % lifetime achieved. Since, little or no $B_2O_3$ erodes into the melt during the first two melting batches, customers discarding first two batches due to high boron content do not longer discard them. Improved operational safety and minimization of environmental contamination is possible. The $SiO_2$-$B_2O_3$ system starts melting at 450 °C compared to >700 °C for the $SiO_2$-HTB system, which requires a little more energy.

Ongoing investigations have shown that, the novel system is also suitable for melting recycled copper. Currently, prefabricated crucibles are being tested in the copper and iron foundries. Further work is based on analyzing the influence/distribution mechanism of the HTB combination sintering agent, and the replacement of the fine crystalline quartz as raw material for the silica product.

**ABSTRACT**

Due to high efficiency and energy-saving, induction furnaces are widely used in foundry and metallurgy industries. Spinel forming dry ramming mixes worked as the lining of induction furnaces for high quality alloy steel casting. Aiming at optimizing properties of alumina-magnesia based dry ramming mixes, white fused alumina and calcined magnesia particles were replaced partially with the novel porous multi-component materials of spinel-calcium aluminate (CaO-MgO-Al$_2$O$_3$, CMA) with the size of 0-1 mm. Properties including the bulk density, apparent porosity, strength and slag corrosion resistance of alumina-magnesia based dry ramming mixes containing CMA were evaluated contrastively. The results demonstrated that the incorporation of CMA can significantly improve manganese-bearing slag penetration resistance of dry ramming mixes, although companying with slight decrease in the bulk density. However, the permanent linear change of dry ramming mix first increased and then decreased with CMA additions. When the addition of CMA reached 8 wt%, the strength of dry ramming mixes was a little lower than the reference, and the slag penetration index was 38% lower than the latter.

**Introduction**

Due to their flexibility and other advantages, medium-frequency induction furnaces are widely used in the foundry industry. As one of the most important components of the induction furnaces, the linings work in an extremely harsh environment during the smelting process [1]. Because of its excellent chemical stability, thermal shock resistance and mechanical properties, spinel-forming dry mixes are suitable to induction furnaces for melting of high alloy steels [2]. During the service of alumina-magnesia based dry ramming mixes, the formation of in-situ spinel would lead to a certain volume expansion (8%) [3-4], which could seriously affect the performance of the linings and shorten the service life of the furnaces [5]. The expansion of refractories was controlled by the incorporation of preformed spinel, which was as the consequence of less in-situ spinel formation [6]. It was pointed out that preformed and in-situ spinel containing castables had immense potential to enhance properties such as strength, thermal shock resistance and corrosion resistance [7].

In the Al$_2$O$_3$-rich part of Al$_2$O$_3$-MgO-CaO ternary system, the first liquidus temperature is higher than 1730 °C. Recently, the novel calcium magnesium aluminate (CMA) materials containing 73% spinel and 25% calcium aluminate have been developed by Imerys. The aim of this study is to systematically investigate effects of CMA particles (1-0 mm) on properties of alumina-magnesia based dry ramming mixes.

**Materials and Methods**

The formulations of dry ramming mixes are listed in Table 1. Coarse white fused alumina (Yufa, Zhengzhou, China) was used as aggregates, and fine particles of white fused alumina and tabular alumina (Higiant, Binzhou, China) served as the matrix. Calcined alumina (Alteo, Gardanne, France) and magnesia (Jinding, Dashiqiao, China) were designed to form in-situ spinel at high temperatures. CMA particles (MagArmour, Imerys, Paris, France) were composed of MA (72.5%), CA (16.5%) and CA$_2$ (9.0%). Samples were marked as X0-X8 according to CMA additions.

Tab. 1: Formulations of alumina-magnesia based dry ramming mixes.

| Raw materials | Content (wt%) | | | | |
|---|---|---|---|---|---|
| | X0 | X2 | X4 | X6 | X8 |
| White fused alumina (<5 mm) | 72 | 71 | 70 | 69 | 68 |
| White fused alumina (<0.075 mm) | 7 | 7 | 7 | 7 | 7 |
| Tabular alumina (<0.045 mm) | 3 | 3 | 3 | 3 | 3 |
| Calcium alumina (AC34B5) | 3 | 3 | 3 | 3 | 3 |
| Calcined magnesia (<0.3 mm) | 8 | 8 | 8 | 8 | 8 |
| Calcined magnesia (<0.075 mm) | 7 | 6 | 5 | 4 | 3 |
| MagArmour (0-1mm) | − | 2 | 4 | 6 | 8 |

Raw materials were mixed for 10 min in a cement mortar mixer. The mixture was pressed into a cylinder with the dimension of Φ 50 mm×50 mm in molds with aluminum foils on the inner surface by a compression testing machine (TYE-2000B, Wuxi Jianyi, China). The pressure of 60 MPa was applied. All samples were dried at 110 °C for 24 h, and then calcined at 1600 °C for 3 h. Cylindrical samples for corrosion tests were also pressed under the pressure of 60 MPa as the following dimensions: Φ 50 mm×50 mm with the hole of 18 mm diameter and 24 mm depth in the center. The calcined cup samples were filled with slag (8 g), and then heated up to 1600 °C and soaked for 3 h.

Tab. 2: Chemical compositions of slag used for testing.

| Compositions | SiO$_2$ | Al$_2$O$_3$ | Fe$_2$O$_3$ | CaO | MgO | MnO | TiO$_2$ |
|---|---|---|---|---|---|---|---|
| Content (wt%) | 36.91 | 31.22 | 5.62 | 0.84 | 3.28 | 20.55 | 1.14 |

**Results**

*Phase composition*

The major phases were corundum and spinel, and unreacted magnesia was detected. The spinel contents in samples calculated by reference intensity ratio (RIR) method were listed in Table 3. It can be seen that the spinel in samples firstly increased and then decreases with the increase of CMA additions.

*Fig. 1: XRD patterns of dry ramming mixes with the addition of CMA after sintering at 1600 °C for 3 h.*

Tab. 3: Spinel content of different samples.

| Spinel | X0 | X2 | X4 | X6 | X8 |
|---|---|---|---|---|---|
| Content (wt%) | 48.7 | 48.3 | 50.7 | 44.3 | 37.9 |

*Physical and Mechanical Properties*

As shown in Fig. 2, the permanent linear change of samples after sintering firstly increased and then decreased. Apparent porosity and bulk density of samples are presented in Fig. 3. It can be seen
Fig. 2: Permanent linear change of specimens with the addition of CMA after sintering at 1600 °C for 3 h.

that the apparent porosity of samples first raised and then decreased after sintering at 1600 °C for 3 h with the increase of CMA contents, and the variation of the bulk density was opposite. Except for a certain decrease of the apparent porosity for the sample with 8% CMA addition, the use of up to 38% porous CMA aggregates (particles with 30% porosity) instead of dense white fused corundum leads to an increase in apparent porosity. The significantly lower bulk density of CMA particle than white fused corundum led to the decline of the bulk density.

Fig. 3: Apparent porosity and bulk density of specimens with the addition of CMA after sintering at 1600 °C for 3 h.

Figure 4 shows the cold crushing strength of samples. As the increase of the content of CMA, the cold crushing strength of samples first decreased and then raised. The strength of the sample with 8% CMA addition is not significantly different from the reference.

Fig. 4: cold crushing strength of specimens with the addition of CMA after sintering at 1600 °C for 3 h.

Figure 5 shows the microstructure of samples X0, X6 and X8. There were many pores in sample X0, X6. In contrast, the junction of aggregates and matrix in sample X8 was relatively denser because of the addition of CMA particles. In addition, 25% calcium aluminate from CMA could form $CA_6$ around the corundum aggregates over 1450 °C, which resulted in a strong bridging effect between aggregates and matrix.

Fig. 5: SEM images of X0 (a), X6 (b) and X8 (c) (d) (A-Corundum, S-Spinel, M-periclase)

EDS mapping and the local magnified SEM images of sample X8 are shown in Fig. 6. It can be seen that a large amount of $CA_6$ was generated at the center of aggregate. Formed $CA_2$ as a bonding phase tightly connected $CA_6$ and spinel. A structure of $CA_6$-$CA_2$-MA with closely combined layers could eliminate pores, absorb stress and improve the mechanical properties of materials. The fracture toughness of this three-layer structure was greater than in MA-alumina region due to the crack-deflection and crack-bridging effects derived from $CA_6$ platelets.

Fig. 6: EDS mapping of X8 (a), (b) Al, (c) Mg, (d) Ca and Partial enlarged images of X8 (e), (f) (S-Spinel)

Figure 7 presents the photos of the crucible samples after the cup tests. The penetration index of samples is listed in Table 4. The penetration index of samples basically decreases with the increase of CMA contents. In theory, slag penetrates into the matrix under the action of capillary force. When the slag comes into contact with CMA, the porous structure of CMA can absorb the slag through capillary force. In addition, the formation of a three-layer structure of $CA_6$-$CA_2$-MA may improve the slag corrosion resistance of ramming mixes.

Tab. 4: Penetration indexes of the corroded samples

| Samples | X0 | X2 | X4 | X6 | X8 |
|---|---|---|---|---|---|
| Penetration index (%) | 25.96 | 21.46 | 21.80 | 18.70 | 16.07 |

## CONCLUSIONS

Enhanced properties of alumina-magnesia based dry ramming mixes were achieved by incorporated a novel kind of multi-component materials of calcium magnesium aluminate (CMA) particles. The addition of CMA promoted the formation of the bond structure of $CA_6$-$CA_2$-MA in dry ramming mixes. Although the incorporation of CMA particles (0-1 mm) slightly reduced the physical properties of dry ramming mixes after sintering at 1600 ℃ for 3 h. But when 8 wt% CMA particles are introduced, the slag penetration resistance has been significantly improved.

## ABSTRACT

The aluminium industry is a major consumer of refractories. Today, most furnaces are lined with aluminosilicate-based materials. To reduce the penetration of Al into the refractory material, non-wetting additives such as barium sulphate, different types of fluorides, and CaO were used. The aim of this study was the investigation of different calcium aluminate-based coatings to reduce the wettability of a metallic substrate by molten aluminium. Feedstock composed of calcium magnesium aluminate CMA, calcium di-aluminate $CA_2$, and $CA/CA_2$ with and without $TiO_2$ were processed via powder and flame spraying to thin coatings on metal substrates. The phase composition, roughness, macro- and microstructure, porosity, and bending strength of the coatings have been analysed. Additionally, a casting test, has been performed by pouring 1.5 kg AlSi7Mg alloy at 800 °C over coated half-pipes using pure alumina as reference coating. The amount of residual Al sticking on the substrates after the casting test indicates the degree of wetting of the coatings. The thermally sprayed CMA and $CA_2$ powder feedstock showed the lowest degree of interaction with the aluminium melt.

## INTRODUCTION

Aluminium is the most important light metal with a consumption of 96.6 million tons in the year 2022 and a growth of 3.3 % compared to the previous year [1]. The aluminium industry is a major consumer of refractories, which are faced with increasing wear by fluxes, the use of oxy-fuel burners, higher furnace temperatures, higher amounts of alloying Mg and recycled Al metal, as well as a requirement for higher efficiencies. The wettability of alumina, silica, Be, $B_4C$, graphite as well as SiC by aluminium and Al alloys has been investigated by several researchers [2]. Today, alumina and aluminosilicate refractory castables are widely used for the lining of holding and melting furnaces due to their good thermomechanical properties and – in the case of the latter - low costs [3]. The castables are composed of coarse aggregates such as mullite, grog, bauxite, and tabular alumina, fumed silica and calcined alumina as fillers, and calcium aluminate cement with an $Al_2O_3$ content in the range of 60 to 80 wt.-% as a binder [4]. Above the metal line, the furnace can reach a temperature up to 1300 °C and the growth of corundum along the walls was observed degrading the lining material [5]. Below the metal line, the temperature is as low as 800 °C and the refractory is attacked by corrosion. Since aluminosilicate castables contain free silica as well as alkalis, they show poor corrosion resistance in contact with molten aluminium [6,7]. The metallic Al reduces the $SiO_2$ or mullite and an adhesive $Al_2O_3$ deposit is formed on the surface of the refractory, which acts as a protective barrier as long as it will not be decomposed by alkalis or a reducing atmosphere in the furnace [8]. Additives such as $BaSO_4$, $CaF_2$, $AlF_3$, $CeO_2$, and $La_2O_3$ promote the non-wettability of aluminosilicates by aluminium, but $AlF_3$ and $CaF_2$ deteriorate the corrosion resistance due to the formation of glassy phases [9,10]. Afshar et al. developed a high-alumina-based low-cement castable with fumed silica to reduce the porosity and pore size and added barite to counterbalance the low chemical resistance of $SiO_2$ [11]. Allaire and Guermazi added wollastonite $CaSiO_3$ to an alumina-based refractory to increase the resistance against corundum above the metal line and also the corrosion resistance against molten aluminium below the metal line by decreasing the penetration and increasing the mechanical properties [4]. Avraham and Kaplan investigated the reactive

wetting of $TiO_2$ by molten Al. The titania will be reduced by Al resulting in the formation of $Al_3Ti$ in the metal and a thin corundum layer at the interface leading to the reduction of the wetting angle [12]. Buhr et al. proposed the use of silica-free calcium hexaaluminate ($CA_6$) refractories for a low wettability and high temperature stability against molten aluminium [13]. Compared to refractories based on bauxite with $BaSO_4$ as anti-wetting agent and silica fume or high purity alumina, the $CA_6$ showed only slight discoloration, whereas the conventional bauxite refractories showed dark discoloration and a reaction with molten aluminium. Next to the low wettability, the enhanced aluminium resistance of $CA_6$ was explained with a micro porosity and lower pore size distribution. Siljan et al. have shown, that the density, porosity, and pore size distribution determines the contact and infiltration of a refractory next to its chemistry [14]. An optimized pore size distribution with a maximum pore size below 1–2 µm can improve materials, that are not thermodynamically stable towards molten aluminium.

Since the literature review has shown that the coarse aggregates are a weak point of the alumina and aluminosilicate castables, CaO was found to reduce the wettability of alumina-based castables by molten aluminium, and $MgAl_2O_4$ as well as calcium aluminates exhibited an enhanced corrosion resistance, the aim of this study was the development of fine-grained calcium aluminate-containing protective coatings for aluminium casting products produced by flame-spraying and the investigation of the interaction of the coatings in contact with molten aluminium.

## MATERIALS AND METHODS

### Materials and sample preparation

To determine the interaction of calcium aluminate-containing coatings with an aluminium melt, CA cement-based raw material mixtures as listed in table 1 were prepared to produce flame-spray feedstocks. Alumina was used as reference material.

Tab. 1: Composition of the feedstock for the flame-spray coatings

| Material | Sample (wt.-%) | | | | |
|---|---|---|---|---|---|
| | A100 | S71 | S71T2 | CA2 | CMA |
| $Al_2O_3$ | 100 | - | - | - | - |
| $TiO_2$ | - | - | 2 | - | - |
| Secar 71 | - | 100 | 98 | - | - |
| Non-standard product | - | - | - | 100 | - |
| CMA 72 | - | - | - | - | 100 |

As ceramic raw materials, Secar 71, a non-standard $CA_2$ product, CMA 72 0-1 mm (all Imerys S.A., Paris, France), $Al_2O_3$ powder spray feedstock (Amdry 6062, Oerlikon Surface Solutions AG, Pfaeffikon, Switzerland), and rutile $TiO_2$ (TR-HP-2, Sachtleben Chemie GmbH, Duisburg, Germany), were used. To generate the coatings, rod (sample S71, S71T2) and powder flame spraying (sample A100, CA2, CMA) have been performed. To produce the rods, the raw materials were mixed with 20 wt.-% of a thermoplastic injection moulding binder (Siliplast HO, Zschimmer&Schwarz, Koblenz, Germany) and a hot melt powder (abifor1625, Abifor AG, Zurich, Switzerland) for 5 minutes. The mixture was extruded at 120 °C using a heatable twin screw extruder from Brabender® OHG (Duisburg, Germany. After extrusion, the rods with a length of 600 mm were debinded and

sintered. The sintered rods of the samples S71 and S71T2 were fed to a Master Jet® flame-spray unit (Saint-Gobain Coating Solutions, Avignon, France) and processed to coatings. The sieved CMA 72 36-71 µm fraction (sample CMA), the CA2-rich powder (sample CA2), and the Amdry 6062 (A100) were automatically powder flame-sprayed with the MetcoTM 6P-II-A ThermoSprayTM gun, which is supplied with the process gases by the 6CE Combustion Control Unit (both Oerlikon Surface Solutions AG, Pfaeffikon, Switzerland) and guided by a robot arm (IRB 2600, ABB Ltd, Zurich, Switzerland). The powders were fed to the flame-spray gun by the 5MPE powder carrier (Oerlikon Surface Solutions AG, Pfaeffikon, Switzerland) using nitrogen as the carrier gas, which allows the processing of powders with low flowability. During the spraying processes, all raw materials were melted in an oxygen-acetylene flame with a maximum combustion temperature of 3160 °C.

## Methods

Free-standing band-shaped samples (approx. $10 \times 100 \times 1$ mm$^3$) for characterisation were produced by guiding the spraying gun perpendicular to a graphite substrate (GM-154e, Graphite Materials, Oberasbach, Germany), which was encircled by steel sheets. The characterisation of structural aspects such as the macro- and microstructure and the roughness was performed with a digital light microscope (VHX-2000 D, Keyence International, Mechelen, Belgium), a confocal laser scanning microscope (VK-X, both Keyence Deutschland, Neu-Isenburg, Germany), and a scanning electron microscope (SEM) (XL30 ESEM FEG D1511, Philips, Eindhoven, The Netherlands) equipped with an energy dispersive spectroscopy (EDS) detector. To obtain detailed information on the portion of open pores and the distribution of their size, mercury intrusion porosimetry, as comprehensively explained in DIN 66133, was applied with an assumed contact angle of 140° using an AutoPore V 9600 (Micromeritics Instrument, Norcross, USA). Three-point bending strength experiments were performed using a TiraTest 2420 machine (TIRA, Schalkau, Germany) according to EN 993-6 with a lower support roller span of 31.5 mm. Phase analysis was performed at milled and sieved (sieve aperture 20 µm) coating samples by XRD with qualitative and quantitative evaluation. To evaluate the interaction of the flame-sprayed coatings with molten aluminium, metal half-pipes were sandblasted and flame-spray coated with A100, S71, CA2, and CMA, respectively. 1.5 kg of solid AlSi7Mg alloy was portioned, filled in a crucible, and melted in a gas-fired furnace at 800 °C with a 2 h dwell time. Afterwards, the molten aluminium was slowly poured for approx. 1 min over the coated halfpipe, which was rested in 10° inclinations into another crucible, where the molten metal was collected. The setup of the casting test is depicted in figure 1.

Fig. 1: Setup of the casting test before (a) and during casting (b) of molten aluminium.

To evaluate the casting test, the mass of the coated halfpipes before and afterwards was detected. The resulting mass difference is the amount of aluminium, which remained in the halfpipe and is a degree of the wetting behaviour of the coating. Additionally, the coating and the cast aluminium melt were investigated in the digital light microscope as well as in the SEM.

## RESULTS AND DISCUSSION
### Coating characterisation

The rod flame-spraying of samples S71 and S71T2 resulted in a very homogenous but rough coating with a $R_a$ of 78.2 µm of sample S71. The addition of 2 wt.-% TiO$_2$ led to a significantly lower roughness of 44.9 µm. The powder flame-sprayed samples CA2

and CMA exhibited a loser structure. In the case of CA2, two different areas, a light grey and a dark grey one, could be identified. Sample CMA contained brownish impurities. The powder flame-spraying resulted in significantly smoother surfaces with a Ra of sample CA2 and CMA of 18.7 and 13.6 µm, respectively. In the SEM, the coatings S71 and S71T2 appear similar. Typically for rod flame-spraying, the coatings have a dense and homogenous character and are composed of overlaid splats with round or pancake-like shapes within a wide diameter range (5–200 µm) as well as pores. According to the XRD analyses, both samples S71 and S71T2 are composed of a very high amount of amorphous phases of 98 % as well as 1 % of CA and CA$_2$ each. In contrast, the coatings of samples CA2 and CMA are composed of molten particles in a narrower diameter range, indicating a good melting of the powder feedstock, but no flattening of the molten droplets and consequently no distinctive densification of the coating took place. EDS analyses of sample CA2 revealed CA$_2$ (37.5 mol.-% CaO, 62.5 mol.-% Al$_2$O$_3$) as a continuous phase. According to XRD, the coating consists of 83 % amorphous phases and 17 % CA$_2$. These two different phase portions were visible in the light microscope. The coating of sample CMA appears more porous with larger particles, which have on the hand a spherical and on the other hand a more edgy shape. According to EDS analyses, the edgy particles are spinel with CaO (26 mol.-% MgO, 54.5 mol.-% Al$_2$O$_3$, 19.5 mol.-% CaO), whereas the particles with a higher degree of melting additionally contain traces of Na$_2$O (0.3 mol.-%), SiO$_2$ (0.5 mol.-%), and P$_2$O$_5$ (0.4 mol.-%) next to MgO, Al$_2$O$_3$ (spinel), and CaO. An EDS mapping showed, that all of the elements Mg, Al, Ca, Si, Fe, and O are homogeneously distributed in the microstructure. The XRD analysis revealed that sample CMA is composed of 47 % MgAl$_2$O$_4$, 14 % CA, 37 % amorphous phases, and traces of Fe$_3$O$_4$ (1 %). Table 2 summarizes the open porosity as well as the $d_{10}$, $d_{50}$, and $d_{90}$ values of the pore size distribution of the as-sprayed coatings. The pore size distribution is additionally displayed in figure 2. The results of the mercury intrusion confirm the findings of the microstructure investigation in SEM. The rod flame-sprayed samples S71 and S71T2 had an open porosity of 7.1 and 5.9 %, respectively, and a $d_{50}$ pore size below 1 µm (44.7 % of the pores in sample S71 and 23.2 % of the pores in sample S71T2 are larger than 2 µm). Hence, both coatings should be proper materials for an application in contact with molten aluminium. The addition of 2 wt.-% TiO$_2$ have a positive effect on the microstructure by further reducing the open porosity and resulting in a narrower pore size distribution with lower pore sizes of coating S71T2 in figure 2.

Fig. 2: Pore size distribution of the as-sprayed coatings with marked (grey) area of maximum pore size for aluminium melts.

The coatings CA2 and CMA, which appeared much more porous in the SEM also have a significant higher open porosity of 24.1 (CMA) and 32.6 % (CA2) analysed by mercury intrusion. With a $d_{10}$ of 6.55 (CMA) and 10.56 µm (CA2), both powder-sprayed coatings contain a high degree of pores (96.5 % in coating CMA and 99.8 % in CA2) being large enough to be infiltrated by an aluminium melt and may encounter a higher degree of infiltration and corrosion during application. However, CMA provides a lower porosity and lower pore sizes compared to CA2. The flame-sprayed alumina reference coating A100 has a porosity of 10.8 %, a low $d_{50}$ in the range of the rod flame-sprayed coatings of 0.62 µm, but a $d_{90}$ with very large pore sizes of 172 µm. Fig. 5 shows the bending strength of the free-standing coatings.

527

Tab. 2: Open porosity (OP), and $d_{10}$, $d_{50}$, and $d_{90}$ values of the pore size distribution of the as-sprayed coatings.

| Sample | OP (%) | $d_{10}$ (µm) | $d_{50}$ (µm) | $d_{90}$ (µm) |
|--------|--------|---------------|---------------|---------------|
| S71 | 7.1 | 0.03 | 0.99 | 26.47 |
| S71T2 | 5.9 | 0.14 | 0.73 | 14.12 |
| CA2 | 32.6 | 10.56 | 18.78 | 48.97 |
| CMA | 24.1 | 6.55 | 14.35 | 42.04 |
| A100 | 10.8 | 0.24 | 0.62 | 172.70 |

The reference alumina coating A100 exhibited the highest bending strength of 16.7 MPa but also a high standard deviation. The rod flame-sprayed samples S71 and S71T2 showed similar strength values (7.5 MPa for S71 and 7.1 MPa for S71T2). Hence, the titania content does not influence the strength of the coatings. The porous powder flame-sprayed samples CA2 and CMA exhibited a much lower strength, whereas sample CMA shows a higher strength of 3.1 MPa compared to CA2 (2.0), but a much higher standard deviation.

**Evaluation of the casting test**
The casting test revealed distinct differences in the behaviour of the coatings in contact with molten aluminium. In the case of the powder flame-sprayed coatings A100, CA2, and CMA, the solidified aluminium could have been torn off residual-free. This is a very important property, as the main degradation mechanism of e.g. furnace walls and refractory casting channels against molten aluminium isn't corrosion or erosion but the manual removal of residual solidified Al and dross that stuck at the wall or in the channel after the casting, which tears not only the aluminium from the wall or out of the channel but a lot of the refractory material, too. Macroscopically (figure 3a, j, and m) as well under the light microscope, no damage to the coatings could be detected.

Fig. 3: Coated half-pipes of sample A100 (a-c), S71 (d-f), S71 (g-i), CA2 (j-l), and CMA (m-o) after the casting test and investigation under the light microscope at 30- (middle) and 200-times (right) magnification.

On top of the reference alumina sample A100, brownish-coloured spots after the casting test were visual (figure 3b and c), which is a sign of interaction with molten alumina. In contrast, the surface of the CA2 and CMA coating didn't show a change in the microstructure (see figure 3k, l, n, and o). At higher magnification (figure 3l and o), both coatings CA2 and CMA revealed their porous character but the molten Al didn't infiltrate the open pores of the coatings during the casting test. However, some Al splash could have been found.

After the casting test, parts of the coating S71 spalled from the metallic half-pipe (figure 3d) and the Al could not have been peeled off without tearing off parts of the coating from the substrate. But the majority of the surface of the coating stayed unaffected (figure 3e and f) and showed no differences in its character compared to the as-sprayed state but brownish-coloured impurities as well as locally residual solidified Al. The addition of 2 wt.-% $TiO_2$ prevented the spalling of the coating S71T2 from the metallic halfpipe after the casting test (figure 3g). Similar to sample S71, the majority of the surface of the coating S71T2 stayed unaffected by the casting test compared to its as-sprayed state.

Table 3 summarizes the casting test by listing the mass of the coated half-pipes before ($m_{coated}$) and after the test and hence, the amount of remaining Al ($m_{Al}$) on the coating. The wettability of the rod flame-sprayed samples S71 and S71T2, and the powder flame-sprayed reference sample A100 were at the same level with remaining Al in the halfpipe in the range of 7.8 to 8.1 g, whereat the newly developed $CA/CA_2$ samples showed slight advantages over the reference. In contrast, the powder flame-sprayed samples CA2 and CMA exhibited a very low wettability by molten Al with only a thin Al foil of 3.8 (sample CA2) and 2.4 g (sample CMA) remaining in the half-pipe after the casting of 1.5 kg AlSi7Mg at 800 °C.

Tab. 3: Mass of the coated half-pipes before ($m_{coated}$) and after ($m_{end}$) the casting test and amount of remaining Al.

| Sample | $m_{coated}$ (g) | $m_{end}$ (g) | $m_{Al}$ (g) |
|--------|------------------|---------------|--------------|
| S71 | 358.7 | 366.2 | 7.5 |
| S71T2 | 372.7 | 380.4 | 7.7 |
| CA2 | 368.2 | 372.0 | 3.8 |
| CMA | 379.1 | 381.5 | 2.4 |
| A100 | 378.6 | 386.7 | 8.1 |

Fig. 4: Light microscope images of ceramic inclusions at the backside (Al-coating interface) of the Al after the casting test with coating S71 (a) and A100 (b).

Figure 4 displays the backside (Al-coating interface) of the Al after the casting test. At different magnifications in the light microscope, ceramic inclusions of different particle sizes embedded in the solidified aluminium could be found after the casting test with each coated halfpipe, exemplarily shown for coating S71 in figure 4a and A100 in figure 4b. The amount of particles which were removed during the casting test from the coating by the molten aluminium is hardly detectable but seems not to differ widely for each coating. However, the maximum grain size of the inclusions at the interface differs: up to 1 mm for coating A100, approx. 200 µm for the coatings S71 and S71T2, 100 µm for CA2, and 150 µm for the CMA coating.

Fig. 5: SEM microstructure of the solidified Al after casting with the S71T2 coating with marked spots for EDS analysis.

In figure 5, the SEM microstructure of the solidified Al after the casting test can be found,

exemplarily for coating S71T2. The matrix consists of typical and characteristic textured Al. Within the solidified Al, several impurities are embedded. According to DIN EN 1706, the AlSi7Mg alloy can contain Al, Si, Mg, Fe, Ti, Mn, Zn, and Cu. An EDS spot analysis showed, that the very fine white particles (below 1 μm), which are homogeneously distributed in the Al matrix, are rich in CaO. The large spherical particle consists of $Al_2O_3$ (72 wt.-%), CaO (26 wt.-%), and $TiO_2$ (2 wt.-%) (spot 1) and represents a part of the coating that had been removed by molten Al during the casting test. Next to $Al_2O_3$-CaO-$TiO_2$, $SiO_2$ can be detected in spot 2. As the coatings don't contain silica, this impurity had been formed by oxidation of the Si portion of the Al alloy. Furthermore, an impurity containing $Al_2O_3$ (69 wt.-%) and $SiO_2$ (20 wt.-%) as well as a lot of trace compounds such as $Na_2O$, MgO, $K_2O$, CaO, S, and Cl was analysed (spot 3). Figure 5 shows another eye-catching part of the microstructure (SEM micrograph at higher magnification), which appears ripped and is only composed of Al (80 wt.-%) and Si (20 wt.-%) without MgO. This is an additional sign of diffusion of Mg from the Al alloy into the coating.

## CONCLUSIONS

More than the chemistry, the state of the feedstock and the spraying technology predetermined the properties of the coatings and hence their interaction with the aluminium melt. The rod flame-sprayed samples S71 and S71T2 are composed of densified overlaid splats and had a roughness $R_a$ in the range of 45–78 μm, a strength of approx. 7 MPa, a low open porosity, and smaller pore sizes. The addition of 2 wt.-% $TiO_2$ to CA/$CA_2$ resulted in an even narrower pore size distribution with 76.8 % of the pores being smaller than the critical pore size of 2 μm. In contrast, powder flame-spraying of CMA and CA2 resulted in a coating composed of spherical particles with a lower strength below 3 MPa but exhibited a lower roughness in the range of 13–18 μm. Both coatings showed a significantly higher open porosity and larger pores with 96.5 % (CMA) and 99.8 % (CA2) of the pores being larger than 2 μm. Even if their open porosity is higher and they have a larger pore size distribution, the powder-flame sprayed coatings composed of $MgAl_2O_4$ (CMA) and $CA_2$ (CA2) showed a better wetting behaviour against Al with less residual Al remaining in the coated half-pipe, which could be peeled-off residual-free after the casting test. However, in the microstructure of the solidified Al after the casting test, fine CaO particles, $Al_2O_3$-CaO-$TiO_2$ spheres (in the case of sample S71T2), and $SiO_2$ could be found. The latter had been formed by oxidation of the Si portion of the Al alloy. Furthermore, Mg from the Al alloy diffused into the coating. In summary, powder flame-sprayed coatings composed of $MgAl_2O_4$ and $CA_2$ are promising barriers to reducing the degradation of refractories by molten aluminium. This is a sustainable resource- and energy-saving approach, as less interaction with the molten aluminium will cause less rejected cast aluminium, which doesn't need to be melted again. Furthermore, the robot-guided automatically powder-flame-spray technology does not only allow the production of coatings but also of three-dimensional refractory components.

**ABSTRACT**

This paper is addressing the influence of hydrogen as an energy source of fuel-fired smelting furnaces within the processes for the production of secondary aluminum. General aspects of gas-fired & hydrogen-fueled burner technologies are touched upon and special features of handling hydrogen are addressed. The scope of relationships within the impacts of atmospheric effects, reflections and reactivities on the combustion of hydrogen, its reaction products and the effect on established refractory ceramics is illuminated in a particularly.

Advanced & complex application oriented tests & evaluations are discussed to determine and simulate loading conditions of refractory ceramics specified for aluminum alloys with reference to the H$_2$ induced operating conditions.

Hydrogen as critical factor

In principle, hydrogen absorption in aluminium melts is related to the surrounding water. The H2 that is formed is absorbed by the melt within a very short time. If the metal temperature drops, the solubility for hydrogen is reduced. In the liquidus-solidus transition, the H2 solubility decreases in a very small temperature interval over several orders of magnitude and leads to the precipitation of H2 and the generation of gas pores in the cast aluminium structure during the solidification of the aluminium melt. Basically, the proportion of H2 dissolved in the aluminium melt depends on the atmospheric pH2 (hydrogen partial pressure) and on the temperature and composition of the aluminium melt. For example, alloying elements such as Si, Zn or Cu slightly lower the hydrogen solubility, while Mg and sodium increase the H2 solubility.

The refractory material approach leads to a discussion about mineral exclusion criteria & the presentation of individual novel material designs to ensure the operation of the hydrogen-fueled (or mostly hydrogen-fueled) smelting furnace systems in a functionally appropriate state.

# COMPARATIVE POST–MORTEM RESEARCH ON THE CORROSION RESISTANCE OF CHEMICALLY BONDED CASTABLES IN CONTACT WITH MOLTEN ALUMINUM

## ABSTRACT
The $Al_2O_3$-based castables are widely used as refractory lining for aluminium melting furnaces. These materials are susceptible to chemical reactions between molten aluminium and refractory compounds. In order to prevent those reactions, commercial additives such as barium sulphate, monoaluminium phosphate or calcium fluoride are generally added in castables. Reduced-density castables containing a highly lightweight aggregates are now an important part of monolithic refractories. Generally, these low-density monolithics are very necessary in terms of enhancing the role of refractories in energy saving and reducing material consumption under demanding working conditions. This article presents and analyses the effect of type of additives and aggregates on the corrosion behaviour of an $Al_2O_3$-based castables with liquid Al alloy.

*Keywords: castables, energy saving, lightweight castables, corrosion tests, a new technology of lightweight castables*

## INTRODUCTION
Aluminium industry is constantly growing and there is a permanent demand of better refractories, especially castables [1]. There are several needs for refractory materials in contact with molten aluminium, such as low wettability by molten aluminium, thermal shock resistance, chemical stability, and good mechanical and thermomechanical properties at temperatures below ca. 1000°C. Many types of aluminosilicate or bauxite refractories containing different additives are generally used in the aluminium industry due to their low cost and availability. Moreover, several anti-wetting additives like barium sulphate, calcium fluoride, zircon or chromium oxide are used to improve the resistance of the refractory to corrosion by molten aluminium [2]. Binder commonly used in these monolithic products is hydraulic i.e. calcium aluminate cement. Regarding the chemical-ones, the bond strength can be developed by the addition or in situ generation of phosphates in the castables fine grained matrix. Phosphoric acid, monoaluminium phosphate or combinations thereof are widely used in the refractory industries as an alternative binder source in castable compositions [3].

### Goal of this work
This study aims to investigate the effect of addition of different components (phosphoric acid, monoaluminium phosphate, barium sulfate and calcium fluoride) on the corrosion resistance of bauxite and lightweight refractory aggregates-based castables at temperature below 1000°C in contact with molten aluminum. For this purpose, the industrial-scale corrosion test in aluminum foundry plant was performed. Comparative post-mortem studies of wear and performance of hydraulically and chemically bonded-castables were conducted based on the results from the macroscopic observations and SEM-EDS.

### Experimental part
Two bauxite-based and one lightweight aggregate-based castables were chosen as the materials for the real-life industrial scale test (Table 1). All castables investigated for the wetting experiment were manufactured by Górbet Refractories company (Trzebinia, Poland) by the standard procedure. The castable compositions were dry and wet homogenized, poured in a mold and compacted through vibration. Then, samples were kept in the molds for 24 h to set completely and then they were removed from the molds, dried and heat treated at 370°C. Firstly, the samples were investigated in term of their physical properties including bulk density (BD), apparent porosity (AP) and cold cursing strength (CCS) according to the procedures presented in the PN-EN ISO 1927-6:2013-06 standard. Secondly, the preheated SAMPLES A, B and C were immersed into molten aluminum alloys at 720°C for durations ca. 6 months. For this purpose the holding furnace was used. The microstructures and chemical compositions of the corroded SAMPLE A were analyzed by scanning electron microscopy (SEM) and energy-dispersive X-ray spectroscopy (EDS) analyzer. SAMPLES B and C without adhesion and infiltration were not analyzed in this regard.

Table 1. The composition of the castables.

| CASTABLES | CASTABLES MAIN COMPONENT | MODIFYING AGENT / TYPE OF BONDING |
|---|---|---|
| SAMPLE A | Bauxite aggregates | Monoaluminium phosphate / chemically bonded |
| SAMPLE B | Bauxite aggregates | Barium sulphate / hydraulically bonded |
| SAMPLE C | Lightweight aggregates | Calcium fluoride / hydraulically bonded |

## RESULTS
### Physical properties of as-delivered materials
The physical and mechanical properties of the three castables heat-treated at 850°C are listed in Table 2. It can be seen that both the bulk density and apparent porosity of the bauxite-based materials (SAMPLES A and B) depends on the non-wetting additive type. Thus, the different apparent porosity of two refractories will affect the wettability of the molten aluminum. It can be also seen that the castables made of the microporous aggregates exhibit low bulk density and relatively high apparent porosity.

Table 2. Physical properties of the castables heat-treated at 850°C.

| CASTABLES | BD / g/cm$^3$ | AP / % | CCS / MPa |
|---|---|---|---|
| SAMPLE A | 2.71 | 20.5 | 60.7 |
| SAMPLE B | 2.91 | 16.6 | 135.7 |
| SAMPLE C | 2.01 | 42.1 | 38.4 |

### Comparative macroscopic observations of corroded samples
The macroscopic morphology of bauxite-based castables after corrosion by molten aluminium is shown in Figure 1. Obvious appearance differences were observed on the samples after the immersion corrosion test under industrial conditions in aluminium casting plant. According to the results obtained, it can be summarized that the chemically bonded SAMPLE A was infiltrated

531

by molten aluminium alloy and the corundum build-up was adhered to the refractory surface. On the other hand, two hydraulically bonded SAMPLES containing barium sulphate (B) or calcium fluoride (C) exhibit a superior resistance to aluminium attack since no adhesion and infiltration were observed.

**SAMPLE A. ADHESION VISIBLE, INFILTRATION.**

**SAMPLE B. NO ADHESION, NO INFILTRATION.**

**SAMPLE C. NO ADHESION, NO INFILTRATION.**

*Fig. 1. Macroscopic morphology of castables after corrosion by molten aluminium. SAMPLE A – phosphate bonded bauxite-based castables, SAMPLE B – hydraulically bonded bauxite-based castables, SAMPLE C – hydraulically bonded lightweight refractory aggregates-containing castables.*

**Results of microstructural investigations**

Photograph showing different regions analysed in the SAMPLE A is shown in Fig. 2. This figure shows the sample used for SEM/EDS analysis, and five regions (1 – metal area, 2 – metal area/corroded area interface, 3 – corroded area, 4 – corroded area/non-corroded area interface and 5 – non-corroded area) can be identified from this sample, and investigation of these zones was carried out.

*Fig. 2. Photograph showing different regions analysed in the SAMPLE A. 1 – metal area, 2 – metal area/corroded area*

interface, 3 – corroded area, 4 – corroded area/non-corroded area interface and 5 – non-corroded area.

The cross-section of the corroded chemically-boned bauxite-based castables with phosphate additive (SAMPLE A) was analysed by SEM-EDS. The microstructure of interface between Al-alloy and castables is shown in Fig. 3-4. The chemical compositions the regions 1-5 are shown in Table 3. The microstructure of the region below the slag/refractory interface is shown in Fig. 5. The chemical compositions the regions 1-5 are shown in Table 4.

Figs 3-4 show the SEM images of the slag/refractory interface (from region 2 in Fig. 2). A deep infiltration/reaction zone can be seen below the metal area/corroded area interface. This part exhibits corrosion of both the coarse grains and refractory matrix. The bauxite grains of different sizes still are firmly embedded in the matrix. Moreover, a build-up was adhered to the refractory surface. Here, a high proportion of Mg can be detected using EDS analysis (Fig. 4, Table 3, Spot 3). Thus, the formation of spinel phase in the form of magnesium aluminate spinel ($MgAl_2O_4$) can be confirmed. Since the build-up contains also alumina ($Al_2O_3$), thus it can be considered as corundum-spinel build-up. Spinel was also detected in the region below the contact line (Fig. 4, Table 3, Spot 5). Fig. 5 presents the SEM image of the region below the slag/refractory interface (from region 3 in Fig. 2), where molten aluminium penetration pathway can be distinguished. A high proportion of Al can be detected using EDS analysis (Fig. 5, Table 4, Spot 4).

## CONCLUSIONS

The reduced-density castables containing a highly lightweight aggregates were successfully obtained. These castables showed a better corrosion resistance in contact with molten aluminium than those of dense bauxite-based samples. There was a definite relationship between the type of both aggregates and non-wetting additives, and the corrosion resistance of castables. The chemically bonded sample made of bauxite aggregates and monoaluminium phosphate as an additive exhibits adhesion and extensive penetration zone. The hydraulically-boned samples made of bauxite or lightweight aggregates exhibit superior corrosion resistance. In these two materials barium sulphate or calcium fluoride were used, respectively.

# STEEL CERAMIC COMPOSITES RESISTANT TO LONG–TERM CONTACT WITH MOLTEN ALUMINUM ALLOYS

Piotr Malczyk, Tilo Zienert, Florian Kerber, Jana Hubálková, Gert Schmidt, Nora Brachhold, Christos G. Aneziris

Institute of Ceramics, Refractories and Composite Materials, Technische Universität Bergakademie Freiberg, 09599 Freiberg

## ABSTRACT

The development and evaluation of novel stainless steel-based composites for direct contact with liquid aluminum alloys has been carried out. The Steel Ceramic Composite consisted of 60 vol% 316L stainless steel powder and 40 vol% of MgO or $TiO_2$ ceramic powder. The sample were manufactured using uniaxial pressing and subsequent surface pre-oxidation at 850, 1000 °C for 24 h.

The corrosion resistance of composite was investigated against molten AlSi7Mg0.3 alloy using crucible corrosion tests. The tests were carried out at 850 °C for 24 h and 168 h. The influence of pre-oxidation on the corrosion resistance of the samples was analyzed using XRD and SEM/EDS. The corrosion phases formed in the aluminum alloy were investigated using SEM/EDS/EBSD and PSEM/ASPEX/AFA and included the assessment of aluminum alloy contamination by evaluation of corrosion precipitation content, quantity and size. The sample Steel-MgO exhibited excellent corrosion resistance with negligible contamination of the aluminum alloy.

## INTRODUCTION

Steels are very prone to corrosion during contact with liquid aluminum alloys. The reactivity of steel and their elements with molten aluminum alloys is well known and has already widely been reported. This phenomenon is to some extend used to form hard Fe-Al-based intermetallics on the steel parts for corrosion protection. Nevertheless, during the longer contact with liquid aluminum the rapid dissolution of steel takes part. This dissolution does not only refer to Fe but includes also another steel alloying elements like Cr, Mn, Ni and Mo. It leads to both, the damage of the steel product and the contamination of aluminum, and thus narrows the utilization of steel-based components in the aluminum industry to very short contact with molten aluminum. Even the application of protective coating on steel parts is extending the corrosion resistance of steel for only a short period, as the high affinity of aluminum to oxygen and its very low half-cell potential causes the reduction of most oxides [1-4].

Conventional refractory parts for contact with liquid alloys are based on coarse grained castables. For the aluminum industry it is commonly alumina-mulite with anti-wetting additives reducing the intrusion of the alloy melt in the refractory material. The production process of these widely used refractory materials, including drying and prefiring steps, is very time- and cost-consuming and can be prone to numerous failures through arising internal stresses and presence of micro-cracking. It is also well known, that thermal shock resistance of these castables is insufficient for demanding and rapidly changing conditions of metallurgical processes. Although, the incorporation of thermo-mechanical properties of steel would be very advantageous for refractory applications, it requires the elaboration of sophisticated multi-material components or the development of novel aluminum melt corrosion resistant material.

The beneficial influence of refractory ceramics on the corrosion resistance of Steel Ceramic Composites was already reported by the authors [2]. These composites, due to the presence of steel powder, are characterized by good machinability, advantageous thermo-mechanical properties, higher ductility and in consequence better thermal shock resistance. On the other hand, when carried out correctly, the addition of refractory ceramic powders significantly increases their corrosion resistance to molten aluminum alloys. Weigelt et al. [3] investigated the influence of addition of 10 vol% and 30 vol% of $TiO_2$ and $Al_2O_3$-$TiO_2$ to the CrMnNi TRIP-Steel on the corrosion resistance against molten aluminum alloy after 4h corrosion test. Although the low Ni-steel should exhibit higher stability to the aluminum alloy, no improvement for the Steel Ceramic Composites by application of these ceramic particles on the corrosion resistance against aluminum alloy as well as on the mechanical characteristics after the corrosion tests was reported. Malczyk et al. [4] reported the beneficial influence of addition of 40 vol% of $TiO_2$ to 316L stainless steel on the differential potential arising between molten aluminum alloy and the composite, resulting in the reduction of the corrosion potential. Nevertheless, the chemical reactivity of aluminum in contact with steel hampers the formation of a dual layer electrochemical interface. In order to benefit from electrochemical characteristics of this composite the interface between aluminum alloy and composite should be characterized with sufficient electrical impedance and partial chemical stability for the contact with aluminum. Basing on these conclusions, Malczyk et al. [2] reported very promising results regarding long-term corrosion resistance against molten aluminum alloy with 60 vol% 316L stainless steel and 40 vol% MgO composites after the pre-oxidation of their surface forming corrosion resistant FeO-MgO solid solution phases.

For the investigation of long-term corrosion in alloy melts finger immersion tests and crucible tests are commonly applied. For the immersion tests the contact with liquid aluminum alloy last mostly up to 12 h and use relatively high amount of aluminum. The crucible corrosion tests are characterized by significantly longer testing times with incorporation of a smaller amount of aluminum, giving the opportunity for in-depth analysis of not only the composite but also the aluminum and its contamination. Taking this into consideration, the samples discussed in this paper were investigated using crucible corrosion tests with the 24 h and 168 h contact duration to the molten aluminum alloy. This paper is a complementary work to the already reported newly developed molten aluminum corrosion resistant composites based on steel matrix with addition of both $TiO_2$ or MgO ceramic powders [7, 14]. The study focuses on the influence of the surface pre-oxidation process on the structure of composites and their corrosion resistance against the melt.

## EXPERIMENTAL

For the manufacturing of composite samples, the gas-atomized 316L-FeCr18Ni10Mo3 stainless steel powder (TLS Technik, Bittterfeld-Wolfen, Germany), electrofused MgO < 3 μm, 98% (Refratechnik Steel, Duesseldorf, Germany and TR HP-2 rutile $TiO_2$ (Sachtleben Chemie, Duisburg, Germany) were used. The composites consisted of 60 vol% of 316L steel and 40 vol% of ceramic powder, MgO or $TiO_2$ respectively.

Samples were pressed into prismatic and cylindrical samples with the aid of a uniaxial press (Rucks, Glauchau, Germany). The prismatic samples used for investigation of pre-oxidation had dimensions of 7 mm x 7 mm x 70 mm, whereas the cylindrical corrosion tests samples had diameter of 50 mm and height of 50 mm. For the pressing procedure two degassing steps at 30 MPa and 60 Mpa for 1 s were applied. The consolidation pressure of pressing was performed for 3 s at 100 MPa. After the pressing, all samples were dried in a convection drying oven at 40 °C for 24 h and

subsequently at 110 C for 24h. The cylindrical samples were hand drilled to prepare cylindrical crucibles with wall thickness of 7 mm and crucible depth of approx. 42 mm.

The binder removal was carried out in a debinding furnace (Xerion Berlin Laboratories, Berlin, Germany) with heating rates of 2 K·min⁻¹ to 200 °C, and 2 K·min⁻¹ from 200 °C to 500 °C, holding time of 30 minutes at 500 °C and cooling rate of 0.5 K·min⁻¹. The samples were sintered at 1350 °C for 2 h using sintering furnace with graphite lining (Xerion Berlin Laboratories, Berlin, Germany) under argon atmosphere, with heating and cooling rates of 5 K·min⁻¹. After the sintering, the 316L40MgO samples had 21.0% open porosity and 4.75 g·cm⁻³ bulk density, whereas 316L40TiO2 samples had 7.5% open porosity and 5.78 g·cm⁻³ bulk density – measured using an AutoPore V mercury intrusion porosimeter (Micromeritics, Unterschleissheim, Germany). The mean value of linear sintering shrinkage was 4.0% and 8.8% for 316L40MgO and 316L40TiO2, respectively.

To carry out the surface treatment, samples of both composite materials were split into two groups, which were pre-oxidized in two different temperatures – 850 °C and 1000 °C. The pre-oxidation was performed for 24 h with 10 K·min⁻¹ heating and cooling rate.

For the investigation of the influence of pre-oxidation on the phase formation at the surface of both composite materials the SEM/EDS aided X-ray diffraction (XRD) experiments were carried out. The measurements were performed on polished cross-sections of prismatic samples. By using divergence slit measuring 1/32°, a narrow area of approx. 0.3 mm × 10 mm was irradiated. The irradiation area was placed parallel and in the nearest vicinity to the sample surface, in order to investigate only the pre-oxidized part of the sample. The experiments were performed with a Bragg-Brentano geometry and with Cu-K$_\alpha$ radiation between 25° and 100° 2Θ using Empyrean DY1946 XRD diffractometer (Malvern Panalytical, Kassel, Germany). The phase analysis of the oxidized part of the composite samples was done using Rietveld analysis with the aid of the SEM/EDS microscopy analysis of the irradiated surface.

Static crucible corrosion tests were performed in a laboratory furnace (Nabertherm, Bremen, Germany). Pre-oxidized crucibles with prepared aluminum alloy inside were placed together in the furnace and heated up to 850 °C. The heating and cooling rate was 10 Kmin⁻¹. After reaching 850 °C the crucibles with molten aluminum alloy were held for 24 h or 168 h at this temperature. The 24 h crucible corrosion test was performed on the samples pre-oxidized at 850 °C only, whereas the longer 168 h test was performed on both 850 °C and 1000 °C pre-oxidized crucibles.

The evaluation of the crucibles after the corrosion tests was performed using images assembly of confocal laser scanning microscope (LSM) micrographs using Keyence VK/X-1000 laser scanning microscope with multifile analyzer (Keyence, Neu-Isenburg, Germany) as well as by SEM/EDS microscopical analysis performed using the XL 30 scanning electron microscope (Philips, Eindhoven, Germany). The analysis of the aluminum alloy after the crucible corrosion tests was performed on selected samples exhibiting sufficient corrosion resistance against aluminum melt. This test was carried out using ASPEX PSEM eXpress (FEI, Delmont, PA, USA) with automatic feature analysis (AFA) focusing on area fraction and composition of corrosion precipitations present in the solidified aluminum alloy after the corrosion tests.

## CONCLUSIONS

The steel ceramic composites with addition of TiO$_2$ and MgO have been successfully developed and the influence of their pre-oxidation performed for 24 h at 850 °C and 1000 °C on the structure of the composites surface has been analyzed. The evaluation of their corrosion resistance against AlSi7Mg0.3 aluminum alloy was performed using crucible corrosion test for 24 h and 168 h at a temperature of 850 °C. The investigations revealed formation of favorable protective FeO-MgO solid solution layer for the samples from 316L40MgO composite. Formed FeO-MgO layer was characterized as stable against molten aluminum alloy even for longer contact time with the melt. The best results were obtained in the case of 316L40MgO composite pre-oxidized at 1000 °C for 24 h. This composite was able to withstand 168 h of contact time with molten aluminum alloy revealing no significant damage of the surface and only minor contamination of the aluminum melt. The contamination of the alloy originated mainly from dissolved $(Fe,Cr)_3O_4$ and $(Fe,Cr)_2O_3$ phases from the composite surface. There are reasonable presumptions that, after dissolution of these phases, no further corrosion of the composite will be observed.

Although the 316l40TiO2 composite was able to withstand 24 h corrosion test with molten aluminum alloy, its protective layer, consisting mainly of mentioned Fe-Cr-O phases, dissolves in longer contact times with the melt leaving the composite exposed for further corrosion. Therefore, the 316L40TiO2 composite was not able to withstand the 168 h contact with molten aluminum alloy.

The analysis of the surface of the pre-oxidized 316L40MgO samples revealed the presence of phases with high Si-content. These Si-containing phases were placed at the boundary between the steel particle and the MgO particle or transforming MgO-FeO solid solution. The phase is based on the MgO-FeO-SiO$_2$ system, with Ni and Cr in its structure. It is assumed that this phase may remain partially liquid during the pre-oxidation process. It was concluded that the Si-containing boundary phase is responsible for diffusion of Fe-O from the steel particles during the pre-oxidation process into the MgO structure facilitating the transformation of MgO into corrosion resistant MgO-FeO. It was also revealed that the presence of this Si-containing phase led to the trapping of Ni-containing steel residuals (encapsulating Ni-Fe phase) in the structure of oxidized MgO-FeO solid solutions. This successfully hampered the contamination of aluminum alloy by detrimental Ni diffusion.

## ABSTRACT

The pressure drop of a ceramic foam filter is an important characteristic indicating the resistance to fluid flow through the filter. Filtration experiments have shown that the filtration efficiency increases with decreasing functional pore size, however, this improvement comes at the cost of a higher pressure drop. Furthermore, trials with increased roughness of the filter struts showed an improved filtration behaviour. In order to compare these two measures with respect to their efficiency, i.e., in terms of filtration per pressure drop, the sensitivity of the pressure drop with respect to surface roughness needs to be known. In the study, the pressure drop of ceramic foam filters was measured for different functional pore sizes, porosity, and surface roughness with a water-based test facility at NTNU in Trondheim, Norway. The flow velocity was varied in the range of 0.6 - 80 cm/s.

## INTRODUCTION

Ceramic foams are used in the area of metal melt filtration for conditioning the melt flow and the removal of non-metallic inclusions [1]. For an existing industrial casting process, most of the influencing parameters are difficult to adjust, except for the parameters of the filter, which can be configured easily. Hence, efforts to improve filtration efficiency are focused on the parameters of the filter. Most geometrical features of filter structures that are beneficial for filtration (e.g., high ppi (pores per inch) number, low porosity, or presence of closed windows) are associated with an increased pressure drop. A higher pressure drop is detrimental to the financial viability and operational reliability of the filtration process. Such filters demand a higher pressure head or pumping power to maintain a desired flow rate. The junior research group PurCo funded by the BMBF (Federal Ministry of Education and Research) do research to understand whether the enhancement of filter surface roughness for improved filtration is advantageous with regard to the pressure drop, its influence on the flow resistance has to be understood. While the effect of the ppi number on the filtration efficiency [2] and pressure drop [3] has been extensively studied, the effect of filter roughness on flow resistance has not yet been reported for CFFs. To investigate the effect of surface roughness on the pressure drop during the flow of liquid metals through CFFs and to assess its magnitude compared to other geometry modifications, an experimental study using CFFs with different surface roughness, porosity, and ppi number was conducted. In the present study, the pressure drop experiments were performed using water instead of liquid metal. After dividing the pressure drop dp by the sample thickness, the pressure gradient dp/dx was obtained.

## MATERIALS AND METHODS

Ceramic foams made of alumina ($Al_2O_3$) with sintered sizes of length 50 mm, width 50 mm, and height 20 mm were prepared for the present study. The sintered $Al_2O_3$ skeleton foams were coated with the combined dip centrifugation procedure with different slurries (see Table 1) to obtain different foam surface roughness. The slurry 33 µm and slurry 70 µm are named according to the $d_{50}$ of the raw

material with the largest particle size. The filters coated with these slurries were labelled in the same way – reference filter, filter 33 µm, and filter 70 µm.

Tab. 1: Composition of the coating slurries for generating different foam surface roughness (* based on the sum of solids)

| | Slurry reference | Slurry 33 µm | Slurry 70 µm |
|---|---|---|---|
| $Al_2O_3$ CT 9 FG $d_{50}$=5 µm (Almatis. Germany) (mass%) | 33.3 | | |
| $Al_2O_3$ CT 3000 SG $d_{50}$=0.8 µm (Almatis, Germany) (mass%) | 33.3 | 50 | 50 |
| $Al_2O_3$ T60/T64 -45µm (Almatis, Germany) m(mass%) | 33.3 | | |
| $Al_2O_3$ P6 $d_{50}$=33 µm (Almatis, Germany) (mass%) | | 50 | |

The pressure drop was determined using a water-based test facility at the Norwegian University of Science and Technology (NTNU, Trondheim, Norway). A filter holder made of acrylic glass was used to keep the filter in place in the water channel. For the measurement of rectangular samples, a sample holder with rectangular openings of 47.5 x 47.5 mm² was used per measurement, and two rectangular filters were stacked above each other. The filter holder was connected to a water tank (970 x 670 x 1000 mm³) filled with 500 l of tap water at 16°C by smooth pipes with an inner diameter of 49.8 mm, which extended 1250 mm in both upstream and downstream directions and, thereby, provided a development length of 25 diameters. A vertical multistage centrifugal pump (maximum pressure 10 bar) with an integrated frequency converter (Grundfos, Denmark)) was employed to pump the water. The flow velocities varied between 0.006 m/s and approx. 0.8 m/s by using different valve settings (low flow velocities) and different power levels of the pump (high flow velocities). The flow velocity was indirectly determined from the mass gain using a balance (Flintab, Germany) that recorded the mass of the water, which was collected at the outlet with an interval of 1 s. Once 20 measurements were recorded, the mass flow rate ṁ (kg/s) was calculated, and the corresponding velocity u was determined.

## RESULTS

Figure 1 shows the variation of pressure gradients with velocities for rectangular ceramic foam filters with different ppi numbers, ranging from 10 to 40 ppi, whereby the porosity of the filters was established to be between 75.2% and 78.5%. The determination of the pressure drop was repeated at least once, whereby the stacked filters were removed and repositioned between measurements. The measurements show good repeatability, and significant differences in pressure drop values between different ppi numbers were obtained. Overall, it was established that the pressure drop was

higher for higher ppi numbers. This is an expected result and is in accordance with various publications [2, 3].

*Fig. 1: Pressure drop independence of the superficial velocity for ceramic foam filters of different ppi numbers*

The influence of the filter porosity on the pressure drop was also investigated for 40 ppi filters, Figure 2. The filter porosity of the stacked filters proved to vary between 72.8% (95 g) and 79.7% (70 g). The obtained differences in the pressure drop are believed to be a result of the interlinking of the pressure drop and the filter porosity. For the lower filter porosities, the pressure drop is higher, as the higher strut volume present in these filters acts as a flow resistor. However, it is notable that the obtained pressure drops for CFFs with 40 ppi, of higher filter porosities, i.e., 75%, 79%, and 80%, are relatively close to each other.

*Fig. 2: Pressure drop independence on the superficial velocity and filter porosity of 40 ppi samples*

In comparison, the lowest porosity of 73% (95 g) possesses a significantly higher pressure drop. This is believed to result from the higher proportion of closed pores with decreasing filter porosity. Overall, the significant influence of filter porosity on the filter performance is clearly shown by the presented experimental data.

Therefore, it must be taken into account during the investigation of the effect of filter roughness The pressure drop independence on the surface roughness was measured for 40 ppi (Figure 3) filters, and showed only small differences between the obtained data for the reference filters and the filters with rougher surfaces.

However, the difference was established to increase with an increasing superficial velocity of the fluid medium (water). The pressure drop differences between the reference filters and the filters with rougher surfaces proved to be significantly lower than the differences obtained between the different ppi numbers and filter porosities.

*Fig. 3: Pressure drop independence on the superficial velocity of 40 ppi filters with different surface roughness*

Further research will be conducted considering the significance of the observed differences. It is, however, notable that the pressure drop of the 33 μm and 70 μm filters were almost the same even if the grain distribution at the surface was different. The 33 μm filters had small but homogenously distributed grains at their surface whereas the 70 μm filters had larger particle sizes at lower numbers.

## CONCLUSIONS

The main objective of the present study was to assess the effect of the surface roughness of ceramic foam filters on the pressure drop compared to other geometrical modifications known to promote filtration. This was accomplished by measuring the variations of pressure gradients with respect to velocity, using a water-based test facility for filters with different ppi numbers, porosities, and surface roughness. The obtained values of the coefficients are in agreement with existing literature data for similar ceramic foam filters and showed the expected trends with respect to the influence of the ppi number and porosity. The surface roughness was, however, found to have only a minor impact on the pressure drop and the permeability coefficients.

## ABSTRACT

Magnesia (MgO)-chromite ($MgCr_2O_4$) spinel-based refractories are applied as lining materials in copper and nickel flash smelting furnaces due to their excellent durability against thermal shocks, heat, and melt erosion forces. In smelters, the refractories experience high temperatures but also thermal gradients due to the cooling of the walls. In addition, the refractories are subjected to an aggressive gaseous environment on the gas-space side with more than 40 vol.% of $SO_2$. For optimal lining performance, more light needs to be shed on the interactions between the refractory and the smelter atmosphere, for example, the reaction mechanisms of refractory wear need to be understood. This work analyzed and compared the unused and reacted genuine refractories from a nickel flash smelting furnace to identify the reactive species and define the reaction mechanisms. The characterization was carried out with SEM-EDS, μ-CT, and XRD. The unused magnesia-chromite refractory had a two-phase microstructure consisting of MgO and $(Fe,Mg)(Al,Cr)_2O_4$ spinel. Compared to the unused material, the reacted refractory was denser and contained several zones with dissimilar chemical compositions, likely driven by the thermal gradient. For example, the hot zone of the refractory was depleted in MgO, whereas sulfur-containing species were identified deeper in the material, towards the cooled external wall of the smelter. Furthermore, the thermal gradient affected the inward diffusion of gaseous chemical species from the flash-smelting process, enabling their reaction with some refractory constituents. Interactions with slag revealed slight dissolution and the formation of silicates. The results from the microstructural characterization of the refractories will be presented and discussed. The results lay the basis for future activities: controlled lab-scale experiments and computational modeling of refractory behavior.

## BACKGROUND

Flash smelting refers to the pyrometallurgical processing of base metals, like nickel and copper, and utilizes the internal energy of the feed material for smelting, making the process very energy-efficient. Refractory lining in the flash smelting furnaces is one key enabler of the continuous operation of the process, as it acts as a thermal barrier between the hot smelting environment and the body of the furnace. However, the lining is exposed not only to high temperatures and thermal gradients but also to the smelter atmosphere and, occasionally, molten slag that is carried along the gas flow.

Magnesia-chromite ($MgCr_2O_4$) spinel-based refractories have been widely used as a lining material in smelters. Due to the harsh operation conditions, the lining gradually degrades over time. Plenty of research effort has been put into understanding the interactions between the operation environment and the refractory lining in copper flash smelting furnaces [1,2,3] in order to maximize the lining lifetime. The published results have acknowledged the important role of infiltration into the lining in the degradation process. In turn, studies on the performance of linings in nickel flash smelting furnaces are rare, yet the composition of the gas atmosphere with high $SO_2$ content is deemed aggressive. Previous work [4] revealed that microstructural changes that occurred in the lining during the service life likely originated from interactions between the lining and both the feed material constituents and the gas phase. However, based on purely examining the specimens taken from the operating nickel flash smelting furnace, the exact contribution by each of the components could not be defined. In this work, we report in parallel the results from the characterization of the as-received lining, spent lining from the nickel flash smelting furnace, and controlled laboratory "finger" experiments conducted for the lining specimens subjected to the slag. The results provide novel insights into the interactions between the gas phase in a nickel flash smelting furnace and the magnesia-chromite refractory lining.

## EXPERIMENTAL

The studied material was a magnesia-chromite product of type MCr50, ISO 10081-2, with a given composition of (in wt.%): 59.5 MgO, 19.0 $Cr_2O_3$, 13.5 $Fe_2O_3$, 6.0 $Al_2O_3$, 1.3 CaO, and 0.5 $SiO_2$, with an apparent porosity of 17.0 vol.%. The microstructure of as-received material was analyzed and compared to that of spent refractories from the roof lining of a nickel flash smelting furnace. The characterization was carried out with scanning microscopy (SEM), energy-dispersive spectroscopy (EDS), electron back-scattered diffraction (EBSD), micro-computed tomography (μ-CT), and X-ray diffraction (XRD) methods.

To understand better the effect of the gas phase on the refractory lining, a comparison was done to bricks with a nickel flash smelting slag contact. For this purpose, a so-called finger test was performed. Brick fingers were immersed into the slag at 1450°C and kept there, in an inert atmosphere, for six hours. After the holding period, the fingers were lifted above the melt and allowed to cool freely with the furnace. Afterwards, they were sliced in half and the samples were prepared for microscopy investigation. The main constituents of the slag were 7% MgO, 4% NiO, 31% $SiO_2$, and 52% of iron oxides.

## RESULTS AND DISCUSSION

Based on the XRD and EBSD results, the as-received material consisted of two phases; MgO (magnesia; periclase phase) and $(Fe,Mg)(Al,Cr)_2O_4$ (magnesia-chromite spinel; picotite phase). In SEM images, the former is seen in dark grey contrast, while the latter corresponds to the areas seen in light grey contrast, e.g., Fig. 1. EDS provided the following average compositions for the main phases: chromite ore particles 33% Cr-12% Fe - 14% Mg - 8% Al- 32% O, secondary chromite 28% Cr - 18% Fe - 15% Mg - 7% Al - 32% O, and magnesia 60% Mg – 35% O – 4% Fe – 2% Cr.

Compared to the intact material, the spent refractory was denser and contained several zones with dissimilar chemical compositions. On the process side of the refractory, a deposit layer existed that had constituents from both feed materials and refractory. It had a two-phase structure as presented in Fig. 2. The phase seen darker in the SEM image had an average composition (in wt%) of 32% O, 24% Ni, 20% Mg, 19% Si, and 4% Fe. The lighter phase was richer in metallic elements and lower in silicon consisting of 58% Fe, 19% Ni, and 18% O. No sulfur was detected in the deposit layer. Cross-sectional analysis revealed a noticeable gradient of silicon, with the hot side showing the highest concentration.

The colder part of the refractory had a chemical composition close to that of the as-received material, Fig. 2. However, the microstructure was less porous and the sub-grain surfaces seemed to contain less secondary chromite. The decrease in porosity originated most likely from the formation of $CaSO_4$, which was identified together with the original magnesia and chromite phases. The presence of sulfur inside the refractory indicates that the material is porous enough for the migration of gaseous species. Once inside the material, sulfur has reacted with CaO either as $SO_2$:

$$CaO\ (s) + SO_2\ (g) + \tfrac{1}{2}\ O_2\ (g) \rightarrow CaSO_4\ (s) \tag{1}$$

or as $SO_3$:

$$CaO\ (s) + SO_3\ (g) \rightarrow CaSO_4\ (s) \tag{2}$$

Reaction with Mg is also possible

$$MgO\ (s) + SO_3\ (g) \rightarrow MgSO_4\ (s) \tag{3}$$
and $MgSO_4$ was also detected. Since the molar volume of $CaSO_4$ is roughly three times the molar volume of CaO, the pores are filled through the increase in the internal volume. Despite the formation of $CaSO_4$, no extensive microcracking was seen close to the $CaSO_4$-rich areas. Thus, the formation of $CaSO_4$ alone does not explain the degradation of the refractory material through cracking.

*Fig. 1: A three-dimensional density map (left) with an SEM image and corresponding elemental maps (right). The brighter areas in the SEM image are magnesia-chromite phase and the darker areas are magnesia.*

*Fig. 2: Two example SEM images of the microstructure of a spent refractory; close to the process environment (left) and in the colder end of the refractory (right).*

In slag contact, the refractory finger retained well its shape. However, reactions between the slag and the refractory had evidently taken place, with some slag being attached to the refractory surface, as shown in Fig. 3 The cross-sectional SEM/EDS analyses (Fig. 4) showed that, after slow cooling, the attached slag consisted of four phases: precipitates (that accounted for the majority of the slag structure) seen in light contrast, internal areas within the precipitates seen in light grey contrast, and two different types of areas within final slag, seen in

539

intermediate and dark grey contrast. The average chemical compositions of the phases are presented in Table 1. In comparison to the original slag composition, the precipitate phases dissolved plenty of chromium and aluminum from the refractory. The two types of areas in the final slag contained roughly the same elements as the original slag, yet with dissimilar proportions of magnesium, silicon, and iron, and with some calcium that likely originated from the refractory. It is further emphasized that the interface between the attached slag and the refractory was dense.

Fig. 4: SEM image of the cross-section of slag and slag-refractory interface after the finger test.

Tab. 1: Average chemical compositions of four different phases in the attached slag (in wt.%).

| Phase | O | Na | Mg | Al | Si | K | Ca | Ti | Cr | Fe | Ni |
|---|---|---|---|---|---|---|---|---|---|---|---|
| Precipitates (A) | 27.6 | | 3.7 | 6.2 | 0.7 | | | 0.2 | 17.2 | 39.7 | 5.3 |
| Precipitates, inside (B) | 31.6 | | 15.0 | 8.8 | 2.1 | | | 0.4 | 33.5 | 9.4 | 0.4 |
| Final slag 1 (C) | 40.7 | 0.5 | 1.8 | 6.9 | 27.2 | 0.9 | 3.4 | | 0.2 | 17.4 | 0.4 |
| Final slag 2 (D) | 35.1 | | 15.9 | 0.9 | 18.1 | 0.2 | 0.3 | | 0.4 | 24.7 | 4.4 |

Tab. 2: Chemical compositions measured from neighboring locations from the refractory gas interface.

| Location | O | Mg | Al | Si | Ca | Cr | Mn | Fe | Ni |
|---|---|---|---|---|---|---|---|---|---|
| Light grey (A) | 32 | 15.5 | 8.4 | 2.1 | | 30.4 | | 10.5 | 0.4 |
| Medium grey (B) | 30.3 | 44.1 | 0.6 | | | 5 | | 17.7 | 2.3 |
| Dark grey (C) | 38.5 | 35.4 | | 13.4 | 1.4 | 1.7 | | 7.7 | |

Three phases could be identified in the refractory material close to the slag contact: areas seen in light grey contrast, those seen in medium grey contrast, and finally areas with dark grey contrast. The phase seen in light grey contrast (area A in Table 2) corresponded to the magnesia-chromite phase, with a similar composition to that in the as-received material. The medium grey phase (area B in Table 2) was the MgO phase, yet with somewhat higher iron content than in the as-received condition. Presumably, FeO from the slag had diffused into MgO and formed $(Mg,Fe)O$ solid solution. The dark grey phase (area C in Table 2) contained oxygen and magnesium but was also rich in silicon. Such composition refers to magnesium silicates, possibly $Mg_2SiO_4$ reported in the literature in the connection of slag-refractory interaction in copper anode furnaces [5]. The refractory microstructure was also partially re-arranged: close to the slag-refractory interface, the secondary chromite phase at the grain boundaries seemed to have disappeared and a more uniform distribution of fine chromite precipitates, was observed. The likely reason for this is grain growth due to elevated temperatures rather than the interactions with the slag. Additionally, the refractory microstructure was densified. This may relate to the enhanced diffusion of elements described above. It is also

evident that the reason for densification is different from the one observed in the gas phase refractories, assigned to the reactions with sulfur-bearing gases and the subsequent formation of sulfates. However, in finger tests with slag, sulfur was not present.

Comparing the results from finger tests to those obtained for spent refractories, it is evident that the refractory may dissolve some elements from the slag, such as iron. However, this plays a minor role in the performance of the refractory. In turn, the slag may dissolve some elements from the refractory, like chromium, aluminum, and calcium. This may eventually influence the stability of the phases and contribute to the selection of elements, which are available to react with the gas phase. For example, if Ca from the refractory surface is dissolved in the slag, it is not available to react with the sulfur-containing gas phase to form $CaSO_4$, therefore, other sulfates, such as $MgSO_4$, will be favored. The results also revealed the development of a new phase, namely magnesium silicate, in refractory close to the slag contact. This phase was also occasionally detected in the spent refractory, but we did not detect any further interaction between the silicate phase and the sulfur-containing species.

## CONCLUSIONS

Based on the characterization of as-received and reacted refractory specimens, the following observations were made:

- The structure of a spent refractories was less porous than that of an as-received refractory.
- Thermal gradient clearly affects both the chemical structure and microstructure of the refractory.
- Thermal gradient clearly affects the diffusion of species.
- Even though $SO_2/SO_3$ clearly reacts with Ca and Mg, forming sulfates, other species diffuse into the refractory material as well, and especially as the feedstocks are becoming chemically more complex, the possible effect of these species on refractory degradation should be studied thoroughly in the future.
- Interactions with slag contribute to dissolution of elements from slag to the refractory and vice versa, yet this is foreseen to play only a minor role with respect to interactions with the gas phase. However, the possible transfer of Ca from the refractory to the slag may emphasize the role of Mg as the sulfate-forming species.
- $CaSO_4$ formation alone cannot explain refractory densification, as the same phenomenon is observed in slag contact without the presence of sulfur.
- Refractory densification is not directly related to spalling, since the main macroscopic cracks in the refractory are located elsewhere.

## ABSTRACT

The work is based on the previously published article [1]. In this work, we show the corrosion of novel Cr-free Al$_2$O$_3$-MgAl$_2$O$_4$ refractory material dedicated to the copper industry against PbO-rich copper slags. The FactSage simulations were conducted to reveal possible changes in the phase composition of the corroded material. Corrosion was tested experimentally by pellet and contact corrosion test at 1300ºC. Corroded materials were characterized in terms of phase composition by XRD and microstructure by SEM/EDS. The results showed that the passive corrosion mechanism predominates, with the formation of platelet-morphology PbAl$_{12}$O$_{19}$ and complex spinel (Mg,Fe,Cu,Zn)(Al,Fe)$_2$O$_4$. PbO-richest slag was found the most aggressive towards refractory.

## 1. INTRODUCTION

Copper is one of the most important metals among all non-ferrous metals, both in Poland and worldwide. In 2020, according to the International Copper Study Group [2], Poland was 13. the biggest producer of Cu worldwide in terms of copper mine production, 7. producer in smelted copper production, and 9. producer in refined copper production. Refractories are indispensable materials for the production of copper. They work as thermomechanical linings in all the heating devices for copper refining. According to statistics from the European Ceramic Industry Association [3], refractory materials account for 18.2 % in terms of the total value of the ceramic market in Europe, while 11 % of total refractory production is dedicated to the non-ferrous industry. With increased worldwide demand for copper, also, the raised demand for refractory materials for this industry is predicted. As copper production is very complex (the average Cu content in Polish copper sulfide ores is 1.99 % [4]) numerous refining devices are used, which are lined with refractories, e.g., fluidized-bed furnaces, electric-arc furnaces, converters or anode furnaces. Currently, magnesia-chromite (MgO-Cr) refractories are used in Cu devices, as they exhibit high thermal shock resistance and excellent corrosion and erosion resistance. However, the application of these refractories relates to the formation of hexavalent chromium compounds, which belong to 1. group of carcinogens, as classified by the International Agency for Research on Cancer (IARC) [5]. Hence, new Cr-free materials are sought worldwide [6][7][8][9][10][11]. In this work, we present the corrosion phenomena in Al$_2$O$_3$-MgAl$_2$O$_4$ refractory material, which can be one of the alternatives for MgO-Cr refractories.

## 2. MATERIALS AND METHODS

In this work, industrially-produced alumina-spinel refractory, Al$_2$O$_3$-MgAl$_2$O$_4$ (A-MA) was subjected to corrosion tests by three types of industrial PbO-rich copper slags. The slag samples, designated as S1, S2 and S3, were characterized by different chemical compositions, due to their different origin in three stages of converting process [12].

Equilibria simulations of high-temperature corrosion reactions between test refractory and slags were conducted based on the oxide composition of Al$_2$O$_3$-MgAl$_2$O$_4$ refractory and the composition of each slag S1, S2 and S3. The simulations were conducted applying FactSage thermochemical software version 7.3, using the *Equilib* module and the databases FactPS, FToxid and FTmisc. The applied proportion of refractory to slag was 50:50 g, and the simulation temperature range was 700-1400ºC.

In experimental route, the refractory material was subjected to corrosion tests against S1, S2 and S3 copper slags by powder and contact corrosion test. The pellet corrosion test was performed on powdered, homogenized mixtures of refractory and slag in a mass ratio of 3:1. The cylindrical samples of 20 mm in diameter and 10 mm in height, prepared by uniaxial pressuring under 65 MPa, were heat-treated in an electric furnace at 1300°C in air atmosphere with a heating rate of 5°C/min. After 3-h of soaking at maximum temperature, the samples were cooled down with the furnace, milled to grain size below 63 μm and subjected to XRD analysis. The application of the pellet test, with an increased surface area of a tested system, enabled the investigation of the liquid phase formation upon heating.

In the contact corrosion test, the refractory sample was prepared by cutting the cuboid out of the original material, while the slag sample was obtained by pressing the powdered slag into a cylindrical shape with its height below ½ of the height of the cut refractory. Then, the disc slag sample was placed on a cuboid refractory. The entire system was heat-treated in the electric furnace at 1300°C with a 3-h dwell time. After contact corrosion tests, SEM/EDS analysis was conducted to reveal the compositional and morphological changes at the cross-section of the corroded material.

## 3. RESULTS

### 3.1 Al$_2$O$_3$-MgAl$_2$O$_4$ refractory and corrosive slags

XRF of Al$_2$O$_3$-MgAl$_2$O$_4$ refractory showed that the dominant oxide component in the test refractory was Al$_2$O$_3$ (94 wt. %). The material also contained MgO (5 %) and SiO$_2$ (0.3 %). The rest oxides (Fe$_2$O$_3$ and Na$_2$O and others) constituted about 0.7 %. XRD identified the following phases: Al$_2$O$_3$, β-Al$_2$O$_3$, Mg$_{7.51}$Al$_{16.33}$O$_{32}$, MgAl$_2$O$_4$ and SiO$_2$ (α-quartz).

The microstructure of refractory consisted of Al$_2$O$_3$ grains with their size from 10 μm to even above 1 mm. The matrix of the material was composed of fine-grained spinel. As confirmed by the EDS analysis, it was primarily Al-rich spinel, where Al/Mg ratio was around 2.1, while it is 2.0 in a stoichiometric spinel.
**Fig. 1**. *SEM image of Al$_2$O$_3$-MgAl$_2$O$_4$ refractory material.*

The corrosive media used in the test were copper converter slags S1, S2 and S3, characterized by the various chemical and phase composition. Corrosive slag S1 contained intermediate content of PbO (21 mol. %) and CuO (23 %) and an increased amount of Fe$_2$O$_3$ (14 %). Slag S2 was distinguished by the greatest amount of CuO (51 %), while S3 contained the greatest amount of PbO (29 %). All the slags were characterized by a low-melting nature, with the slag S2 (greatest CuO$_x$ content) melting as first at 680ºC, while S1 at 780ºC and S3 (greatest PbO content) at 800ºC according to FactSage equilibria simulations.

## 3.2 Simulations of high-temperature corrosion reactions

**Fig. 2.** Phase composition changes of $Al_2O_3$-$MgAl_2O_4$ refractory by slags.

Equilibria simulations of $Al_2O_3$-$MgAl_2O_4$ refractory in contact with copper slags in FactSage were shown in Fig. 2. Reactions of refractory under the influence of slag S1 were the least dynamic and produced the lowest amount of liquid phase (Fig. 2a). The intensive increase of liquid slag amount started at 1100°C and was directly related to $PbAl_{12}O_{19}$ phase decomposition (red curve for all slags). $Al_2O_3$, which was released to slag due to $PbAl_{12}O_{19}$ decomposition, was partly grabbed to form solid spinel phase (1100-1200°C) and partly liquid slag. Slag S1 of intermediate composition in terms of PbO (39 %) and CuO (16 %) content, seems the least detrimental for the work of refractory at 1120°C.

## 3.3 XRD after pellet corrosion

**Fig. 3.** Changes in phase composition of $Al_2O_3$-$MgAl_2O_4$ refractory by copper slag.

After pellet corrosion at 1300°C for 3h, $Al_2O_3$ was still the most abundant phase after corrosion (Fig. 3). The greatest decrease in alumina content was identified for slag S2. This sample contained the greatest amount of complex spinels, including ($Mg_{8.11}Al_{4.76}Fe_{1.12}O_{32}$-14%, $Cu_{0.08}Mg_{7.92}Al_{16.08}O_{32}$-19%). Spinel with copper ions was present only in sample with slag S2 (greatest Cu content). This sample also contained the greatest amonut of Pb, Ca, Al-silicates. Slight amounts of Cu were present in a form of $Cu_2O$ (0.8 %) and CuO (1.3 %).

## 3.4 SEM/EDS after contact corrosion

Fig. 4, Fig. 5 and Fig. 6 present microstructure from hot face to cold face of cross-sectioned $Al_2O_3$-$MgAl_2O_4$ refractory after 3h-contact corrosion at 1300°C corroded by slag S1, S2 and S3, respectively. Refractory was penetrated by slag which was liquid at the tested temperature. This penetration was initiated via open pores of refractory containing 18 % open porosity. The open pores present in the refractory material facilitated the diffusion of the ions as they increased the exposed surface area to corrosion reactions.

**Fig. 4.** SEM images of $Al_2O_3$-$MgAl_2O_4$ refractory after corrosion by slag S1.

**Fig. 5.** SEM images of $Al_2O_3$-$MgAl_2O_4$ refractory after corrosion by slag S2.

**Fig. 6.** SEM images of $Al_2O_3$-$MgAl_2O_4$ refractory after corrosion by slag S3.

543

The chemical composition of all the phases in corroded samples was attached in Tab. 1. After corrosion it was observed that the slag infiltrated mostly the spinel matrix at the hot face of refractory, which was seen for all slags. Interestingly, the newly formed spinel phase - crystallized out of the liquid phase - accepted numerous slag components into its structure, mostly di- and trivalent ions like $Cu^{x+}$, $Fe^{x+}$, $Zn^{2+}$, $Ni^{2+}$. This phenomenon allowed the material to partly inhibit further diffusion of aggressive components towards the inside of the refractory. The new spinel of multicomponent composition $(Fe,Cu,Mg,Ni,Zn)(Fe,Al)_2O_4$ most abundantly occurred at the contact zone (Fig. 4a, Fig. 5a, Fig. 6a).

The grains of corundum absorbed comparable amounts of Pb and Ca of about 2.5 %, which can be seen by the brighter colour of some $Al_2O_3$ grains (Fig. 4d, Fig. 5e, Fig. 6e). This phenomenon initiated the formation of new, platelet-morphology crystals which were clearly seen for all the slags, in Fig. 4b (S1), Fig. 5b (S2), Fig. 6b (S3). The average thickness and length of these small crystals were 1 and 10 μm, respectively. The numerous EDS analyses confirmed its relatively stable chemical composition, represented by Al (about 44 %) and comparable amounts of Pb and Ca (about 8 % as a sum) as shown in Tab. 1.

**Tab. 1.** *EDS analysis in selected microareas of refractory sample corroded by slag S1, S2 and S3, corresponding to Fig. 4, 5 and 6, respectively.*

| Name | Phase | Chemical composition, mol. %* | | | | | |

P-PbO, A-$Al_2O_3$, S-$SiO_2$, C-CaO, *rest to 100 % is oxygen.

Slag S3 of greatest PbO content (51 %), infiltrated the refractory $Al_2O_3$-$MgAl_2O_4$ mostly, evidenced by the largest amount of bright-colour slag in the hot, middle and cold face of the sample, as shown in Fig. 6. In the area of the hot face, corundum grains were significantly dissolved by the slag, as the nearer to hot face the smaller alumina grains were observed (Fig. 6a).

In the middle part of all the samples additional Pb, Ca aluminosilicate phase of needle-like morphology, designated as PACS, crystallized within the glassy slag phase. This was the non-stoichiometric ternary phase from the system PbO-CaO-$SiO_2$.

Glassy silicate slag in the corroded samples was composed of multiple elements, including Al, Pb, Ca, Cu, As and Zn (Tab. 1). Cu did not diffuse into cold face, as spinel in this zone was of original composition (Mg-Al-O) with no other elements observed in the composition. Infiltration of Pb nearby $Al_2O_3$ grains was also confirmed, mostly for S1 and S3.

# 4. DISCUSSION

The refractory $Al_2O_3$-$MgAl_2O_4$ was composed mainly of corundum (α-$Al_2O_3$) and magnesia aluminate spinel ($MgAl_2O_4$, $Mg_{7.51}Al_{16.33}O_{32}$) with amounts of 77 % and 23 %, respectively. The microstructure of the material covered the large alumina grains located among the fine-grained Al-rich spinel matrix. The refractory was characterized by the bulk density of 3.1 g/cm³, while its open porosity reached 18.4 %. The typical Cr-containing magnesia refractory possesses a density of 3.3 g/cm³ and open porosity in the range of 14-17 % [13].

The fastest increase in liquid slag amount was observed for S3 of the greatest PbO-content, which is demonstrated in Fig. 7a,b. The amount of liquid phase for S3 raised from 700°C, with a maximum at 820°C reaching 0.3 g/°C. At 1120°C it reached the second maximum of 1g/°C. S1 possessed a similar maximum with 0.9 g/°C at the same temperature of 1120°C. Corrosion by S2 exhibited the lowest but most dynamic changes in a liquid phase formation with peaks at 1040°C (0.4 g/°C), 1120°C (0.3 g/°C) and 1240°C (0.4 g/°C).

**Fig. 7.** a. Change in amount of liquid slag vs. T, b. change in the liquid slag amount at every 1°C, in the system refractory - copper slag.

Up to 1100°C, the formation of the liquid phase was the result of various silicates and aluminosilicates decomposition. Above about 1100°C, it was directly connected with the decomposition of $PbAl_{12}O_{19}$ (PA6, magnetoplumbite-like structure, hexagonal plate morphology). This is confirmed for all the slags, as the liquid phase started to be greatly enriched with PbO and $Al_2O_3$ from about 1100°C [1]. Decomposition of $PbAl_{12}O_{19}$ was also evidenced by SEM/EDS as the new, platelet-morphology corrosion product was characterized by Al/(Pb+Ca) ratio of 6.0 for S1 and 5.8 for S3 (Ca was assumed to substitute Pb, as $r_{Ca2+}$=100 pm and $r_{Pb2+}$=108 pm). PA6 was formed due to a reaction between PbO from slag and $Al_2O_3$ from refractory acc. to reaction (1):

$$PbO_{(slag)} + 6Al_2O_{3(refractory)} \rightarrow PbAl_{12}O_{19} \quad (1)$$

PA6 is one of three phases existing in the system PbO-$Al_2O_3$ acc. to [14], namely, PbO·6$Al_2O_3$ (PA6), PbO·$Al_2O_3$ (PA), and 2PbO·$Al_2O_3$ (P2A). PA6 melts the highest (>1000°C) among the rest of PA and PA2.

The PACS needle-morphology phase revealed at SEM images for all the slags is most probably the solid solution phase between two phases $C_2PS_3$ - $C_2P_3S_3$ from the system PbO-CaO-$SiO_2$, in which Si is partially substituted by 31 % larger Al ($r_{Si4+}$=32 pm, $r_{Al3+}$=42 pm) [15]. The three ternary phases exist in this system PbO-CaO-$SiO_2$ ($C_2PS_3$, $C_2P_3S_3$, $CP_8S_6$) [16].

The second interesting observation is that selected ions from the slag (Cu, Fe, Ni, Zn) are prone to interact with the starting refractory components of $Al_2O_3$ and $MgAl_2O_4$ and form secondary multicomponent spinels acc. to reaction (2) and (3):

$$Al_2O_{3(refractory)} + CuO_x + FeO_x + NiO + ZnO_{(slag)} \rightarrow (Mg,Fe,Cu,Zn)(Al,Fe)_2O_4 \quad (2)$$

$$MgAl_2O_{4(refractory)} + CuO_x + FeO_x + NiO + ZnO_{(slag)} \rightarrow (Mg,Fe,Cu,Zn)(Al,Fe)_2O_4 \quad (3)$$
Spinel phase was confirmed in FactSage simulations, mostly in S1 and S3-corroded samples. Also, spinel phase was identified experimentally by XRD in samples after the powder test (closest to equilibria simulations). SEM/EDS analysis confirmed this finding, as demonstrated in Fig. 4a, 5a, 6a. Especially, this complex spinel

544

crystallized out of the liquid slag in the contact zone of the material. In general, spinel-structure compounds tend to crystallize in conditions of fast cooling, which is evidenced by the presence of spinels in meteorites [17]. Thus, the formation of spinels is favoured in a copper converter which works in a periodic work system, including loading, converting and unloading. This phenomenon partly blocks the slag ions against further penetration towards the inside of the refractory. The new dense spinel layer formed at the top of the test material which indicates that, the spinel phase can be potentially beneficial to improve the protection of refractory against progressing infiltration of specific ions which are present in the copper converting slag, like $Cu^{x+}$ or $Fe^{x+}$. Corrosion studies conducted previously for MgO-chromite refractories showed that, if Cu is present in the slag, it rather diffuses to MgO than to chromite spinel [18][19]. According to the phase diagram $MgO-CuO_x$ [20], the maximum solubility of $CuO_x$ in MgO is 20 % at 1050°C, and it lowers with the increased temperature up to 10 % at 1200°C and 7 % at 1300°C, with the latter temperature corresponding to the typical temperature in Cu processing devices. As can be seen from this work, Cu is not dissolved in $Al_2O_3$.

Moreover, the formation of complex spinels increases liquid slag viscosity and inhibits infiltration of the refractory. Also, precipitation of the needle-morphology PACS phase out of the liquid slag additionally increases viscosity at high temperatures, which has a dampening effect on slag penetration. In comparison to recently tested $MgO-Cr_2O_3$ refractory [18], in this work the slags penetrated significantly, but only part of the material.

In summary, the corrosion mechanism of $Al_2O_3-MgAl_2O_4$ refractory by Pb-rich copper slag (visualized in Fig. 8) can be described as follows: **1.** Entering the liquid copper slag into refractory via open pores, **2.** Penetration of refractory grain boundaries by the liquid slag, **3.** Formation of new products due to reaction between refractory and slag components, namely, attack of $Al_2O_3$ by PbO resulting in the formation of platelet-morphology $PA_6$, needle-morphology solid solution phase from the system $C_2PS_3$ - $C_2P_3S_3$ and complex spinel phase $(Mg,Fe,Cu,Zn)(Al,Fe)_2O_4$. This confirms mostly passive corrosion of $Al_2O_3-MgAl_2O_4$ refractory, resulting in the formation of new products which block diffusion of aggressive ions ($Cu^{x+}$, $Pb^{2+}$, $Fe^{2+}$) towards further zones of refractory.

*Fig. 8. Corrosion mechanisms in the system $Al_2O_3-MgAl_2O_4$ refractory - PbO-rich copper slag.*

## 5. CONCLUSIONS

Passive corrosion mechanism predominates in the system $Al_2O_3$-$MgAl_2O_4$ – copper slag. XRD and SEM/EDS showed the formation of a complex spinel phase, via the incorporation of aggressive ions from slag ($Cu^{x+}$, $Fe^{x+}$, $Zn^{2+}$, $Ni^{2+}$) into the original spinel phase in a smart matrix, formation of platelet-morphology $PA_6$ and needle-morphology transitional phase from the system $C_2PS_3$ - $C_2P_3S_3$.

## ABSTRACT

In the present study carbon-bonded alumina filters, have been investigated as a potential filter material for filtration of aluminium. The first time, short- and long-term pilot scale filtration trials were conducted, and the filter behaviour during filtration of aluminium alloy was determined by the use of PoDFA (Porous Disk Filtration Apparatus) for the short-term trials and LiMCA (Liquid Metal Cleanliness Analyzer) for the long-term trials with wrought alloy 6xxx aluminium. All applied filters were also investigated post-mortem by SEM (Scanning Electron Microscopy) analysis. Furthermore, sessile drop experiments with capillary purification were performed to evaluate the wetting behaviour.

## INTRODUCTION

The filtration of metal melt with ceramic foam filters is state of the art since the 1960s. Ceramic foam filters used for the filtration of aluminium and aluminium alloys are typically made of alumina ($Al_2O_3$) or silicon carbide (SiC). In comparison, for the filtration of steel melts ceramic foam filters predominantly based on zirconia ($ZrO2$) or carbon bonded alumina ($Al_2O_3$-C) are industrially applied. $Al_2O_3$-C is a refractory material with a low thermal expansion, negligible sinter shrinkage and improved slagging resistance caused by the low wetting (high contact angle) between carbon bonded alumina and metallic melts. The main drawback of $Al_2O_3$-C is the low resistance against oxidation at high temperatures. $Al_2O_3$-C materials are comprised of alumina, carbon fillers (e.g. carbon black and graphite) and carbon binders (e.g. pitch, tar, or phenolic resin) as well as appropriate additives [1]. The aim of this study was to test the suitability of $Al_2O_3$-C filters for the aluminium melt filtration. Furthermore, the wetting behaviour between aluminium and $Al_2O_3$-C was examined with the help of different test setups of sessile drop measuring devices. The sessile drop technique is often used due to the relatively simple experimental setup. The testing procedure comprises the placing of a piece of metal on the substrate and subsequent heating in a furnace. During the heating and dwelling time, the metal drop shape is recorded and analysed [7].

## MATERIALS AND METHODS

The measurement of the contact angle was conducted using bulk substrates in form of tablets having a diameter of 10 mm and a height of 6 mm prepared by uniaxial pressing.

Three types of sessile drop tests were conducted
- conventional sessile drop test and
- sessile drop test with capillary purification unit
- simplified sessile drop test with capillary purification unit

The conventional sessile drop test was performed at a high-temperature tube furnace with a high vacuum and an inert gas system (Carbolite Gero, Neuhausen, Germany) at the Institute for Nonferrous Metallurgy and Purest Materials (TU Bergakademie Freiberg, Germany). The aluminium alloy AlSi7Mg (Trimet Aluminium, Essen, Germany) was cut to masses between 90 mg to 95 mg, thereafter, placed on the substrates ($Al_2O_3$-C 800 °C and $Al_2O_3$ reference) at room temperature and positioned in the furnace. Before starting the heating procedure with 350 °C/h to the temperature of 950 °C, the furnace was evacuated to reach a pressure of $p \leq 1.5 \cdot 10^{-5}$ mbar. After a dwell time of 180 min, the pressure of $p < (2.8 \pm 0.4) \cdot 10^{-5}$ mbar was achieved.

For the evaluation of the contact angle $\theta_{cal}$, following equation valid for small droplets (m < 100 mg)

$$\theta_{cal}=2 \arctan(2h/d) \qquad (1)$$

was used [3]. The height h and the diameter d of the aluminium droplet were read off from the digital images recorded with a digital camera (The Imaging Source, Bremen, Deutschland).

The sessile drop tests with capillary purification unit were carried out at the Krakowski Instytut (Krakow, Poland). The aluminium alloy AlSi7Mg (Trimet Aluminium AG, Germany) was melted in a graphite syringe separately from the $Al_2O_3$-C substrate. At a temperature of 730 °C and a pressure $p < 1 \cdot 10^{-5}$ mbar, an oxide-free droplet was placed on the substrate. The shape of the drop was recorded by high-resolution CCD camera with a rate of 100 images per minute.

In the third test, a simple sessile drop setup with a dropping unit made off boron nitride (Henze Boron Nitride Products AG, Germany) was used. The dropping unit consists of a hopper for the melting of aluminium and a steel plunger pulling the melted aluminium through a bottleneck to retain the oxide skin. The hopper filled with a cylindrical piece of Al99.7 (Rheinfelden, Germany) was placed on the substrate and positioned in the hot stage microscope. The kiln was heated with 10 K/min to a temperature of 730 °C with a holding time of 10 min. During thermal treatment, the kiln chamber was flushed with argon to minimize the oxygen level.

For the filtration trials, $Al_2O_3$ skeleton filters coated with $Al_2O_3$-C slurry (compositions see [2]) were used. The coating was applied using a combined dip-spin technique where the $Al_2O_3$ skeleton was immersed completely in the slurry followed by a centrifugation step for the removal of excess slurry. In the next step the filters were sintered at 1600 °C ($Al_2O_3$) or coked at 800°C ($Al_2O_3$-C).

The short-term filtration trials were conducted at the metal foundry Georg Herrmann Metallgiesserei (Muldenhütten, Germany) with the aluminum alloy AlSi7Mg (EN AC-42100) from Rheinfelden Alloys (Rheinfelden, Germany) whereby the aluminum melt comprised 50 % ingots and 50 % scrap (recycled aluminum consisting of solidified feeders and runners) for the introduction of non-metallic inclusions.

The long-term filtration trials were conducted in a pilot filtration line at Hydro Aluminium AS primary aluminum plant (Sunndal, Norway), which consists of a melting furnace, a launder system, a filter box, and a lifting pump. The line is equipped with two LiMCA II units (ABB Ldt., Canada), which allow the continuous monitoring of inclusion number and size in the front and behind the filter box.

For every trial about 8 mT wrought aluminum alloy 6082 (main alloying elements of Si ~ 0.95 %, Fe ~ 0.2 %, Mn ~ 0.6 % and Mg ~0.65 %) were transferred to the melting furnace and circulated in the loop with the help of the lifting pump. Altogether two long-term filtration trials were conducted: one trial with a reference filter (labeled $Al_2O_3$) and one trial with carbon bonded alumina filters labeled as $Al_2O_3$-C. The aluminum melt temperature at the priming procedure was 740°C for both trials.

The employed filters were cut out and embedded in epoxy resin, ground, polished and analyzed with SEM/EDX.

## RESULTS

The contact angles determined with the different procedures possess discrepant results (Table 1). The underlying causes for the differences are manifold: The different testing temperatures, the intended flat deepening on the part of the substrate using the simplified dropping setup, a relative high mass of the aluminum

droplet. The contact angles measured using sessile drop measurement with capillary purification at 730 °C are therefore more reliable.

Tab. 1: Contact angles of the sessile drop experiments

|  | INEMET 950 °C Vacuum | Krakowski Instytut 730 °C Vacuum | IKFVW 730 °C Argon |
|---|---|---|---|
| $Al_2O_3$ | 100 | 108 | 132 |
| $Al_2O_3$-C | 92 | 157 | 132 |

The short-term filtration trial took approximately 16 s and showed an equal filling of the aluminum. The PoDFA index (given in area of inclusions per kilogram analyzed aluminum) yields the sum of total detected inclusions. The lower PoDFA index indicates a smaller number of non-metallic inclusions in the aluminum sample and hence the better is the melt quality. The PoDFA analyses found $Al_2O_3$ films, carbides, magnesium oxide, spinel, refractory material, iron and manganese oxides as well as grain refiners in the castings. The PoDFA indexes of 0.106 mm²/kg (trial 1) and 0.482 mm²/kg (trial 2) of the $Al_2O_3$-C filter samples were half of the PoDFA index of the $Al_2O_3$ reference filter samples [2]. This indicates an improved filtration when using $Al_2O_3$-C filter.

The SEM images of the used filters of the short-term filtration trials show large inclusions consisting of mainly Al, Mg, Si and O captured by the filters.

Tab. 2: PODFA results of short-term filtration trials

|  | PODFA / mm²kg⁻¹ | |
|---|---|---|
|  | Trial 1 | Trial 2 |
| $Al_2O_3$ | 0.246 | 1.06 |
| $Al_2O_3$-C | 0.106 | 0.482 |

The N20 values of the long-term filtration trials of the LiMCA measurements of the $Al_2O_3$ and the $Al_2O_3$-C filter possessed a comparable behaviour before and after the filter box. The N20 values before the filter box decreased at the beginning of the trial until they reached a relatively stable level [4].

Fig. 1: SEM image (BSE) of filter coated with $Al_2O_3$-C used in short-term filtration trials

The N20 values after the filter box showed a decrease at the beginning of the experiment which is a common behaviour observed at other filtration experiments. It is obvious that the N20 values after the filter box possessed a higher standard deviation than the N20 values in the front of the filter. The N20 levels before and after the filter box are comparable for the $Al_2O_3$ and the $Al_2O_3$-C filtration trials. For the stable filtration areas, the filtration efficiency was calculated with 91.2 ± 6.7 % (for the $Al_2O_3$ between 23.1 and 45 min) and 88.8 ± 12.3 % (for the $Al_2O_3$-C between 15 and 25.9 min). So, the filtration behaviour of the two trials is comparable.

*Fig. 2:*
SEM image of $Al_2O_3$-C coating after long-term filtration trial

An intensive SEM investigation of the used filters revealed few typical inclusions captured in the filter.

Furthermore, it becomes evident that the $Al_2O_3$-C coating possessed different structures. Figure 2 shows areas with a very homogenous, dense, and compact coatings with nearly no pores or larger carbon structures. But there are also areas with $Al_2O_3$-C coating with large pores. No dependence on the location of the different structures in the filter was observed. It appears that only thinner areas of the coating have been affected of this phenomenon. EDX analysis implicates that in the denser structures the carbon is partly disappeared and left behind pores or a very dense structure made of mostly alumina particles. The latter is very surprising due to the high temperature needed to compact alumina grains (> 1400°C). The temperature during the filtration trials was not higher than 750°C, i.e., significantly lower than the required compaction temperature.

**CONCLUSIONS**

In the present overview carbon-bonded alumina filters have been investigated as a potential filter material for filtration of aluminum. In the first step, sessile drop test with different parameters were conducted yielding different results regarding the measured contact angle. In the next step, filtration trials were conducted - for the short-term filtration trials a better filtration behavior compared to $Al_2O_3$ reference filters was obtained. In contrast, the long-term filtration trials did not reveal a beneficial filtration effect of carbon-bonded alumina filters regarding the LiMCA results. An SEM analyses disclosed a partial transformation of the $Al_2O_3$-C coating layer from a heterogenous and porous layer into a dense and compact layer.

# APPROACHES TO SOLVING ADVANCED PROBLEMS OF ESTABLISHED REFRACTORY DESIGNS IN NON−FERROUS METALLURGY

Alessio Vezzuli, Angelo G. Vezzuli
EKW Italia S.R.L., Concorezzo MB, Italy

Thomas Heikaus, Daniel Cölle
EKW GmbH, Eisenberg, Germany

**ABSTRACT**

The article outlines exemplary interactions between smelting technology and typical refractory ceramics within the non-ferrous metallurgy. In the context of this, the historical expertise is illuminated, critically questioned and compared with some essential of the more recent findings and resumed. One particular focus is on a comparative presentation illustrated by the specific example of the secondary metallurgy of copper-based alloys.

Thermomechanically complex stress conditions for the installed refractory structures are to be expected due to melting, transporting, but especially due to continuous casting by inductively actuated pouring systems. A contribution to accentuate and selectively illuminate thermally induced stress conditions is the identification of structural "mismatches" of complex linings, which are indicated step by step and are solved and discussed on the approach by applying specific thermomechanical calculations. The aim is to improve a refractory concept for a defined plant technology in such a way that the extrinsic and intrinsic conditions are counterbalanced by the best possible refractory structures, which is the perspective with which the article will conclude.

# 5 REFRACTORIES FOR NON-METAL INDUSTRIES

# CHALLENGES FOR A CEMENT PRODUCER

Dr. Volker Wagner, Heidelberg Materials AG, Heidelberg, Germany

## ABSTRACT

Refractories play a vital role for us as a cement producer. The yearly consumption of bricks and monolithic materials is causing significantly costs. Changing clinker production conditions, caused by continuously increasing alternative fuel rates or new production technologies, are the basis of new refractory developments. Based on a good cooperation between Heidelberg Materials and some refractory suppliers excellent solutions have been verified over the past few years.

However, old and solved problems are always replaced by new challenges. Our plants are looking for a continuous production without any unplanned stoppages. A reliable refractory lifetime predictability for any application area is required. But the tools available are still on a very basic level. So far, the detection of potential damages/pre-damages is not possible at all.

## Sudden unexpected failures

In an ideal world we would know exactly which part of the refractory lining must be replaced respectively repaired during a planned maintenance stop. For example, in the rotary kiln the remaining brick thickness is measured, and based on the wear rate a total lifetime can be predicted. Unfortunately, this is a view on the surface and valid only for certain brick sections. A brick which still looks good might fail shortly after start-up of the kiln, as it is infiltrated heavily by any kind of salts, resulting in the loss of roughly half of the brick. The more alternative fuels we are using, the heavier the degree of infiltration. And here we are not even talking about the additional effect of steel shell corrosion, which is another topic the cement industry must deal with [1].

## Blockages

Modern monolithic materials are showing an excellent behaviour towards the conditions inside the kiln. However, they are fixed with metallic anchors. And the major failure cause is the corrosion of these anchors. During operation we sometimes observe falling blocks in the cyclones, the cooler roof or other areas like for example inlet chamber. The blocks consist of a perfect lining, just the metallic fixation is gone completely.

*Pic. 1: Corroded anchors, roof section*

## Safety Issues

During a planned maintenance stop we always check the remaining refractory lining. It might look good, but we must be extremely careful. Safety nets are nowadays installed in almost all our kilns during inspection. This is done not only to prevent coating dropping down. There is a significant danger of complete monolithic blocks falling as the anchors are severely corroded. Of course, there is another mechanism leading to anchor failures, and that is the formation of σ-Phase, leading to embrittlement.

## What do we need?

Our target is clinker production within a certain timespan without unexpected interruption. This leads to an efficient planning and costs are under control. What is missing are tools which enable us predicting the remaining lifetime of refractory linings. Ideally, we install sensors of any type, which finally give us online information about the status of infiltration, corrosion, and phase transformation.

## CONCLUSIONS

In terms of refractory quality, we acknowledge the developments of the refractory industry. Modern bricks and monolithic materials can withstand the conditions in our production lines quite well. And for all problem areas some special solutions are available. It does not mean that we do not welcome further optimization based on innovative products. But our major problem are unpredictable failures. These failures do not only produce high costs, but they are also a major cause for safety issues. Traditional measures like the identification of remaining lining thickness are still necessary, but they are not sufficient. We need an "online" detection of upcoming refractory failures.

# NEAR–CUSTOMER ENGINEERING MANAGEMENT FOR ADVANCED APPLICATIONS IN THE CEMENT INDUSTRY

Bastian, Vesenberg, Nicole, Schlimm Daniel, Cölle
EKW GmbH, Eisenberg, Germany

Thomas, Weiss, Lennart, Hapke.
IKN GmbH, Neustadt, Germany

**ABSTRACT**

An engaging route to the realization of a technologically advanced alkali-resistant and particularly abrasion-resistant high-temperature material with reliable thermal shock behavior is outlined, from the idea through the development process to the final product. Novel testing methods are integrated into the development, which systematically assist the matrix optimisation of selected refractory castables in a targeted approach. Under implementation of a calculated, widely spread grain size interval, alkali tests at 1100 °C using potassium carbonate and sodium carbonate on the one hand and potassium sulfate and sodium sulfate on the other mark reliable results for the functional stability of the refractory ceramics in corrosive process routines. The design and prototyping of preformed components was used to successively optimize the material properties under real conditions close to the customer. A particular challenge was the adjustment of certain structural properties in order not to lose the resistance of the refractory ceramics to erosively acting particle streams and gases in favor of a robust behavior against abruptly occurring load peaks, for example abrupt temperature changes or locally occurring pressures. For this purpose, a test procedure was developed to test the so-called impact behavior under hot conditions, and both interventions in the bonding system of the refractory material and in construction elements led to improved robustness of impact zones.

The aim of optimizing the material, from an economical point of view in particular, was fulfilled, which was confirmed by the successful application on the customer's plant site. Last but not least, the potential transferability of the product solution to other industries is demonstrated, e.g. in the aluminum industry.

# EFFECTIVE CO$_2$–REDUCTION FOR ROTARY KILN BURNING PROCESSES BY USING ENERGY EFFICIENT LININGS

Hans-Jürgen Klischat*, Holger Wirsing, Peter Groger, Stefan Puntke
Refratechnik Cement GmbH, Göttingen, Germany

## ABSTRACT

The carbon challenge or carbon emission challenge is a major topic especially for cement and lime production, as carbon dioxide is released from the raw material and from the material burning process. To reduce the latter, new refractory lining concepts have been developed by designing a new finer-ceramic microstructure. These novel basic and non-basic brick grades with porosities up to 25% reduce the heat losses due to their exceptionally low heat transfer. All other properties, including refractoriness, strength, structural elasticity, permeability, and thermal shock resistance, are kept at values which are well-proven for the application in refractory rotary kiln linings. Emphasis is also laid on kiln linings which are exposed to increased alkali atmosphere, so silicon carbide containing high alumina bricks are an essential part of this emission- and energy-saving concept. The installation of these new products is as easy as for standard products, no additional effort like two-layer linings is necessary. The results of recent installations show a significant decrease of the kiln shell temperature. The reduction in overall CO$_2$ emission is calculated with approx. 5 kg/t clinker, the thermal energy input at the main burner comes down by 4-5% and the wall heat losses drop by up to 25%, which is enormous considering the already well-matured rotary kiln process. In addition to a lower lining weight, even reducing the necessary operating power, the reduction of 10% in refractory lining material use is responsible for an improved sustainability and reduced carbon footprint not only for the kiln operator, but also for the refractory producer and the environment: carbon challenge accepted.

## INTRODUCTION

At the latest since the first energy crisis in the recent century, high temperature processes required consideration of energy saving to keep the heat within the process, i.e., avoiding its escape to the environment. In the cement industry the effect of CO$_2$ emissions has to be considered, (1) which originates from the limestone and from the burning process. To increase the energy efficiency and reduce the impact of cement production on the environment, several measures have been taken, from the reduction of the amount of clinker in cement and development of technological solutions of the manufacturing equipment to measures on the refractory side, (2). For all these measures it has to be ensured that the cement quality is reliably stable. This paper deals with a novel refractory concept to minimize the energy consumption for cement clinker production.

## OVERVIEW ON CONCEPTS FOR ENERGY SAVING

Since the first oil crisis in the early 1970s, saving energy and improving energy efficiency in industrial (and private) sectors has become important. Especially in the cement industry, the carbon footprint and the reduction of gases presumably responsible for global warming have come more and more into focus, Fig. 1.

Fig. 1: Worldwide CO$_2$ emissions from 1971 until 2019 (in Gt)

The focus was not only laid on energy saving whilst maintaining operational performance, but even more emphasized on emission saving to counteract the harmful effect of CO$_2$ on the climate. Also costs for thermal fuels and their emissions, or for the prevention of emissions, have to be considered, as together with electricity they account for around 50-60% of operational production costs, Fig. 2.

Fig. 2: Cost per ton of CO$_2$ produced (in €)

Therefore, the application of refractories to save energy has quite a long tradition, initially for non-basic refractories. For basic refractories, this was impossible due to technical reasons (a high porosity was connected to a low strength, insufficient for cement kiln applications). Still, several attempts were made to overcome this technical obstacle and develop a system to reduce thermal losses through the kiln shell, Fig. 3, (3).

Fig. 3: Various concepts for thermal insulation of basic lined zones in rotary kilns

Due to typical wear patterns, none of these concepts were successful, as the main requirement – similar performance as standard bricks – could not be achieved reliably. Only in the field of non-basic refractories, several brick grades performed satisfactorily, providing a reliable performance and the ability to reduce the heat losses through the kiln shell.

Due to the high temperatures in the sintering and transition zones and the high thermal conductivity of basic bricks, a specific development was needed to reduce energy consumption and emissions. To provide a wholistic concept and to decrease the emissions to a maximum, also the non-basic lined areas must be emphasized. This would bring advantages in energy and emission saving, CO$_2$ reduction and thus reduction of the carbon footprint, cost, stockkeeping, etc.

## BREAKTHRU IN EMISSION-SAVING REFRACTORIES
### Basic refractories

A major obstacle for the development of bricks is that density and porosity directly influence other properties like strength, elasticity, refractoriness under load etc., usually in a way that prevents

successful installation. Usually, strength and refractoriness were negatively affected when porosity was increased.

To overcome this limitation, a new brick structure, completely different from the ones used up to date, was developed. It is characterized by a fine-grained structure and a porosity in the range between 20 and 25%, up to now unfamiliar to the typical refractory materials for working linings of rotary kilns, Fig. 4.

*Fig. 4: Structure of typical magnesia-spinel bricks and bricks with reduced thermal conduction (ES concept)*

To strengthen the performance and widen the application area, the modulus of elasticity was decreased by an increase of the alumina content, which resulted in a further decrease of alkali susceptibility and ability to deal with mechanical tensions in cement clinker and lime rotary kilns. Porosity and strength are barely influenced by this further structural modification, Fig. 5.

*Fig. 5: Properties of magnesia-spinel bricks with reduced heat transfer*

The successful proof has already been pointed out in [2].

**Non-basic refractories**

Due to the promising results for basic bricks, the so-called ES concept was also applied to non-basic materials. A special challenge were the requirements on these brick types, not only that their thermal conductivity is already lower, but they also have to withstand the chemical and mineralogical attacks taking place in modern rotary kilns fired with large amounts of alternative fuels. This means that the alkali resistance of these materials has to be similar to that of the already used high-performance SiC-containing products, despite their higher porosity and the concomitant higher inner surface.

It was figured out that by careful adjustment of the composition and a special firing regime, the high porosity concept known for basic bricks could be transferred to bricks based on mullite, andalusite, and fireclay as well. Fig. 6.

*Fig. 6: Structure of 60% alumina-SiC bricks and bricks with reduced heat transfer (ES concept)*

All necessary properties for a successful performance were met, while the porosity was adjusted at the required high level and the gas permeability at the required low level, Fig. 7.

*Fig. 7: Various high alumina-SiC bricks with reduced heat transfer*

As a result, density was also significantly lower than for the standard products, while strength levels and refractoriness were maintained.

An examination of the alkali resistance was performed with the well-known cup corrosion or crucible test at a temperature of 1100 °C and with $K_2CO_3$ as corrosive agent, Fig. 8.

*Fig. 8: Alkali resistance of high alumina-SiC bricks with and without application of the ES concept*

The results clearly show the formation of a protective layer that prevents the undesired alkali corrosion reaction.

**Installation in lime rotary kilns**

Kiln shell temperatures (providing a directly measurable parameter) of installations in lime rotary kilns, which include kilns in the pulp & paper industry, show the positive effect of an ES lining. A standard lining consisting of an andalusite working lining and an insulating fireclay lining result in a kiln shell temperature of 247 °C, Fig. 9.

555
*Fig. 9: Reduction of kiln shell temperature in a lime kiln by application of the ES concept*

When exchanging the dense andalusite brick by an ES product, the shell temperature can be reduced to a value of 223 °C. At the same time, the heat loss through the wall is reduced by 17%.

It is well-known that a two-layer lining is susceptible to mechanical influences, possibly caused by a deformed kiln shell, ovality, or lack of skilled workers, as a proper installation is decisive for refractory performance, Fig 10. So, by installing a single-layer lining, compared to a classic double layer lining, the kiln shell temperature can be reduced to 239 °C. This stable single-layer lining still offers the saving of 5% energy.

*Fig. 10: Mechanical destruction of a two-layer lining*

**Conclusion for bricks with high porosity**
Due to the fact that the performance-relevant properties of bricks with high porosity are met, these refractories are currently being installed to qualify their performance, and to probably set a new standard for rotary kiln linings that counteract $CO_2$ emissions and energy losses. As the firing processes in the cement industry with varying raw materials and fuels prevent an experimental proof of the savings, mathematical simulations were performed by the Verein Deutscher Zementwerke, the VDZ (German Cement Manufacturer's association), (4), (5).

**CALCULATION OF THE SAVINGS WITH THE ES LINING**
For this calculation, a BAT (best available technique) state-of-the-art rotary kiln with a production capacity of 5000 $t_{clinker}$/day was chosen, with a single-string 5-stage precalciner and a grate cooler. Its length is 75 m, with a diameter of 5 m. The kiln is fired with a thermal substitution rate of 75% coal dust and 25% mix of alternative fuels. Whereas the kiln is fired with coal dust, the calciner is fired with a combination of coal dust and an alternative fuel mix (fluff, animal meal, mechanically dewatered sewage sludge).
For the calculation, two refractory lining patterns were evaluated.

**Calculation for a kiln with regular conditions**
This type of kiln represents the average of kilns which are not fired with alternative fuels, but with standard gas, oil, coal, or the like.
In the reference lining concept for conventional kiln operation conditions, fireclay bricks and high alumina bricks with 60% $Al_2O_3$ are installed in the calcining and safety zone, Fig. 11.

*Fig. 11: Conventional and ES lining for a kiln with regular conditions*

In the higher thermochemically stressed transition zones and burning zone, basic magnesia-spinel bricks, low iron as well as iron-rich grades (for coating-enhancing purposes) are applied.
In the ES lining concept, the calcining and safety zone are lined with KRONEX® 30 ES and KRONEX® 60 ES. The transition zones and the burning zone are lined solely with the magnesia-spinel brick ALMAG® A1 ES.

**Calculation for a kiln with demanding conditions**
Demanding kiln conditions are characterized by thermochemical influence due to use of alternative fuels and raw materials as well as elevated process requirements as such. Mostly, a mechanical strain influence is present as well, probably caused by kiln shell deformation, ovality, axial distortion, and the like. If there is a need for the installation of a special alkali-resistant AR lining, the use of an emission-saving ES AR lining is the installation of choice, Fig. 12.

*Fig. 11: Conventional and ES lining for a kiln with demanding conditions*

Therefore, a mechanically and alkali-optimized lining concept includes high alumina alkali-resistant brick grades in the calcining and safety zones. In the transition zones and burning zone, basic brick grades are installed.
In the ES AR lining concept, the safety and calcining zones are lined with KRONAL® 50 AR ES, KRONAL® 60 AR ES, and even optimized fireclay KRONEX® 30 ES bricks. The transition zones and the burning zone are lined with ALMAG® A1 ES magnesia-spinel bricks.

**Results for emission savings**
The results for emission and energy saving are exceeding a value of 1% by far, Table 1.
Although this value seems to be not too high, it must be stated that the cement clinker burning process in terms of energy consumption is one of the best optimized processes in the industrial world.

Table 1: Calculated savings by application of the ES concept

| | Regular conditions | ES Concept | Severe Conditions | A1 ES Concept |
|---|---|---|---|---|
| Savings specific energy demand | | 1.8% | | 1.5% |
| Wall losses kJ/s | 11360 | 8832 | 12331 | 9256 |
| CO$_2$ emissions t CO$_2$/t clinker | 0.829 | 0.814 | 0.820 | 0.815 |
| Savings coal t/a | | 3429 | | 2875 |
| Savings CO$_2$ t CO$_2$/a | | 8580 | | 7331 |
| CO$_2$ emissions t CO$_2$/t.m. (for refractory production) | 19.6 | 17.0 | 18.3 | 17.3 |
| CO$_2$ emissions t CO$_2$/t.m. (cement clinker production) | 18022 | 17917 Δ=105 | 18032 | 17934 Δ=98 |

The CO$_2$ emissions are reduced, but also the savings of coal of up to 3500 t/a must be noted, coming along with emission savings of up to 8600 t/a.

From a cost and environmental perspective not only the emissions (including emission certificates) have to be noticed, but also the reduced purchase of coal and CO$_2$ certificates. With its high technology readiness level (TRL) over the all relevant refractory categories (basic and non-basic), the ES concept serves the industry pledge of compliance towards sustainability as well as cost competitiveness.

Overall, installation of products from the ES concept results in significant economic and ecological savings, which cannot be bypassed to meet the carbon challenge.

## CALCULATION OF THE CARBON FOOTPRINT

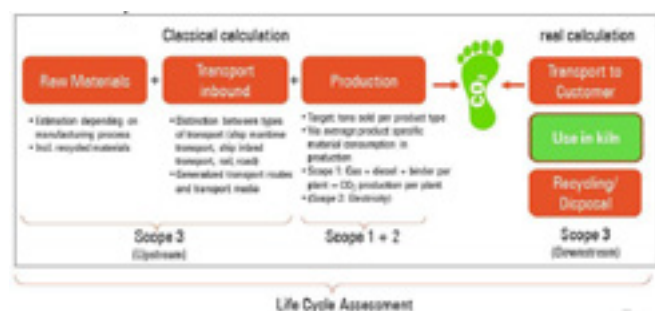
The carbon footprint is a parameter which may describe the emission impact on the environment as a new decisive KPI for the industry. Although it makes sense to have such a figure, it leaves room for misinterpretation and even wrong conclusions. The classical calculation considers the production emissions (Scope 1) as well as energy-related emissions (Scope 2). This usually results in a KPI which is reported as t CO$_2$/t refractory. This figure has to be compared to other figures, but fails miserably when various product groups are compared, e.g., dense refractories with porous materials. It is more meaningful and robust if pieces or linings (or emissions per running meter installed in the case of rotary kilns) are reported. Even more robust are statements when the whole Scope 3 is considered, which includes raw materials (essential for the carbon footprint of refractories) and the use and beneficial performance in the kiln.


*Fig. 12: Definition of scopes for carbon footprint calculation*

While the CO$_2$ emissions per ton are comparable for dense and ES products, it has to be respected that for a given area, much less material is needed for the lining. This keeps the environmentally relevant carbon footprint much lower for ES products, Table 1. Not only the emission for the product is important, but even more the savings which are possible due to its use, as already pointed out in Table 1. A comprehensive overview is given in Table 2, where the savings in weight (contributing to a lower carbon footprint Scope 1, 2, and 3 upstream) as well as thermal conduction (contributing to a lower carbon footprint Scope 3 downstream) are shown.

Table 2: Weight reduction and reduced thermal conduction of bricks according to the ES concept

| | Density g/cm³ | | Thermal conduction W/m·K at 1000°C | | Savings by ES concept | |
|---|---|---|---|---|---|---|
| | ES | Standard | ES | Standard | Weight | Thermal conduction |
| ALMAG ES | 2.68 | 2.9 – 3.05 | 2.1 | 2.9 | 10 % | 28 % |
| ALMAG A1 ES | 2.76 | 2.9 – 3.05 | 2.1 | 2.8 | 7 % | 25 % |
| RETRALUSIT ES | 2.35 | 2.6 – 2.8 | 1.3 | 1.6 | 13 % | 19 % |
| KRONAL 60 AR ES | 2.4 | 2.5 – 2.7 | 1.5 | 2.5 | 8 % | 40 % |
| KRONAL 50 AR ES | 2.37 | 2.35 – 2.55 | 1.5 | 2.0 | 7 % | 25 % |
| KRONEX 60 ES | 2.22 | 2.4 – 2.6 | 1.5 | 1.8 | 11 % | 17 % |
| KRONEX 30 ES | 2.02 | 2.1 – 2.3 | 0.9 | 1.2 | 8 % | 25 % |

This explains the tremendous effect, which can be achieved by the application of the ES concept for refractory manufacturer and user.

CONCLUSION

In a comprehensive way, the following conclusions can be drawn:

- Through the application of the ES concept for refractory brick production and its application in the industry, significant saving of energy and reduction of CO$_2$ emissions is possible.
- Less use of coal and CO$_2$ certificates costs for kiln services can be achieved.
- Due to less material needed for brick production (density!) production becomes more sustainable.
- Brick performance-relevant properties (strength, refractoriness, chemical resistance, elasticity) are maintained.
- Lower weight of bricks facilitates the installation (health & safety aspects).
- Lower electricity costs due to less weight and less necessary cooling of the kiln shell.
- Protection of mechanical aggregates such as main drive and tyres by reduced kiln shell temperature.
- Lining of a two-layer brickwork possible, but not necessary, simplifying installation and reducing cost and installation time.
- Due to high TRL (technology readiness level) over the total refractory application categories, immediately applicable in global scale within the industry.

# ENERGY-SAVING REFRACTORY BRICKS FOR SUSTAINABLE LINING OF ROTARY KILNS

Ufuk Akkasoglu, Nuri Sarioglu

KUMAS Manyezit Sanayi A.Ş., Kutahya, Turkey

## ABSTRACT

Reducing carbon footprint is a significant challenge for energy-intensive industries- including cement and lime- due to the usage of extensive thermal processes in production. One possible way to decrease energy consumption is using an energy-saving lining in which the thermal conductivity is reduced by increased porosity. However, mechanical, chemical and thermal limitations of the rotary kilns should be considered in brick design since porosity will degrade relevant properties. In this study, novel basic refractory bricks with reduced thermal conductivity were developed to reduce kiln shell temperature and hence reduce energy consumption. In this study, a novel energy-saving basic refractory brick with reduced thermal conductivity by induced porosity is developed without compromising the refractoriness as well as mechanical and thermal properties.

## INTRODUCTION

The pursuit of net zero emissions has become a paramount goal in mitigating the impacts of climate change. With the target of achieving net zero emissions by 2050 gaining global momentum [1-3], there is an urgent need to explore sustainable and energy-efficient solutions across various industries. In the field of refractories, which play a vital role in high-temperature applications, the development of advanced materials with improved thermal insulation properties is of great significance.

One such material of interest is MgO-Spinel refractories, which possess excellent thermal stability, corrosion resistance, and mechanical strength, making them suitable for various industrial applications including steelmaking, cement production, and non-ferrous metal processing [4-6]. However, the high thermal conductivity of MgO-Spinel refractories limits their energy-saving potential, leading to increased heat losses and reduced overall efficiency in high-temperature processes.

A possible way to decrease thermal conductivity is to induce porosity in the microstructure. However, thermo-chemical and thermo-mechanical limitations of rotary kilns must be considered since induced porosity will degrade both infiltration resistance as well as thermal and mechanical properties.

There two types are porosity: Open pores and closed pores. Open pores have access to the surface and thus they are prone to the infiltration, while closed pores have no access to the surface and thus they can reduce thermal conductivity without sacrificing the infiltration resistance. Interconnected porosities degrade permeability and thus infiltration resistance. Therefore, non-permeable pores are desired (Fig. 1).

*Fig. 1: Schematic diagram showing the open, closed, permeable and non-permeable pores.*

The literature includes different studies about synthesis of porous aggregates (i.e., $MgAl_2O_4$) to reduce thermal conductivity of the refractories [7-10]. However, the mass production of porous aggregates is hindered due to the complex preparation conditions and significantly higher cost of raw materials involved in the majority of processes. Consequently, this poses considerable challenges to the economic viability of industrial production.

The aim of this study is to produce an energy-saving MgO-Spinel refractory brick, which is feasible to mass production, by inducing controlled and non-permeable porosity to decrease thermal conductivity without sacrificing physical, mechanical and thermal properties.

## EXPERIMENTAL PROCEDURE

A standard 85 wt.% MgO – 15 wt.% MA-Spinel composition is used to optimize the packing density, pore structure, and thermal conductivity. The raw materials are mixed in a mixer and then shaped by a uniaxial hydraulic press. Green compacts are fired by a tunnel kiln in mass production conditions. Produced bricks are characterized according to relevant ISO or ASTM standards.

## RESULTS & DISCUSSION

The microstructural analysis of the developed energy-saving bricks was conducted by using Scanning Electron Microscopy (SEM) to examine the pore characteristics and their impact on the thermal conductivity and mechanical properties of the samples. The SEM analysis revealed the presence of both large and sub-micron sized pores within the refractory matrix (Fig. 2). The presence of large pores in the refractory samples is beneficial for reducing thermal conductivity. Large pores act as thermal barriers by impeding the transfer of heat through the refractory material and lowering the overall thermal conductivity.

The development of sub-micron sized pores in the refractories plays a crucial role in maintaining the high mechanical strength and low permeability characteristics of the material. It is observed that the presence of sub-micron sized pores does not compromise the cold crushing strength of the developed refractories.

The combination of large and sub-micron sized pores in the refractory matrix provides a synergistic effect on thermal conductivity reduction without sacrificing mechanical strength and permeability. The large pores act as thermal barriers, while the sub-micron sized pores ensure low permeability and maintain the cold crushing strength. This dual porosity system optimizes the energy-saving potential of the refractory material for rotary kiln applications.

*Fig. 2: SEM image of the energy-saving brick. Large and sub-micron sized pores are shown with white circles.*

Table 1 summarizes the physical, mechanical and thermal properties of the commercialized energy-saving refractory bricks compared to the standard MgO-Spinel brick. It was observed that

the cold crushing strength remained within acceptable limits, indicating that the mechanical integrity of the refractories was maintained. Additionally, gas permeability values were comparable to those of standard MgO-Spinel bricks, ensuring adequate infiltration resistance within the kiln environment. The commercialized energy-saving bricks exhibited a lower thermal conductivity at 1000 °C, resulting in a 23-25% reduction compared to the standard brick. This reduction in thermal conductivity translates into significant energy savings in clinker production. Furthermore, the thermal expansion values of the developed bricks were within an acceptable range, ensuring their compatibility with the kiln system. Since the bulk density of the energy-saving bricks is ~5-10% lower than the standard MgO-Spinel bricks, the overall weight of the refractory lining is decreased by almost 10% which increases the kiln ring lifetime while decreasing the electricity consumption to rotate the kiln.

Tab. 1: Physical, mechanical and thermal properties of the commercialized energy-saving bricks in comparison to standard MgO-Spinel brick

| | Physical & Mechanical Properties | | | | Thermal Properties | | | |
|---|---|---|---|---|---|---|---|---|
| | Bulk Density | Apparent Porosity | Cold Crushing Strength | Gas Permeability | RUL ($T_{0.6}$) | Thermal Conductivity (1000°C) | Thermal Expansion (%) | |
| Unit | g/cm³ | % | N/mm² | cd | °C | Kcal/m.°C.h | 1000°C | 1400°C |
| Standard | ASTM C 830-00 | | ASTM C 133-97 | EN 993-4 | EN ISO 1893 | EN ISO 8894-2 | NETZSCH DIL 402 PC | |
| KÜM SP 87 LC | 2,70 | 23 | 60 | 32 | >1700 | 2,10 | 1,25 | 1,85 |
| KÜM SP 90 LC | 2,75 | 21 | 65 | 26 | >1700 | 2,15 | 1,29 | 1,89 |
| KÜM SP 87 A (Std) | 2,92 | 17 | 65 | 25 | >1700 | 2,80 | 1,28 | 1,87 |

The KÜM SP 90 LC brick is specially designed for RDF (Recycle Derived Fuel) burning kilns with higher alkali ratio, in which lower permeability and lower apparent porosity are required. Due to the higher MgO ratio and lower porosity, its thermal conductivity is slightly higher than the KÜM SP 87 LC brick, while KÜM SP 87 LC brick focuses more on thermal conductivity with its slightly higher porosity and permeability.

The thermal conductivity as a function of temperature graph is given in Fig 3. The thermal conductivity of the KÜM SP 90 LC brick is higher than the KÜM SP 87 LC brick at lower temperatures since it has higher MgO ratio and higher porosity. The gap between the thermal conductivity of KÜM SP 87 LC and KÜM SP 90 LC decreases with increasing temperature, since the pore size and distribution are similar between these two bricks and radiation mechanism plays a vital role at higher temperatures in thermal conductivity.
Fig. 3: Thermal conductivity as a function of temperature graph of commercialized energy-saving bricks in comparison to standard MgO-Spinel brick
Fig. 4: Kiln shell temperature as a function of kiln meter showing both single layer and conventional double layer lining

Field tests were conducted to evaluate the performance of the developed refractories in actual kiln operations for white clinker production. The field test results showed that the single-layer lining of the low conductivity bricks reduced the kiln shell temperature even more than the conventional double-layer lining (Fig. 4). This improved insulation led to a total energy saving of approximately 0.8 kcal/kg clinker in a 5-meter area. Additionally, the developed refractories demonstrated better insulation properties over time compared to a competitor energy-saving brick, resulting in a difference of approximately 0.5-0.6 kcal/kg clinker in energy savings (Fig. 5). Moreover, after 8 months of operation, the developed low conductivity bricks remained 4-5 cm thicker than the competitor bricks, indicating better performance under high thermal loads in the combustion zone.
Fig. 5: Kiln shell temperature as a function of kiln meter showing single layer lining of both competitor and developed energy saving bricks

**CONCLUSION**

It has been concluded that:

1. The optimized brick design has no negative effect on refractoriness, and provides the ability to control the degree of the porosity, thus altering the relevant properties. The sub-micron sized porosity ensures no sacrifice on cold crushing strength as well as low permeability.
2. Comparable gas permeability to the standard MgO-Spinel bricks is achieved.
3. Thermal conductivity of the refractory brick is achieved to be decreased by 25% at 1000 °C by induced porosity.
4. Reduction in thermal conductivity resulted in 0,8 kcal/kg clinker energy saving in clinker production.
5. Single layer lining of the low conductivity brick decreased kiln shell temperature even more than the conventional double layer lining in white cement production.
6. The weight of the overall refractory lining is decreased by ~10% which would increase kiln ring lifetime and decrease electric consumption to rotate the kiln.
7. The weight reduction of the refractory lining provides less refractory consumption per meter lined.
8. Developed energy-saving bricks proved themselves in white cement production. The field tests are still ongoing in conventional rotary kilns.

# CUSTOMIZED LININGS FOR UPPER TRANSITION ZONES OF ROTARY KILNS FOR CONTEMPORARY CEMENT CLINKER PRODUCTION CONDITIONS

Holger Wirsing, Carsten Vellmer, Hans-Jürgen Klischat
Refratechnik Cement GmbH, Göttingen, Germany

## ABSTRACT

Refractories for linings of cement clinker rotary kilns have been developed according to the process conditions resulting from the mineral phase transformations of the kiln feed and the kiln gas atmosphere. Even under standard conditions the requirements for refractory bricks used for linings in the upper transition zone are complex, and the increasing use of alternative fuels and raw materials intensifies the loads drastically. In kilns with thermal substitution rates exceeding 80 %, especially in the upper transition zone, burning conditions again became more severe. New combinations of inside temperature profile, kiln shell temperature, oxygen content, concentration of volatile compounds, new compounds and clinker melt activities never observed before in that area, are then constantly present or occur as temporary effects. Refractory lifetime monitoring, lining inspections, and post-mortem investigations showed that lining concepts must be reviewed and adapted. To meet this increasing demand, refractory brick materials have been developed to withstand these stress combinations in a better way. The refractory linings used today in the upper transitions zones of cement clinker kilns with high thermal substitution rates are designed to cope with the specific combinations of stresses. This includes not only new non-basic brick types with high resistance to sulfur oxide attack, but also linings for better performance that directly and indirectly contribute to a reduction of emissions and to energy savings.

## THE KILN PROCESS

In the kilns of the cement industry, cement clinker is burned from limestone, quartz sand, clay and components containing iron oxide. In addition to natural raw materials, alternative raw materials are also used for this purpose. Via the cyclones, the raw material is fed into the kiln as fine meal, which is heated until, at a sufficient temperature, calcination of the limestone begins. In the calciner, large amounts of energy are supplied for this highly energy-consuming reaction. Consequently, during the decomposition of the limestone in the kiln feed, its temperature rises only slowly, due to the endothermic reaction. After the raw meal has entered the rotary kiln, the reaction continues in the calcining zone and comes to an end in the safety zone. After complete calcination, the continuous energy input cause rapid heating of the material to be burned, and the clinker mineral phase formation begins. As an intermediate product of these phase formations, clinker melts are formed which are strongly basic, table 1. The kiln zone in which the clinker melts begin to occur in the material to be fired is referred to as the upper transition zone. Here, contact reactions of the clinker melt with the refractory material become possible. If a refractory lining made from acidic alumosilicate refractory materials would be affected by that basic clinker melts, a fast corrosion of the brickwork by erosion would be the consequence, figure 1.

Therefore, when planning the refractory lining of the rotary kiln, the change from aluminosilicate to basic products is usually made at this point.

| Typical chemical composition | | Cement clinker | Cement clinker melt |
|---|---|---|---|
| CaO | weight% | 63-70 | 57.0 |
| SiO$_2$ | weight% | 19-24 | 7.5 |
| Al$_2$O$_3$ (+ TiO$_2$) | weight% | 3-7 | 22.6 |
| Fe$_2$O$_3$ | weight% | 1-5 | 12.9 |
| Melt content (1450 °C) | weight% | 20-30 | - |

Tab. 1: Composition of cement clinker and clinker melt [1][2]

While in the later course of clinker phase formation in the central burning zone a coating layer can form on the lining, which reduces the interaction of refractory material with the material to be fired and with the kiln gas atmosphere, the bricks in the upper transition zone remain free from coating. They are in direct contact with the material to be fired and the kiln gas atmosphere. The thermal situation of the kiln shell therefore solely depends on the temperature reduction of the refractory lining.

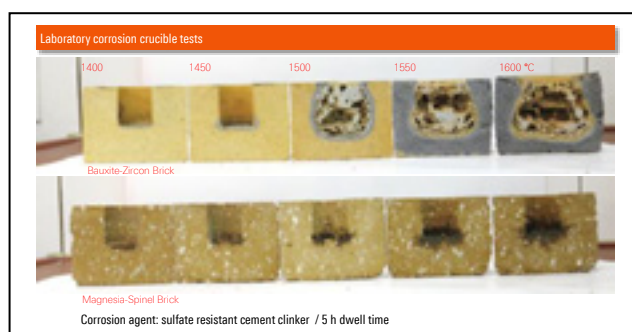
Often, the upper transition zone is in the vicinity of the second tyre, which may add mechanical stresses. The materials used there must be sufficiently resistant to all the resulting stresses to enable effective kiln operation.


Fig. 1: Cut face sides of crucibles made from alumosilicatic (top) and basic bricks (bottom) after corrosion tests with sulfate resistant cement clinker as corrosive agent.

## EFFECT OF ALTERNATIVE FUELS ON THE PROCESS

An important aspect to be considered is the impact by an intensive use of alternative fuels. In some cement plants, the substitution rate has already reached 80 %. As a result, higher contents of volatile components, mostly alkali salts, are present in the kiln gas atmosphere. The alkali salts accumulate in the sulphate and chloride alkali cycles up to very high concentrations, figure 2. Depending on the type, quantity and feed location (main burner, calcinator, kiln inlet) of the alternative fuels, the temperatures in the different kiln sections are changing. Temporary, more unstable firing conditions become possible. An excess of sulfur in the kiln gas atmosphere can occur. Especially in plants without a tertiary air duct, which are operated with high feeding rates of alternative fuels at the kiln inlet
*Fig.2: Location of alkali circles in cement clinker kilns*

(e.g., tyres, sewage sludge), an extremely reducing atmosphere can result locally in the kiln gas atmosphere close to the surface of the lining of the upper transition zone.

**IMPACT ON THE REFRACTORY PRODUCTS**

Bricks used in linings of the upper transition zone interact with the kiln gas atmosphere via the surface and the inner surface, which is the open porosity. The changes in the composition of the kiln gas atmosphere thus have a direct influence on the refractory material.

In the open pores of the elastified magnesia bricks, condensation and crystallization of salt compounds occur when the atmosphere is highly alkaline, following the temperature gradient toward the cold side of the lining, figure 3. This zonal saturation of the pores leads to an increased stress sensitivity of the products. In interaction with additional mechanical stresses, spalling occurs when the structural strength is exceeded by these stresses. This can lead to premature wear of the refractory lining.

562

*Fig.3: Structural cut face side and microstructure of a magnesia-spinel brick after use in an alkali loaded cement clinker kiln.*

With zonal saturation of the pores, there may also be an increase in heat transfer. If this leads to kiln shell temperatures that can be harmful to the steel structure, countermeasures must be taken. Often, the furnace shell is cooled by means of external blowers or water spraying. These cooling measures do not reduce heat loss and only mitigate the effects of high thermal flow.

Excess sulfur in the kiln gas atmosphere can occur when sulfureous lignite and petroleum coke are used as fuel. Sulfur components in the flue gas which are not saturated by alkalis can lead to an attack on the calcium silicate secondary phases of the magnesia component of the basic bricks. The porosity in the affected brick horizons is reduced by the formation of anhydrite, due to the interaction with $SO_2$ from the flue gas as a first step of corrosion. An embrittlement of the bricks upper parts may occur. At the prevailing temperatures, the products from this reaction are mobile

in the microstructure of the refractories and migrate in a second step of corrosion toward the lower brick parts.

*Fig.4: Structural cut face side of a magnesia-spinel brick after use and lining showing signs of sulfur attack.*

This results in a formation of monticellite and forsterite and in a loss of strength of the hot side, figure 4. The embrittlement shifts to the middle part of the brick. As with saturation with alkali salts, these changes in the microstructure of the brick increase the risk that that mechanical loads will exceed the structural strength of the brick. Spalling of the affected areas may reduce the service life of the material.

Reducing atmosphere and redox conditions may change the valence state of the iron in iron oxide containing refractory compounds from trivalent to bivalent. This transformation can lead to volume changes of the iron oxide-containing mineral phases. The reducing atmosphere also can influences the salt compounds which turns to sulfites. Under conditions like this infiltration down to the kiln shell becomes possible.

If solid fuel burns off on the surface of the refractory lining, elemental carbon can be precipitated from the gas phase in accordance with the Boudouard equilibrium in the brick structure, figure 5. The microstructural stresses increase as a result. Iron oxide containing compounds have a catalytic effect on this reaction, and extreme mechanical stresses can occur due to localized deposition of carbon.

*Fig.5: Outside view and structural cut face side of a magnesia-hercynite brick after use in strongly reducing atmosphere.*

These specified types of stress can occur in different combinations and act on the refractory material. The refractory material must be selected according to the actual combination of stresses present.

**SELECTION OF REFRACTORY MATERIALS**

In kilns with low substitution rates, the thermodynamic parameters of the clinker burning process and the mechanical kiln specifics determine the choice of refractory material. In general, magnesia spinel, magnesia pleonast and magnesia hercynite bricks based on magnesia raw materials of varying purity are used.

Starting from these linings, which can be regarded as standard, the changes in the wear situation due to the intensive use of alternative fuels and possible ceramic solutions are discussed below.

In many cases, these effects can be compensated using elastic magnesia spinel bricks with a denser microstructure, which enhance infiltration resistance and offer higher resistance to spalling due to higher microstructural strength (AF products). By slowing down the speed of saturation with alkali salts, the critical stress sensitivity is delayed. The higher microstructural strength ensures that the strength limit is exceeded later or not at all. In the latter case, spalling is avoided even with zonal saturation of the brick.

Tab. 2: Characteristics of refractory brick types related to be used under specific conditions of kiln operation.

In case of additional mechanical stress, e.g., due to a higher ovality as well as deformation of the kiln shell or a strong influence of the tyre, it is more difficult to achieve this goal. In the case of combined loading of salt infiltrations and kiln mechanics, products as described above, which have been additionally superelastified, can be used (A1 products). With denser microstructure and higher elastifier content, the gain in elasticity outweighs slight strength losses compared to AF products. These superelastified bricks are also used in applications with increased mechanical stress without significant alkali load.

If a reduction of the kiln shell temperature is intended to protect the outer kiln structure or to specifically reduce heat losses, the use of the superelasticized products mentioned above can already be helpful. The higher content of elastifying minerals, which have a lower thermal conductivity compared to magnesia, already reduces the heat transfer.

Brick grades from another product group are targeting to reach lower kiln shell temperature (ES products). These magnesia spinel bricks have the characteristics of high resistance to infiltration and spalling as well as increased porosity [3]. Heat transfer can thus be reduced by 25% to 30% compared to dense products. Regardless of the salt load of a kiln, such products can be used to reduce heat loss, energy use, and hence the $CO_2$ emissions of the clinkering process. In the form of A1 ES products they can also be used in areas of kilns with high mechanical load.

A low content of calcium silicate secondary phases or a low CaO to $SiO_2$ ratio of approx. 1 are added as selection criteria to achieve the highest possible resistance to excess sulfur in the kiln gas atmosphere for basic brick grades. All the product groups listed in Table 2 are containing brick grades which meet this criterion.

If a locally strongly reducing atmosphere occurs in the upper transition zone, attention must also be paid to low iron oxide contents when selecting the elastified magnesia bricks in order to reduce the influence of redox conditions and the risk of carbon deposits and associated stress increase.

A more recent approach is the extension of the area of non-basic bricks with SiC reinforced corundum bricks including the upper transition zone and partly the central burning zone. The higher resistance to clinker melt compared to other aluminosilicate products is sufficient at low clinker melt activity, figure 6 on the right side. Other properties of these products are very suitable to lead to good service behavior under the complex stress situation. The alkali resistance is high and depends on the manufacturing conditions of the products. This is also given under highly reducing conditions, figure 6 on the left side. The alkali resistance of these bricks differs from the resistance of elastified magnesia bricks. Constituents of the SiC reinforced corundum bricks react with the alkalis in the pores near the surface, which results in the formation of a highly viscous and thus sealing melt phase. Further alkali penetration is prevented, the porosity of the deeper brick areas is not saturated with alkalis, and the porosity therefore continues to contribute to the reduction of heat transfer in favor of lower kiln shell temperatures.

Example KRONAL® 90 AR: Structural cut of crucibles after testing with…

…potassium carbonate/ reducing atm. /1100 °C /5 h dwell time    …sulfate resistant cement clinker/1500 °C /5 h dwell time
Fig.6: Cut face sides of crucibles made from corundum-SiC brick grade KRONAL® 90 AR after corrosion tests with potassium carbonate (left side) and sulfate resistant cement clinker (right side) as corrosive agents.

Since these products, including the binding matrix, are free of calcium silicates, unlike basic bricks, $SO_2$ resistance is high. Lower thermal expansion than in basic products and high strengths contribute to reduced stress in the lining and good thermomechanical resistance. If, on the other hand, the clinker melt activity is high, the neutral thermochemical character of the corundum is no longer sufficient and a change to the basic products already described must be made to avoid high wear rates.

**CONCLUSIONS**
Using the example of the upper transition zone, it was shown that especially modified basic, and under special conditions also corundum-SiC refractory materials are available for linings of this area even in complex stress situations. A suitable selection for a successful application can only be made if the existing stresses can be correctly assessed and the material is correctly installed. This requires intensive contact between kiln operators and refractory manufacturers. Furnace inspections and post-mortem analyses on the refractories provide important hints.

# REFRACTORY LININGS FOR CEMENT ROTARY KILNS CONTRIBUTING TO ENVIRONMENTAL IMPACT REDUCTION

Makoto Ohno*, Shiho Takeuchi and Yasutaka Yoshimi
MINO CERAMIC CO., LTD., JAPAN

## ABSTRACT

As one of the most carbon-intensive industries, the cement industry is required to reduce environmental impact in order to tackle climate issues. Refractory manufacturers can primarily contribute to the efficiency of cement burning process, in other words, environmental impact reduction by providing durable and energy-saving refractories. From the view point of environmental footprint reduction, many cement plants have been using a larger amount of alternative fuels (AFs) and alternative raw materials (ARMs) and consequently this has caused premature wear of refractories inside the kilns. Additionally, with regards to thermal energy released from the process it seems not much effort has been made about the reduction of heat radiation from the kiln shell surface, whereas a lot has been implemented about recovery of waste heat from exhaust hot gases.

This paper describes our latest progress on the development of a magnesia-spinel brick coping with the increasing use of AFs and ARMs and an alkali resistant alumina-silica brick contributing to shell temperature reduction.

## INTRODUCTION

Tackling climate change by reducing greenhouse gas (GHG) emissions is an urgent global challenge. The cement industry has been facing increasing pressure to reduce its carbon footprint due to its large contribution to greenhouse gas emissions. Currently, for reducing the emissions a great effort has been made on some CCUS projects and more breakthrough innovative projects have been attempted. The short-term measures include increasing the use of AFs, improving thermal and electric energy efficiency, and reducing the clinker-to-cement ratio by blending with mineral substitutes. Increasing the AF substitution rate is one of the most important measures and cement plants in many countries are attempting to enhance the substitution rate. However, the increasing use of AFs and ARMs has made the refractory lining in cement rotary kilns exposed to severe conditions such as unstable coating and high chemical load, often causing premature wear of lining bricks and high heat radiation eventually lowered efficiency and economic loss. As a refractory manufacturer, we believe we can contribute to environmental impact reduction by providing refractories that can cope with harsh conditions and lower the shell temperature.

In the cement industry in Japan, a large amount of wastes and byproducts have been used in the manufacturing process and the unit amount per ton of cement has reached around 470 kg/t-cement recently. Figure 1 shows the transition of the specific amount of wastes and byproducts per ton of cement and the usage of plastic waste. As seen in the graph, the specific consumption of wastes and byproducts has increased significantly from 1990 to 2010. Additionally, while the specific consumption of wastes and byproducts remained flat since 2010, the usage of plastic waste has increased continuously. For the plastic waste, it could make a local reducing atmosphere in part of burning zone and upper transition zone since a large amount of oxygen is consumed during combustion. Furthermore, it tends to have less uniformity in size and type, leading to temperature fluctuations especially when it is fed from the main burner. These characteristics can result in unstable coating conditions and enhancing circulation of volatile components such as alkali, chloride and sulfur, more adversely affecting the bricks.

In this study we present our latest progress on the development of a magnesia-spinel brick coping with the increasing use of AFs and ARMs and an alkali resistant alumina-silica brick contributing to shell temperature reduction.

Fig. 1: Transition of specific amount of wastes and byproducts per ton of cement and usage of plastic waste.

## HIGH WEAR-RESISTANT BASIC BRICKS
### Postmortem analysis of conventional magnesia-spinel brick

Figure 2 shows the appearance and cross section of a concentional magnesia-spinel brick used for five months at L/D of 5.6 in a precalciner kiln. This precalciner kiln utilizes various kinds of AFs and ARMs such as waste plastics, wood chips and sewage sludge and its AF substitution rate is approximately 40%. The photo on the left side of Figure 2 shows that one of two bricks was severely damaged from the hot face to over 100mm depth while the other was kept its original thickness. As this brick was used near a tire section and found to be damaged in the actual kiln, it would have been subject to mechanical stress. Table 1 shows the results of measured physical properties and XRD identification of the magnesia-spinel brick divided into layers every 30mm. Intense densification was observed at the 3rd to 5th layer and a large amount of KCl and $CaSO_4$ was identified at the 3rd to 5th and the 4th to 5th respectively. It is evident that the densification was caused by the deposit of KCl and $CaSO_4$. The deposit at the deep part from the hot face is explained by the following; CaO components, which were contained in the brick and/or came from the outside, reacted with infiltrated $SO_X$ to form $CaSO_4$ and then the low temperature eutectic of KCl-$CaSO_4$ was formed by the existence of KCl and it moved toward the shell side. This will lead to the microstructure deterioration near the hot face and lack of flexibility at the densification part (3rd to 5th layer in this case). We believe the damage observed from the hot face to the 5th layer was caused by the microstructure deterioration by chemical attack, densification with infiltrated minerals and mechanical stress from the tire. Similar damages have been observed in several kilns, in some cases shortening the life of the lining bricks, which led to its necessity for improvement to enhance the process efficiency.

**Development of high wear resistant magnesia-spinel brick**

<u>Characteristics required for magnesia-spinel bricks under chemical attack and mechanical stress</u>

1. Reinforced microstructure in the matrix with spinel (MgAl$_2$O$_4$) bonding

Controlling the amount of CaO and SiO$_2$ is an important factor in terms of bonding formation. Adjusting it to proper amount and ratio of CaO and SiO$_2$ makes the bonding in the matrix primarily formed with spinel bonding, contributing to hot strength, volume stability after repeated heating, and resistance to sulfur, chlorine, and alkali.

2. Low permeability for foreign components

Optimizing grain size distribution and firing conditions and using easily-sinterable raw materials makes the dense microstructure composed of smaller pores, contributing to low permeability.

3. High flexibility for mechanical stress

Adding some spinel materials of proper sizes and optimizing grain size distribution makes it possible to have high flexibility while achieving high strength.

Based on the required characteristics and determined product concept, we developed a magnesia-spinel brick that can overcome the harsh conditions. The properties of the developed magnesia-spinel brick are shown in Figure 3 as indexes with the properties of a conventional magnesia-spinel brick set at 100. Although the developed one has the same level of apparent porosity as the conventional one, it has lower permeability. Furthermore, it has lower volume change after repeated heating (700-1300ºC, 100 times) and high hot bending strength at 1200 ºC due to its reinforced microstructure. An increase in damage resistance parameter was also observed.
Fig. 3: Several quality characteristics of the developed magnesia-spinel brick as indexes with the properties of the conventional magnesia-spinel brick set at 100.

Figure 4 shows the appearance and cross section of the developed magnesia-spinel brick used for one year at L/D of 5.8 in the same precalciner kiln as Figure 2. The photo on the left side of Figure 4 shows that the hot face was almost flat and no significant damage was observed. In the cross section, although some tiny

deterioration was observed near the hot face, no definite cracks were found throughout the brick. Table 2 shows the results of measured physical properties and XRD identification of the magnesia-spinel brick divided into layers every 30mm. Infiltrated minerals identified are the same as shown in the conventional one (see Table 1) but the amount and depth of infiltration was reduced in this sample even though it was used for one year (2 campaigns). Figure 5 shows the apparent porosity of the developed one (Table 2) and the conventional one (Table 1). The result clearly shows that densification in the developed one was more reduced than in the conventional one. The developed magnesia-spinel brick achieved one year life, demonstrating no deep infiltration, severe densification and crack generation. The characteristics of reinforced microstrucure, low permeability and high flexibility in this brick can contribute to stable operations and process efficiency under harsh conditions due to increasing use of AFs and ARMs.

**HIGH ALKALI-RESISTANT ALUMINA-SILICA BRICK WITH LOW THERMAL CONDUCTIVITY**

High alumina bricks containing over 50% alumina content are commonly used in the safety/calcining zone in many cement kilns worldwide. Particularly for the adjacent area to the upper transition zone where basic bricks are installed in most cases, high alumina bricks with higher alumina content tend to be installed due to concerns about erosion by reaction with CaO components. Recently, however, the increasing of AFs and ARMS has caused an

increase in volatile components including alkali and chlorine circulating through the lower temperature zone, leading to premature wear of the lining bricks. In general, alumina-silica bricks in this zone are worn by peeling-off near the hot face caused by alkali attack and the resistance to alkali attack increases as the alumina content decreases. Moreover, alumina-silica bricks with lower alumina content have lower thermal conductivity and thus if they have sufficient erosion resistance and mechanical strength, then they can satisfy the needs for reduced heat loss from the kiln shell along with longer service life. Therefore, we will propose a high alkali resistant alumina-silica brick with low thermal conductivity for the safety/calcining zone, even for the adjacent area to the upper transition zone. Table 3 shows the several quality characteristic values of the high alkali resistant alumina-silica brick with low thermal conductivity (hereinafter referred to as AS) in comparison with other alumina-silica bricks, which are measured by our laboratory based on JIS. AS has the following features, which allows it to be installed from the uphill side of upper transition zone depending on kiln conditions;

1. Prevent alkali infiltration with the formation of viscous liquid phase at the hot face by adding special raw materials
2. Prevent crack growth with absorbing stresses from the kiln by introducing microcracks and using raw materials with low thermal expansion

| Reduction of CO2 emission /ton・year$^{-1}$ | 2,835 | 0 | - | - | |

(Conditions)

Hot face temp.: 1200ºC, Ambient temp.: 20ºC, Wind speed: 0 m/s, Blackness: 0.85

Calorific value for coal: 26.6MJ/kg, $CO_2$ emission for coal: 2.409kg-$CO_2$/kg

In terms of environmental impact reduction, AS also has an advantage of light bulk density in addition to low thermal conductivity. In order to evaluate the $CO_2$ reduction by reduced shell temperature, we calculated hypothetical radiation heat losses and $CO_2$ emission reductions if we install a 30 linear meter of bricks in a 5.0m ID kiln. Table 4 shows the thermal calculation results of AS and other alumina-silica bricks on the conditions described in the below part of Table X. As you can see, AS is much more energy-efficient than typical high alumina/fireclay bricks and a little superior to two-layer combined bricks. Compared to typical high alumina bricks, AS can save 1,177 ton/year of coal and reduce $CO_2$ emissions by 2,835 ton/year.

Figure 6 shows the cross sections of AS used for five months (left) and two years (right) at 9.2 (left) and 9.7 (right) of L/D in a precalciner kiln, in which magnesia spinel bricks were installed downward from 9.2 of L/D. This precalciner kiln utilizes various kinds of AFs and ARMs such as waste plastics, waste tyres and construction soil and its AF substitution rate is approximately 30%. Since these bricks were installed at the same time and in close proximity to each other, there would be no issues with the assumption that they were used under the same conditions. Although some yellowish-brown discoloration was found at the shell face side due to iron content came from the kiln shell, no cracks and damage was observed inside the bricks. Table 5 shows the results of measured physical properties and XRD identification of AS divided into layers every 30mm. In the five-month sample, a large amount of lucite ($K_2O・Al_2O_3・4SiO_2$), which was formed by the reaction of brick with foreign alkali, was identified at the 1$^{st}$ layer and some alkali salts were identified up to the 4$^{th}$ layer.

Considering the infiltration of foreign components was inhibited in the shell face side (4th to 6th layer), this result implies that viscous liquid phase formed in operation prevented the infiltration. In the two-year sample, leucite is identified at the 1st layer and some alkali salts were identified up to the shell face side. Although some alkali salts infiltrated toward shell face side after two years of use, it was likely that the infiltration hardly affected the inside part of the brick. At the 1st layer in both samples, a large amout of leucite was identified, indicating a glassy protective layer was formed at the same time. In terms of erosion, no cement attack was confirmed in both samples, thus no excessive concern is likely to be needed. Judging from the comparison of these bricks, AS would be mainly worn out by about 20mm thick (structural spalling) from the hot face over time because leucite expands when it forms and its expansion coefficient is large. In many cement kilns, AS is gradually and stably worn by thin structural spalling and performs well for long periods. We believe this is because the formed viscous glassy phase prevents the infiltration of foreign components and inhibits the crack generation at the deep position.

Although AS has a lower alumina content, which may raise concerns about erosion by cement materials, it has been installed from the adjacent area to UTZs where magnesia spinel bricks have been installed in dozens of cement kilns in Japan. They have seldom shown erosion, significant wear or any issues concerning its material itself. Figure 7 shows the shell temperature profile at the boundary area between the upper transition zone and safety zone in a precalciner kiln. Magnesia-spinel bricks had a residual thickness close to original size after one year of use, while AS had a residual thickness of 50 to 60 mm thinner than the magnesia brick after two years of use. The average shell temperature was 313ºC and 231 ºC at 10.5 and 11.2 of L/D respectively. As the theoritical caliculations show the shell temperature difference between AS and magnesia-spinel bricks is approximately 100ºC on the conditions of 1200 ºC hot face, coating or other conditons may have been different in each zone. Despite the fact that AS has a lower residual thickness, the shell temperature was kept low due to its low thermal conductivity and its ability to inhibit the penetration of foreign elements, and no abnormal temperature changes were observed near the boundary. Furthermore, inside the kiln, no brick displacement and abnormal movement was observed neat the boundary area. The characteristics of high alkali resistant and low thermal conductivity in AS can contrubutes to the kiln operation with environmental impact reduction.
**CONCLUSION**

With the increasing pressure to reduce $CO_2$ emissions, the cement industy has been increasing the use of AFs and ARMs and working on improving the energy efficiency as short-term measures. However, the increasing use of AFs and ARMs has made the refractory lining in cement rotary kilns exposed to severe conditions such as unstable coating and high chemical load, often causing premature wear of lining bricks and high heat radiation eventually lowered efficiency and economic loss. This paper presented our latest progress on the development of a magnesia-spinel brick coping with the increasing use of AFs and ARMs and an alkali resistant alumina-silica brick contributing to shell temperature reduction. Based on the postmortem analysis, we developed a durable magnesia-spinel brick that features reinforced microstrucure, low permeability and high flexibility. The develoed brick has exhibited its features in the actual kiln, achieving a longer service life under harsh conditions due to increasing use of AFs and ARMs. We believe this developed magnesia-spinel brick can contribute to stable operations and process efficiency in cement plants. Likewise in the safety/calcining zone, volatile components such as alkali and chlorine are rising due to the increasing use of AFs and ARMS, exposing the refractory linings to alkali attack. Under the situations that high alumina bricks containing over 50% alumina content are commonly used in the safety/calcining zone in many cement kilns, we have proposed a high alkali resistant alumina-silica brick with low thermal conductivity for the safety/calcining zone, even for the adjacent area to the upper transition zone. It features preventing alkali infiltration and crack growth and has superiority in terms of $CO_2$ emission reduction to common high alumina and fireclay bricks. Our alumina-silica bricks have demonstrated their gradual and stable wear and thier energy-saving propoerties in actual kilns, contributing to the kiln operation with low $CO_2$ emissions

# SOLIDIFICATION OF TWO FUSED CAST AL$_2$O$_3$–ZRO$_2$–SIO$_2$ MATERIALS IN AN AERO ACOUSTIC LEVITATOR

Jonas, Niessen; Dirk, Muehmer; Thorsten, Tonnesen; Rainer, Telle; Jesus, Gonzaelz-Julian

Institute of Mineral Engineering, Chair of Ceramics, RWTH Aachen University, Aachen, Germany

## ABSTRACT

Due to their excellent high-temperature properties and corrosion resistance, AZS ($Al_2O_3$-$ZrO_2$-$SiO_2$) materials are widely used as refractories. Especially in the glass industry, these products are essential to withstand the corrosive environment. Two industrially available fused cast AZS materials were chosen for this study. One composition was close to the ternary eutectic of zirconia, mullite, and corundum. The other material was close to mullite composition with approx. ten wt% $ZrO_2$. The microstructure and phase composition of the received material was analyzed. Additionally, the materials were remelted in an aero acoustic levitator. A pyrometer and a high-speed camera recorded the crystallization. The fused cast grains and the remelted samples showed significant microstructure and phase composition differences. Due to the high cooling rates and homogeneous nucleation under containerless conditions, both materials tended to form a glassy phase. Cooling samples with a pre-existent nucleus or controlled conditions yielded a fine-grained crystalline microstructure. For conventional cooling, the silica and alumina-rich material exhibited large corundum precipitates. In contrast, the containerless processed sample showed primary precipitation of mullite.

## Introduction

Refractories are essential for metal, glass ,or cement production. They have to resist corrosive media, mechanical loads ,and extreme temperatures. For an extended service lifetime, optimizing the refractories for the given process conditions is mandatory. Fused AZS products are state of the art in glass making due to good mechanical properties and corrosion resistance [1]. Despite the technological importance of the AZS system, there is still an ongoing controversy about a congruent[2,3] or incongruent melting mullite [4,5].

Due to their high melting point, studying the liquidus phase regions of ceramics is difficult. Finding a sufficient container material that resists such high temperatures is challenging. Moreover, dissolution of the vessel material can contaminate the melt. Containerless processing like aero acoustic levitation circumvents these problems. The contactless processing enables direct observation of the crystallization process via a high-speed camera, improving the understanding of the solidification process [6]. Moreover, high cooling rates and high undercooling are achievable. Therefore, the technique is excellently suited to study metastable processes. Most scientists used levitation techniques for high-purity materials. Here we want to study the solidification of refractory-grade AZS materials under containerless conditions.

## Experimental

Two different AZS aggregates were used for the study. One will be referred to as AZS-mullite, which is alumina-rich. The other contains more zirconia and will be referred to as AZS-Zirconia. The exact composition was determined by X-ray fluorescence spectroscopy (XRF) on fused glass discs using a PW2404, Malvern PANalytical B.V, Eindhoven, Netherlands. Both compositions' beads were produce by laser sintering the ground raw materials in a copper mold. A stirring motion yielded a spherical shape necessary for levitation.

Nordine et al. [7] describe the aero acoustic levitator (Pyhsical Property Measurements Inc., Evanston, Illinois, USA) used for this study in detail. The ceramic beads are levitated above a nitrogen gas stream. Additionally, three orthogonal ultrasonic transducer couples create a pressure node to stabilize the sample's position. Two 240W CO$_2$ lasers (SynradInc., Mukliteo, WA, USA) can heat the samples up to 3000°C. To induce solidification the lasers are switched off. A high-speed camera (V5.2, PhantomVision Research Inc., Wanyne, NJ, USA) and a pyrometer (Exactus BF 8402, Bayer Catalysts LCC, Rome, Italy) record the solidification process at1000 fps.

The experimental procedure begins with introducing the bead into the central position of the acoustic node with a vacuum chuck and carefully adjusting the gas flow. Then the laser power is gradually increased while controlling the sample's rotation. When the sample is completely molten, the laser is turned off to record the solidification. Repeating the process several times yields statistical temperature data.

The received and levitated samples were studied by X-ray diffraction using a D8 Advance, Bruker AXS Advances GmbH, Karslruhe Germany, copper tube 2θ 5-90°). The resulting microstructures were studied by scanning electron microscopy (SEM) and energy dispersive spectroscopy (EDS) (FESEM Gemini 500, Zeiss, Oberkochen, Germany; EDS detector XMax80, Oxford Instruments, Abingdon, Oxfordshire, UK).

## Results and Discussion

*Raw material characterization*

Table 1 gives the composition of both materials determined by XRF. Besides the main components, the products contain 2.3-2.5 wt.% impurities. Na$_2$O is the most prominent one.

*Tab. 1: Composition of refractories determined by XRF.*

| Component | Portion in wt.% | |
| --- | --- | --- |
| | AZS-ZrO$_2$ | AZS-mullite |
| SiO$_2$ | 14,5 | 18,4 |
| Al$_2$O$_3$ | 50,0 | 69,3 |
| Fe$_2$O$_3$ | 0,1 | 0,5 |
| TiO$_2$ | 0,1 | 0,1 |
| CaO | 0,0 | 0,1 |
| K$_2$O | 0,1 | 0,1 |
| Na$_2$O | 1,3 | 1,1 |
| ZrO$_2$ | 33,0 | 10,1 |
| HfO$_2$ | 0,7 | 0,1 |
| Co$_3$O$_4$ | 0,0 | 0,1 |
| Y$_2$O$_3$ | 0,2 | 0,1 |

The AZS-ZrO$_2$ material contains only corundum and baddeleyite as crystalline phases. In the SEM micrographs, large interpenetrating Al$_2$O$_3$-ZrO$_2$ grains with a eutectic-like structure are embedded in a silica-rich glassy matrix. Mullite, which would be expected according to the ternary phase diagram [4], is absent. However, various authors reported suppressed mullite precipitation for slow cooling rates [5,8]. Assuming an incongruent melting of mullite, corundum starts to precipitate from the melt. If the peritectic reaction kinetics are sluggish, the Al$_2$O$_3$ cannot be consumed to form mullite. Instead, the remaining silicarich melt solidifies as a glass.

The AZS-mullite material contain besides corundum and baddeleyite, also mullite and cristobalite. As both compositions are in the Al$_2$O$_3$-ZrO$_2$-mullite compatible triangle, cristobalite is not an

equilibrium phase. Again, sluggish peritectic kinetics is a suitable explanation.

*Levitation experiments*

Figure 1 depicts exemplary cooling curves of the AZS-ZrO$_2$ material. At zero seconds, the beads are molten. After approx. one second, the lasers are turned off, inducing rapid cooling. The blue curve cools approx. 300 K below the ternary eutectic temperature (1700-1710°C [4]) before recalescence leads to a temperature increase. In contrast, the orange curve does not reheat and belongs to a glassy completely transparent bead. Bot compositions yielded crystalline and amorphous beads after melting. Under containerless conditions, preferred nucleation sites are missing. Therefore, homogenous nucleation occurs. The statistical nature of homogenous nucleation and high silica content in the samples could explain, that some bead crystalize, while others do not.

*Fig. 1: Cooling curves of AZS-ZrO$_2$; glass formation without crystallization (orange); recalescence after undercooling, indicating crystallization (blue)*

High-speed camera recordings revealed that several nuclei form in the samples. During crystallization, latent heat is released in proximity to the growth front. The interface between approaching nuclei becomes significantly brighter, indicating a local temperature increase due to heat accumulation. The solidification microstructure of the AZS-ZrO$_2$ is shown in figure 2. Compared to the crushed aggregates, the grain size is significantly refined due to the high undercooling prior to solidification. Around the nucleation sites a radiated structure forms. The interface between two nucleation cells becomes coarser (Fig. 2c) due to the local temperature increase promoting grain growth. Figure 2b shows a coarser structure in the center of a nucleation cell. We assume that it is an unmolten residue acting as a nucleation site. Besides the statistical nature of homogenous nucleation, unmolten solids could explain the different solidification behavior. The microstructure of the AZS-mullite material exhibits comparable features, like an overall small grain size and a coarsening at the interfacial regions.

XRD results of levitated AZS-ZrO$_2$ exhibit mullite and tetragonal zirconia as only crystalline phases. AZS-mullite contains monoclinic as well as tetragonal zirconia, mullite, and some traces that could not be identified. Tetragonal zirconia could be stabilized by the small grain size and pressure from surrounding grains. In contrast to the conventional cooled samples, both compositions do not contain corundum. Likely, due to the high undercooling prior to nucleation, mullite can nucleate directly from the melt [8].

*Fig. 2: Corss-section of a solidified AZS-ZrO$_2$ bead; a) overview; b) coarse structure in the center of a nucleation cell, surrounded by a fine-grained matrix; c) transition zone; d) interfacial eutectic structure.*

**CONCLUSIONS**

The results show the high importance of cooling conditions on the phase selection in AZS materials. In conventional fused cast materials, corundum precipitation is favored above the mullite melting point. Sluggish peritectic reaction kinetics suppress mullite precipitation. The high cooling rate under levitation conditions promotes direct nucleation and precipitation of mullite from the supercooled melt. The results strongly support an incongruent melting of mullite, as it is the only explanation for the suppressed mullite formation in the refractory aggregates.

# STUDY OF THE MICROCRACKING EFFECT IN AN ALUMINA−MULLITE−ZIRCONIA  REFRACTORY CERAMIC

Amélie Bigeard, David Jauffres, Didier Bouvard
Univ. Grenoble Alpes, CNRS, Grenoble INP, SIMaP, 38000 Grenoble, France

## ABSTRACT

A complex alumina-mullite-zirconia refractory ceramic including a calcium aluminate cement binder was studied in terms of thermal and mechanical properties. The evolutions of the deformation (dilatometry) and of the elastic modulus (impulse excitation technique) during thermal treatments were investigated. Three successive phenomena were observed, namely dehydration, liquid phase sintering and microcracking. The latter one was studied more in details by examining separately the matrix and the aggregates of the material. It was demonstrated that the microcracking effect during cooling originates from the thermal expansion mismatch between the mullite zirconia aggregates and the matrix.

## INTRODUCTION

Refractory materials are used in industrial furnaces (e.g. steelmaking, cement, petrochemical and glass industries) thanks to their resistance to high temperatures, thermal gradients, thermal shocks and chemical attacks (leading to corrosion). Alumina castable refractories containing mullite zirconia aggregates and a calcium aluminate cement (CAC) binder, referred to as CAC bonded alumina mullite zirconia (AMZ) refractories, are an example of such refractories. Although they have an important industrial role, CAC-bonded AMZ refractories have not been widely studied in the literature. To improve the formulation and thermal treatments of these refractories, it is important to gain a better understanding of their thermomechanical behaviour and their microstructural evolutions during heating and cooling.

The thermal treatments applied to refractory materials are expected to improve their strength thanks to consolidation through sintering. Nevertheless, a possible consequence of these thermal treatments is the damage occurring during cooling, mainly in the form of microcracking. This damage can come either from the difference of coefficients of thermal expansion (CTE) between the phases or from the physicochemical transformations in the material [1].

Fogaing et al. [1] proposed a simplified microcracking model during cooling, that considers a biphase material containing spherical inclusions (CTE $\alpha_p$) surrounded by an isotropic homogeneous matrix (CTE $\alpha_m$). Three configurations are possible:

- $\alpha_m < \alpha_p$: partial or complete decohesion between the matrix and the inclusions is expected.
- $\alpha_m = \alpha_p$: no damage is expected.
- $\alpha_m > \alpha_p$: radial cracks are likely to appear in the matrix, around the inclusions.

This theoretical model was verified experimentally on industrial products. For instance, Chotard et al. [2] observed a thermal damage in a cordierite-mullite refractory due to the thermal expansion mismatch between the cordierite matrix and the mullite grains. Microcracking was also observed in refractory ceramics containing andalusite and bauxite aggregates [3].

In zirconia containing refractories, the zirconia phase change can also lead to microcracking. During heating, zirconia transforms from monoclinic to tetragonal around 1100°C and during cooling the reverse phase change occurs around 1000°C [4, 5]. Not only the intrinsic elastic modulus of the monoclinic phase is higher than that of the tetragonal phase [6] but this phase transformation can also lead to large volume changes (4% for pure zirconia). Therefore, it can favor microcracking as well [7-9].

In this context, the objective of this study is to understand the mechanisms of consolidation and damage during high temperature cycles of an alumina mullite zirconia refractory bonded with CAC. The evolution of the physical (density, porosity, crystal phases), thermal (thermal expansion) and mechanical (modulus of elasticity) properties as a function of temperature was studied. The analysis of the phenomena occurring during different temperature ranges will be described and the origins of the microcracking phenomenon will be specifically investigated in this paper.

## MATERIALS AND METHODS

Two refractory materials were designed with a mix of coarse particles, larger than 200 µm, referred to as aggregates, and a matrix containing particles smaller than 200 µm. The compositions are given in Table 1. The raw materials were mixed in a Perrier planetary mixer for 15 min. The mixture was then cast into bar-shaped molds of size 150*25*25 mm³. After 6 hours, the parallelepiped bars were demolded and cured at ambient temperature for approximately 24 hours. Finally, the specimens were oven-dried at 250°C. Unless mentioned otherwise, the considered refractory is the oven-dried mat_MZ material, referred to as 'green material'. An extra composition consisting in only the matrix particles was also prepared by adjusting the water level to be castable (viscosity lower than 20 Pa.s).

*Table 1: Composition of the studied materials.*

| | Mat-MZ (ref) | Mat-Al |
|---|---|---|
| **Aggregates (>200 µm, 70 wt%)** | Mullite zirconia (<3mm) | Tabular alumina (<3mm) |
| | Tabular alumina (<2mm) | Tabular alumina (<2mm) |
| **Matrix (<200 µm, 30 wt%)** | Alumina, silica, zirconia | Alumina, silica, zirconia |
| | Binder: CAC | Binder: CAC |

The density and apparent porosity were measured by Archimedes immersion technique with water as the immersion fluid (DIN EN 623-2). Dilatometry experiments up to 1350°C with 1h dwell time, using 100°C/h heating and cooling rates, were performed with specimens core drilled as cylinders of 50 mm height and external diameters and 12 mm central inner diameter (Afnor NF EN 993-19). The coefficient of thermal expansion of the materials was measured from the dilatometry experiments between 600 and 200°C during cooling. The Modulus Of Elasticity (MOE) was measured with bars of dimensions 150*25*25 mm³ by the impulse excitation technique, using a laser doppler vibrometer to capture the signal (ASTM E1816-01). Continuous measurements were performed up to 1350°C, with heating and cooling ramps of 200°C/h and a dwell time of 2h. Chemical analyses were carried out by X-Ray fluorescence and phase analyses by X-Ray powder diffraction.

## RESULTS AND DISCUSSION

### Composition of the material

The bulk density of the refractory is 2.991 ± 0.004 g/cm³ and the open porosity is 17.7 ± 0.1 %. The chemical composition and the phases of the refractory are presented in Table 2 and Table 3.

Table 2: Chemical analysis

| Compounds | Amount (wt%) |
|---|---|
| $Al_2O_3$ | 75 |
| $ZrO_2$ | 12 |
| $SiO_2$ | 10 |
| CaO | <1 |
| MgO | <1 |
| $Na_2O$ | <1 |

Table 3: Main phases

| Compounds | Amount (wt%) |
|---|---|
| Corundum | 67 |
| Mullite | 19 |
| Monoclinic zirconia | 11 |
| Alumina β | 3 |

It is worth noting that during a temperature cycle, 'liquid phases' might appear. In this paper, 'liquid phases' refer to:
- The phases formed by the reactions between the impurities and the raw materials that promote the formation of low melting-points eutectics.
- Amorphous phases that soften above their glass transition temperature.

**General material evolution scenario during a thermal cycle**

Different phenomena can be highlighted during a thermal treatment on the green material. They are illustrated in Figure 1 and specified below. A second MOE cycle, presented in Figure 2, was performed as well and provides additional information on the material. The evolution of the deformation of the material during a thermal treatment was followed by dilatometry and is presented in Figure 3.

Figure 1: Evolution of the hot modulus of elasticity during a cycle up to 1350°C, with heating and cooling rates of 200°C/h and a dwell time of 2h.

Figure 2: Evolution of the hot modulus of elasticity during two successive cycles up to 1350°C, with heating and cooling rates of 200°C/h and a dwell time of 2h.

Figure 3: Deformation vs temperature, during two successive cycles, up to 1350°C, with heating and cooling rates of 100°C/h and a dwell time of 1h.

Phase a: heating from 25 to 800°C

The initial MOE value is 32 GPa. At room temperature, the calcium alumina cement in the material reacts with water to form hydrates, responsible for the consolidation of the material. At the beginning of heating, the elastic modulus slightly declines, reaching 22 GPa at 800°C. This loss is associated to a mechanical degradation of the material, explained by the dehydration of the previously formed hydrates. According to thermogravimetric measurements, the hydrates are fully decomposed after 800°C, which is coherent with the MOE stability during the second cycle between 25 and 800°C. During heating, the dilatometry test shows a continuous and linear thermal expansion of the refractory.

Phase b: heating from 800 to 1200°C

In this temperature range, the elastic modulus starts increasing. Dehydration is over and consolidation of the material by sintering begins, promoted by liquid phases. In this temperature range, according to Figure 3, the material continues its expansion without shrinkage.

Phase c: heating from 1200 to 1350°C

Above 1200°C, the MOE loss indicates that the consolidation effect of sintering is overcome by high temperature softening of the matrix due to the presence of a large amount of liquid phases. During the two-hour dwell time at 1350°C, the MOE increase confirms that the sintering still operates, this time with a low shrinkage (0.1%). The fact that the shrinkage observed is very limited is explained by the multiscale composition of the refractory. Indeed, while the matrix shows a high shrinkage due to sintering (4.5% measured by dilatometry), the aggregates do not sinter due to their large size, leading to the constrained sintering of the matrix. The matrix shrinkage generates tensile stresses between matrix and aggregates. These tensile stresses lead to the opening of mesoporosity between the sintering matrix and the skeleton formed by the aggregates [10, 11]. The sintering shrinkage of the matrix is thus not transferred to the aggregate skeleton but accommodated by the opening of mesoporosity, which leads to a very small macroscopic shrinkage.

Phase d: cooling from 1350 to 800°C

During this step, the elastic modulus increase is explained by the solidification or stiffening of the liquid phases. The inflection around 1000°C corresponds to the indirect effect of the tetragonal to monoclininc zirconia phase change. Indeed, the MOE of the tetragonal phase is higher than that of the monoclinic phase [6] but the volumetric expansion induced by the transformation explains the slight decrease of elastic modulus. The zirconia phase change also results in an expansion that is observed in the dilatometry test around 1000°C.

Phase e: cooling from 800 to 25°C

In this temperature range, the continuous decrease of the MOE can be attributed to damage or microcracking in the material. A second expansion occurs in the dilatometry test around 800°C, that can also be explained by microcracking in the material, as proposed by Mouiya et al [12]. The second MOE cycle shows a similar behavior than the first one after 800°C. This suggests that the microcracking phenomenon is reversible, with closing / healing of microcracks during heating and new opening during cooling. This was also verified with a third cycle.

**Origin of the thermally-induced damage**

Microcracking is expected to play a major role in the thermal shock resistance of the refractory. Therefore, it is worth studying in detail the origin of this phenomenon in order to be able to control it.

To begin with, the evolution of the MOE of the matrix alone is plotted as a function of temperature in Figure 4. At the beginning of heating, the modulus slowly decreases due to cement dehydration. From 800°C, the rise of the MOE shows a consolidation in the material due to sintering, facilitated by liquid phases. From 1200°C, the softening of the material is explained by the viscosity decrease of the liquid phases. During the dwell time and at the beginning of cooling, the elastic modulus continuously increases due to the solidification of the liquid phases. From 800°C to room temperature, unlike the composite refractory material, the modulus of the matrix is stable. It can be deduced that neither the physicochemical transformations in the matrix (sintering, mullitization, cement dehydration, phases cristallizations, zirconia phase change) nor the CTE difference between constituents of the matrix are responsible for microcracking in the refractory. The microcracking is either occurring in the aggregates or due to interactions between the matrix and the aggregates.
*Figure 4: Evolution of the hot modulus of elasticity of the matrix during a cycle up to 1350°C, with heating and cooling rates of 200°C/h and a dwell time of 2h.*

Next, the influence of the type of aggregates was specifically studied. Material mat_Al was prepared by replacing the mullite zirconia aggregates by alumina aggregates with the same particle size distribution. The evolution of the elastic modulus as a function of temperature for mat_MZ and mat_Al is shown in Figure 5. The behavior of both materials is similar during heating but strongly differs from 800 to room temperature during cooling. Indeed, no damage is observed in mat_Al, supporting that the alumina aggregates do not play a significant role in microcracking.

*Figure 5: Evolution of the hot modulus of elasticity mat_MZ (green) and mat_Al (grey) during a cycle up to 1200°C, with heating and cooling rates of 200°C/h and a dwell time of 2h.*

Then, the influence of the mullite zirconia aggregates, and more specifically of the zirconia phase change, was investigated. Four thermal treatments were applied on four mat_MZ samples:
- T1) Maximum reached temperature: 700°C (red curve).
- T2) Maximum reached temperature: 1000°C (orange curve).
- T3) Maximum reached temperature: 1100°C (blue curve).
- T4) Maximum reached temperature: 1200°C (green curve).

The curves are presented in Figure 6. The same behaviour than in Figure 1 can be underlined, with dehydration until 700 (T1) or 800°C (T2, T3, T4), liquid phase sintering until the maximum reached temperature (except for T1) and microcracking during cooling. It is worth underlining that this damage is observed, independently of the maximum reached temperature. Knowing that the monoclinic-tetragonal phase change of the zirconia occurs around 1100°C during heating, this graph suggests that this physicochemical transformation is not the main cause of microcracking in the material.

*Figure 6: Evolution of the hot modulus of elasticity mat_MZ during different thermal cycles with heating and cooling rates of 200°C/h and a dwell time of 2h.*

The last possible origin of microcracking lies in the thermal expansion mismatch between the phases. It was previously shown that such mismatch within the matrix constituents is not creating damage (see Figure 4). A thermal expansion mismatch between the matrix and the aggregates is thus suspected to be at the origin of the thermal damage. The dilatometry experiments allowed determining the coefficients of thermal expansion of the matrix, the alumina aggregates and the mullite zirconia aggregates. The values are presented in Table 4.

*Table 4: Coefficients of thermal expansion of the matrix, a mullite zirconia aggregate and an alumina aggregate, measured on the dilatometry tests between 600 and 200°C during cooling.*

|  | Matrix | MZ | Alumina |
|---|---|---|---|
| **CTE 600-200°C ($10^{-6}$/°C)** | 7.0 | 3.3 | 8.5 |

The CTE of the matrix is more than twice the CTE of the mullite zirconia aggregates, respectively 7.0 and 3.3 * $10^{-6}$/°C. Therefore, during cooling, the matrix tends to contract more than the MZ aggregates, likely leading to damage in the form of radial cracks,

according to the model developed by Fogaing et al. [1]. Furthermore, the coefficient of thermal expansion of the alumina aggregates is closer to the matrix one and less damage is therefore expected in mat_Al, which is coherent with Figure 5.

These results thus indicate that the thermal expansion mismatch between the matrix and the mullite zirconia aggregates is the main origin of microcracking in the AMZ refractory.

## CONCLUSIONS

A high alumina refractory castable was prepared with alumina and mullite-zirconia aggregates (particles larger than 200 μm) embedded in an alumina, zirconia and silica matrix (particles lower than 200 μm), bonded with calcium aluminate cement. The material was characterized with elastic modulus and dilatometry measurements during successive thermal cycles. Three main phenomena were observed during these thermal treatments:

- In the first cycle, dehydration at low temperatures, due to dehydration of the cement hydrates formed during setting at room temperature.
- Sintering promoted by liquid phases during heating, mainly in the first temperature cycle.
- Microcracking during cooling.

It was shown that microcracking was mainly driven by the thermal expansion mismatch between the matrix and the mullite zirconia aggregates. In addition, the reversibility of this phenomenon was observed with microcracks closing / healing and opening during a second cycle.

These investigations allowed in-depth understanding of the thermomechanical behavior of the material. The study of the microstructure of the material is on-going and will complete these first results. For instance, in-situ Xray tomography at the European Synchrotron Radiation Facility and SEM during different thermal treatments can provide complementary and novel information on sintering and microcracking in the material.

# FUSED CAST AZS BLOCKS AND THEIR MINERAL PHASES AFTER PRODUCTION, AFTER ANNEALING THE FURNACE AND IN USE

Bernhard Fleischmann
Hüttentechnische Vereinigung der Deutschen Glasindustrie (HVG) e.V. Offenbach am Main, Germany

Christian Thieme,
Fraunhofer-Institut für Mikrostruktur von Werkstoffen und Systemen IMWS, Halle / Saale, Germany

## ABSTRACT

Fused cast alumina-zirconia-silica (AZS) blocks are used in glass contact area as well as lining of the combustion room among other things.

The changes of their mineral phases during production and use (annealing of the furnace during glass production and during furnace shut down) are analysed in detail with modern microscopic techniques to learn about the interpretation of the presence of distinct phases.

If present, mullite is a crystalline phase that leads to discussion about its origin. The microscopic analysis of these materials with scanning electron microscopy in combination with elemental analyses (EDXS) as well as X-ray diffraction are primarily used for this purpose. Thermodynamic, kinetic considerations are made about the cooling of the blocks during production, during the annealing of the furnace and during usage regarding the equilibrium and semi stationary states that are reached within the single steps. Taking phase diagrams into account mullite may be present in AZS blocks after production, when annealing a block but may it originate from corrosion, too? The investigations with modern microscopic methods allow the detection of smallest amounts of crystalline and amorphous phases and will give evidence for the importance of the different corrosion and phase formation mechanisms and so help to decide whether the presence of a phase, especially mullite, is the consequence of failure in production or use or is just 'natural'.

## INTRODUCTION

The corrosion of AZS materials in glass melting tanks, with direct contact of these materials to the melt, may be summarized in a simplified way by the following process [1, 2]:

At the interface glass melt and refractory, alumina and the high silica vitreous phase of the blocks are dissolved and enriched in the glass melt near the refractory block. The viscosity near the interface glass/refractory increases and a highly viscous layer is formed, saturated with $Al_2O_3$. Due to a common solubility limit of alumina and zirconia, the solubility of $ZrO_2$ is decreased and the reason for the high corrosion resistance of the AZS fused cast refractories.

The typical AZS refractories produced in Europe consist of zirconia (baddeleyite), alumina (corundum) and a vitreous phase (aluminosilicate glass). If used blocks are examined for their mineral phases mullite often is present [3, 4]. The question of interest is, when and how the formation of mullite happens or why sometimes mullite is not found?

## TESTING PROCEDURE

A detailed description of the sample preparation and the testing program is given in [5]. The investigated samples, used for microscopic and mineralogical phase detection can be categorised as:

- Samples from an AZS block after production.
- Samples of the same block with a thermal treatment similar to the annealing of a typical container glass furnace.
- Samples that undergo the annealing process and emulate the temperature cycling of the combustion space of a regenerative furnace ($\Delta T= 50$ K, $\Delta t=20$ min.).
- Samples from dismantled furnaces.

## RESULTS AND DISCUSSION

### Production of AZS fused cast blocks

The raw materials (zirconia with traces of CaO or $Y_2O_3$; zircon; alumina, sodium carbonate) are molten in an arc furnace with graphite electrodes. Sub-stoichiometric $ZrO_2$ is oxidised by blowing oxygen into the melt which will also oxidise polyvalent impurities and helps to homogenise the melt. The melt is then cast into moulds made of sand. These moulds are removed as soon as the stable casting skin formed around the melt and allows further handling. The block is then placed into a cooling bed. The crystallization process is completed after some hours, but to reduce mechanical stresses slow cooling of the huge (soldier) blocks is necessary over weeks.

If the cooling rate is small enough so that the formation of the phases in equilibrium state is feasible (enough time is available for chemical reactions, diffusion and crystallisation), phase diagrams may help to discuss the process of crystallisation.

Fig. 1 focus on the subarea of the phase diagram of the main components of AZS soldier blocks [6] that helps to understand the cooling and crystallisation process of AZS materials.

*Fig. 1: Part of the phase diagram $ZrO_2 – Al_2O_3 – SiO_2$, [6] that helps to understand the cooling process. Following the crystallisation path (golden yellow arrows) of specific fused cast AZS blocks from starting point (red circle) to phase border zirconia with alumina, following the phase border until eutectic point is reached*

The starting point (red circle in Fig. 1) marks a block with 42 wt.-% zirconia, 45 wt.-% alumina and 12 wt.-% silica as main components and disregarding sodium oxide and other trace components. Zirconia (at least baddeleyite as metastable low temperature phase) crystallises as the only phase during first cooling until the phase borderline with alumina is reached. The melt depletes zirconia until the phase border between the zirconia and the alumina region is reached. Now two phases crystallise simultaneously: zirconia and corundum. The crystallisation path follows now the border line in the direction of lower temperatures until the eutectic point is attained (golden yellow arrow in fig. 1). If equilibrium conditions (enough time, all components have the same temperature, no kinetic obstruction and pure composition) would be present all three phases would crystallise simultaneously that "meet" at the eutectic point: baddeleyite, corundum and mullite.

Instead, the relatively high viscosity of the aluminosilicate melt, the presence of impurities and intentional minor components prevent

the crystallisation of mullite more or less complete and only zirconia and corundum were built together with the vitreous phase.

To follow the crystallisation process an additional phase diagram would be necessary: alumina – silica – sodium oxide. Even though the equilibrium state is abandoned, the presence of the vitreous phase in the block is reasonable.

The phase diagram allows to determine the overall composition of the crystal phase and the changed composition of the residual melt as long as the cooling of the block represents the equilibrium state which is given for temperatures above the eutectic point.

The questions to be answered with this paper are:

- Does blocks with the typical composition of European AZS soldier blocks show reasonable mullite after production?
  Even the investigations with its high resolution in [5] showed no mullite in AZS blocks after production.

- Will the presence of mullite increase if heating up the furnace with newly installed soldier blocks? Is the temperature high enough so that reactions occur to serve the equilibrium state and are times long enough [7]?

**Annealing the furnace**

Neighbouring samples, cut from the block that was used to investigate the block after production, were used to run through a two-staged heat treatment. The first two weeks simulate the annealing curve of a typical container glass furnace (see Fig. 2). After reaching 1580°C samples were taken out of the furnace, cooled down quickly and investigated with the high resolution methods.

*Fig 2: Heat treatment of samples simulating the annealing of the furnace and the temperature cycling of regenerator furnaces. The continuous change between 1580 and 1530°C within 20 minutes is not visible. The missing part is due to a malfunction of the documentation software whereas the test continues without any problems.*

After annealing, a small amount of mullite is found. The mullite does not occur as needles but as blocky crystals [5].

**Temperature cycling of regenerative glass furnaces**

Samples that were investigated after running through the second heat treatment, i.e. thermal cycling between 1530 and 1580 °Ca (Fig. 2), that simulates the behaviour of superstructure blocks placed in the side wall of the combustion space of glass furnaces, showed a higher content of mullite than the merely annealed one.

Fig. 3 compares the results of XRD measurements of untreated samples after refractory production, of samples after annealing and of samples after temperature cycling. The XRD analyses showed the absence of mullite after production and increasing intensity of the mullite signal with increasing treatment time at high temperature. Even the signals height, i.e. the mullite concentration, increases with longer treatment.

*Fig. 3: XRD of samples after refractories production (bottom curve), after annealing and 10 hours at 1580°C (center line) and after additional temperature cycling between 1530 and 1580°C for about 14 days (upper curve). The unlabelled peaks can be assigned to baddeleyite ($m\text{-}ZrO_2$).*

**Post mortem investigations**

Fig. 4 represents the top part of a corroded soldier block after years of glass contact. The results of XRD measurements on this material are summarised in Fig. 5.

*Fig. 4: Slice of a top part of a soldier block after years of use in a glass furnace*

With XRD, mullite is not detected but nepheline ($Na_3K[AlSiO_4]_4$) is present. This alkaline aluminosilicate is found in areas where alkaline from the glass melt or evaporated alkaline infiltrated and could be proved with EDXS in the vitreous phase of the block. The parts of the block that show no diffusion of alkaline consist only of the crystalline phases baddeleyite and corundum beside the vitreous phase. The temperature gradient and the duration the sample was exposed to higher temperatures are unknown.
*Fig. 5: XRD results of the post mortem analyses of a soldier block*

## CONCLUSIONS

If investigating refractory materials after dismantling of a furnace or after breaking down, the presence of mullite may be the reason of intense discussions. The following questions arise:

- Which conditions lead to mullite formation?
- Does the presence of mullite give a hint for the failure of an AZS material?
- Is mullite a "natural" component of fused cast AZS blocks?

The investigation of refractory samples of AZS materials after production, after a temperature treatment that simulated the annealing of a glass furnace, after thermal cycling to imitate the behaviour of a regenerator furnace and after furnace lifetime with electron microscopy and XRD helps to find answers for these questions.

1. Typical European fused cast AZS soldier blocks for glass contact do not contain mullite after refractory production. They consist of baddeleyite, corundum and a vitreous aluminosilicate phase.
2. Phase diagrams representing the equilibrium state suggest that mullite should be present due to thermodynamic considerations. Kinetic aspects and the presence of impurities or trace elements inhibit the formation of mullite within the available time at elevated temperatures during AZS production.
3. Temperature treatment similar to annealing the furnace results in the formation of mullite crystals in fused cast AZS blocks. Temperature is high enough and time long enough to approximate equilibrium and to compensate kinetic constraints.
4. Longer times at temperatures above 1530°C enhance the number of mullite crystals and their size. The thermodynamic equilibrium is not yet reached.
5. Mullite is not mandatory in blocks with glass contact. It cannot be found if corrosion is faster than mullite formation. At temperatures below 1500°C, other phases might be more stable.
6. Small mullite (needles) may be found beside nepheline surrounded with vitreous phase in blocks after dismantling the furnace. These two crystalline phases may be formed as devitrifications from the vitreous phase of the block, saturated with glass and corrosion components, when cooling the furnace slowly. If sodium and/or potassium penetrates the block at temperatures below 1500°C, nepheline seems to be the more stable crystalline silicate.

SHORT COMMUNICATIONS

# FUSED SILICA – THE ANSWER TO CHALLENGING FURNACE CONDITIONS

M. Dietrich[1]; S. Redik[2], S. Postrach[1]; A. Roncaglia[1]; G. Reif[2]

[1]RHI Glas GmbH, Wiesbaden, Germany; [2]Technologie Center, Leoben, Austria

Silica ($SiO_2$) dry vibrating mixes with sintering additive boric acid or boron oxide ($B_2O_3$) are the standard refractory lining products used for crucible induction furnaces in the iron foundries worldwide. The sintering agent is used to control the reaction with $SiO_2$ that forms a melt phase on the surface of the grains, which protect the refractory linin g, reduces infiltration and extend the campaign life of the lining. Though, the sintering agents have shown a high performance of the refractory lining life, they are classified as reproductive toxicity "1B" to humans, presents challenging health effects and environmental disposal problems. Currently delivered products are labeled with 1B and regulatory institutions are proposing a further reduction in concentration of less than 0.3 % $B_2O_3$ in all products.

This paper presents recent developments on a novel sintering agent for $SiO_2$ refractory lining products. The sintering additive is not classified by legislation and is envisaged to minimized health risks to humans and the environment. For a better evaluation of the suitability of the novel sintering agent for binding the $SiO_2$ matrix, a chemical and mineralogical analysis was performed with lining samples hammered from the furnace. Field applications revealed equivalent performance comparable to current sintering agents.

# DEVELOPMENT OF A HIGH–TEMPERATURE–TES SYSTEM USING REFRACTORY MATERIALS FOR LONG–TERM STORAGE OF RENEWABLE ENERGY

## ABSTRACT

With rising energy prices and the expansion of renewable energy sources, the ability to store energy reliably and cost-effectively is becoming increasingly important for homes and industry. Thermal energy storage (TES) is an option for storing thermal energy and converting it back to electricity. The advantage of this storage method is that it is comparatively inexpensive and poses no risk to the environment in the event of possible disasters such as fire, flood or earthquake [1].

This research is concerned with the design of a sensitive high-temperature TES system (Fig. 1) that can be further developed to provide a self-sufficient power supply for a four-person household using photovoltaics. There are no moving parts or other sensitive, complex components inside the TES, and recirculation is enabled solely by thermal radiation. To this end, computational fluid dynamics (CFD) simulations are being carried out and a demonstrator made of industrial refractory materials is being built. Two different refractory bricks for storage and four different insulation materials were used in the construction of the TES unit. The two refractory brick variants for the storage core are based on fireclay and corundum bricks, which have specific thermal conductivities and heat capacities. The wall insulation was made of two different microporous silicate boards and a high temperature insulation wool. The properties of these refractories were characterised to assess their suitability. Thermocouples were placed in different areas of the TES unit to record the temperature in the core and wall insulation during the initial heating process over a period of four weeks. This allowed the system-related heat capacity and thermal conduction to be determined. The data obtained was fed into the previous model and used in the CFD simulation for further optimisation.
The results - after 4 weeks of cyclic heating - showed that the thermal energy was successfully delivered to the refractory storage core with the required temperature distribution. However, as expected, the wall insulation was too thin, so the thermal insulation was not sufficient for complete heating. The measured temperature values could be transferred to the CFD simulation and used for further virtual designs.

Energy storage options are an important aspect of the current energy transition. The focus is on cost, safety and versatility. In addition to electrical, mechanical and chemical energy storage systems, thermal energy storage systems are particularly well established. TES is divided into latent and sensible heat storage, with latent heat storage storing and releasing thermal energy via a change in aggregate state and sensible heat storage via a change in sensible temperature. For this project, a sensitive high-temperature solid state thermal storage system was chosen. Compared to the other storage options mentioned above, it is characterised by low cost, high storage density, almost unlimited application possibilities and low risk. For example, electrical or chemical storage systems such as batteries are very expensive [2]. Positional (mechanical) energy storage systems, such as pumped storage power plants, are not flexible or are tied to local conditions and are expensive to install. Latent thermal energy storage systems, for example molten salt storage, have high requirements for the materials used, which in turn lead to high costs and, in the event of damage, pose a certain potential risk to people and the environment [3].

The TES used here was initially designed for a 4-person household in a single-family house in Berlin in such a way that, after further optimisation of the thermal insulation, a permanent self-sufficient power supply is possible.

The thermal energy is fed via heating wires into a central cavity (furnace chamber), which is heated by the electricity fed supplied by the PV system and released for recirculation by pure radiation through an opening in the ceiling above. The storage core, which is divided into two sections (inner and outer), is located around the furnace chamber and is itself surrounded by wall insulation. The opening over the furnace chamber can be assumed to be a black body according to Planck's law of radiation if the temperature distribution in the cavity below is homogeneous [4]. Thus, a Stirling engine or a liquid to be heated for a steam turbine can be placed on top of this opening and heated by thermal radiation. The TES must not fall below a certain minimum temperature in order to ensure sufficient re-powering when required. Similarly, the TES must not be heated above a maximum temperature to protect the materials used from thermal failure.

At the same time, a CFD simulation was carried out to verify the design of the TES and to test the influence of various conditions such as ambient temperature and feed rate. Subsequently, the simulation allowed further dimensioning in relation to the wall insulation and application for future development.

## EXPERIMENTAL

For the experimental implementation, the dimensioning of the TES with the available materials was first determined based on solar irradiance and electricity consumption measurement values. With the CFD simulation, the functionality of the storage could be

*Fig. 1: CAD-Modell of the TES with the storage core and the surrounding insulation.*

mapped over a longer period of time. With the real measured temperature values and the thermal properties calculated from them, the simulation could be used for further optimisation of the TES.

**Calculation for TES dimensioning**
The TES should be of suitable size for a detached house while having a square base. The furnace chamber should be centred in the middle of the TES area with a square side length of approximately 50 cm (Fig. 2).

*Fig. 2: Top view of the central TES cavity.*

For the design of the heat storage system, the electricity consumption of a 4-person household was compared with the electricity production of a PV system of a single-family house. For this purpose, the measurement data of the solar irradiance (University of Applied Sciences Berlin) on a conventional photovoltaic system of a single-family house in Germany (south orientation, tilt angle: 35°, surface area: 45 m², PV efficiency: 0.2, maximum power: 240 Wp) over a period of two years were evaluated [5]. The measured values for the electricity consumption of this single-family house were taken from the standard load profile of the VDEW [6]. In this way, the exact amount of energy fed in or consumed could be determined at 15-minute intervals, with the respective differences in the course of the day and night, as well as the influence of the different seasons.
The efficiency of the re-conversion was set at ηws = 0.2 (e.g., Stirling engine) and the maximum operating temperature of the storage tank was set at 1100 °C, while the minimum temperature was set at 400 °C.

**Materials**
The storage core was built around the furnace chamber using two different types of bricks: Corundum bricks measuring 254 x 62 x 66 mm (REFRAL® B 85, REFRATECHNIK), which have a high thermal conductivity and heat storage capacity, were used inside the storage core, while fireclay bricks measuring 250 x 124 x 64 mm (BURTON® 40 T, REFRATECHNIK), which have a lower thermal conductivity and heat storage capacity, were used in the outer storage core. The fireclay bricks provide a thermally storage and insulating transition to the wall insulation. From the inside to the outside, the wall insulation around the storage core consists of high-temperature wool 2.5 cm thick (Fiberfrax® Durablanket® S, Unifrax), rice husk ash panels 0.8 x 0.8 x 0.07 m (Prolite® 125/26 LC-S, REFRATECHNIK) and highly porous calcium silicate panels 1500 x 1250 x 50 mm (Silcal 1100, Silca).
The inner storage core was made of corundum bricks and the outer one of fireclay bricks. Two (side walls) or three panels (ceiling) of rice husk ash and high temperature insulation wool were placed around the storage core. Finally, the outer wall was made of two layers of calcium silicate boards. The side wall panels were fixed with steel straps.

The thermal conductivity and heat capacity of each material are listed in the Tab. 1.

Tab. 1: Heat conductivity and Heat Capacity of the used materials.

| | Heat conductivity at 1000 °C [W/(m·K)] | Heat capacity At 1000 °C [kJ/(kg·K)] |
|---|---|---|
| REFRAL® B 85 | 2,45 | 1,25 |
| BURTON® 40 T | 1,40 | 1,22 |
| Fiberfrax® Durablanket® S | 0,28 | - |
| Prolite® 125 | 0,32 | 1,16 |
| Silcal 1100 | 0,18 | 1,09 |

During construction, more than thirty thermocouples (type K) were installed in the TES at various points in the cavity, storage core and wall insulation, and the temperature curves were recorded by a data recorder throughout the test procedure. From these measurements, the material data in Tab. 1 could then be used to determine the stored energy and the heat transport through the TES to the point of heat loss to the environment.
The TES was heated for 8 hours daily, except for holidays (Easter) and weekends, over a period of 32 days with 25 heating days (heating period: 12.04.-14.05.2022). To investigate the influence of highly reflective materials on the insulation effect within the wall insulation, two non-area-covering steel plates were installed in the ceiling and floor insulation. In addition, on the 18th heating day, the entire TES was wrapped in aluminium foil.
Theoretically, the TES was designed so that in its final state with optimised wall insulation, at a temperature of 1100°C in the storage core, it would emit 140 W/m² of thermal energy to the environment (25°C) via the wall insulation.

**Flow simulation**
For the flow simulation, the TES was made as a CAD model and the heating and holding process was simulated in a CFD simulation with the given dimensions and material data. The three heat transport variants of radiation, (natural) convection and conduction were considered in the calculation. Literature values were used for the emissivities [7]. Cyclic heating (8 hours per day) with different input powers up to the maximum temperature of 1100 °C and cooling at different ambient temperatures were then investigated. The simulation included simplifications, neglecting certain undesirable gap dimensions due to the construction, in order to represent a perfect construction of the TES without thermal bridges. The conductive influence of the steel sheets was also not taken into account in this simulation, as they were thermally too thin for the flow simulation. However, the surfaces of the steel sheets were included in the simulation for radiative heat transfer processes.

**RESULTS**
The calculation using the above specifications gave a maximum storage capacity of 2750 kWh for the TES, giving a width for the square storage core of 1.63 m at a height of 1.12 m for a self-sufficient power supply (Fig. 3).

*Fig. 3: Curves of the amount of energy stored (black) and the temperature (grey) in the TES.*

The inner storage core around the square one, consisting of the REFRAL® B 85 bricks, had a thickness of 124 mm and that of the outer storage core built of the BURTON® 40 T bricks 435 mm. Overall, the storage tank had dimensions of 2.2 x 2.2 x 1.85 m at the outer edges.

After heating the TES for 8 hours on 25 days over a period of 32 days, the temperature curves in the storage core were as shown in Figure 4.

*Fig. 4: Temperature distribution after 25 heating days over a period of 32 days in the inner (black) and outer (grey) storage core.*

The temperature in the storage core stagnated at around 350 °C after 23 days, whereupon the TES was wrapped in aluminium foil after 24 days. This caused the temperature to rise to 420 °C within 3 days. Temperatures increased by an average of 19 °C per heating day during the heating process (8 hours), decreased by about 5 °C during the remaining 16 hours, and decreased by about 30 °C on cooling days. The stored heat energy in the storage core could be determined from the evaluation of further thermocouples. The curve of the stored heat energy over the 25 heating days is shown in Fig. 5.

*Fig. 5: Curve of the stored thermal energy in relation to the 25 heating days in the inner (black) and outer (grey) storage core as well as the daily amount of electricity fed in (dotted black line).*

After 25 heating days with a daily input of about 80 kWh, the TES contains about 800 kWh of stored thermal energy and has reached about 25% of its maximum storage capacity. During this period, approximately 2000 kWh of electricity was fed into the TES. The losses through the wall insulation could be determined from the measured temperature distribution in the storage core and the wall insulation. For the emitted heat flux densities through the central ceiling area, the area through which the highest heat fluxes escape, the curve shown in Fig. 6 was obtained from the 10th heating day onwards.

*Fig. 6: Heat flux densities through the ceiling insulation from the 10th heating day.*

At a storage core temperature of approximately 350 °C, the heat flux is approximately 180 W/m². At 400 °C the heat flux density increases to 200 W/m². The thermal conductivity coefficient is approximately 0.19 W/m·K at a thickness of 0.35 m through the entire ceiling insulation.

The influence of steel sheets could also be assessed by evaluating further thermocouples. Fig. 7 shows the heat flux density curves through the ceiling insulation. Square steel sheets with an edge length of 1.15 m were placed centrally in the ceiling insulation between the high-temperature rolls (central recess for the furnace chamber opening) and the heat transfer in this area and the edge area without steel sheets was measured with thermocouples. As the steel sheet ceiling area is centrally located and therefore in the immediate vicinity of the furnace chamber, higher temperatures prevail here, resulting in generally higher heat flux densities.

*Fig. 7: Course of heat flux densities through areas with (black) and without (grey) steel sheets in the ceiling insulation.*

While the heat flux density through the steel plates in the temperature range of 350 - 400 °C remains constant over time in the range of 165 W/m², the curve of the heat flux density without steel plates increases from 50 W/m² to 125 W/m². After wrapping the TES with aluminium foil, the heat flux through the steel plates increases less than the heat flux through the area without steel plates.

Using computational fluid dynamics (CFD), it was possible to set up the same heating cycle as the real one. Figure 8 shows the temperature distribution in the storage core (without wall and ceiling insulation) after the 2nd and 3rd heating days.

*Fig. 8: TES models with a CFD-simulated temperature distribution after two (left) and three (right) heating days.*

The temperatures in the TES storage core range from 73 °C to 138 °C after two heating cycles and are between 98 °C and 198 °C after three heating days. The actual measured values are approximately 20 °C lower than the simulated values with a similar distribution.

**DISCUSSION**

The results confirm, as expected, that the wall insulation of the TES is not sufficient to provide a self-sufficient energy supply for a 4-person detached house. However, the basic principle of storing thermal energy in refractory bricks seems to be an adequate method of energy storage, as the temperature is distributed centrally around the furnace chamber. The corundum and fireclay bricks absorb the thermal energy sufficiently to prevent the furnace chamber from

overheating. In addition, the heating cycles used here, where the maximum power (based on the PV system mentioned above) is fed into the TES for 8 hours a day, rarely occur in practice.

The wall insulation would have to be approximately 1.45 m thick at the calculated thermal conductivity coefficient of 0.19 W/m-K at a temperature of 1100 °C, if the thermal conductivity coefficients remained constant. However, with the materials used, the thermal conductivity coefficient increases with higher temperature, so it can be assumed that the wall thickness required for this design would have to be up to 2,3 m thick at 1100 °C in order to dissipate a maximum heat flux density of 140 W/m² to the environment.

The CFD simulation shows that for the same heating cycle, the temperatures in the virtual TES are higher than the measured temperature by thermocouples installed in the real TES. The heat flux densities in the simulation are also approximately 10 W/m² lower. These differences are due to the missing gap dimensions in the simulation, which were caused by design errors in the real TES.

Thermal energy loss was reduced by the aluminium foil, which acts as a reflector of thermal radiation. The aluminium foil also created gaps in the sheathing, offering potential for improving the insulation effect. The reflective effect of high emissivity surfaces was also evident in the use of steel sheets in the ceiling insulation.

If the wall insulation were increased to achieve a maximum average heat flux density of 140 W/m² from the TES, the TES demonstrator would be capable of providing electricity to a 4-person detached house all year round. The materials used for the wall insulation appear to be suitable for this application, in particular the transition from the high temperature resistant and mechanically stable Prolite® 125 panels to the Silcal 1100 panels placed on top, which have a lower strength and maximum operating temperature, but a lower thermal conductivity. Between the panels, the high temperature insulation wool act as a suitable filler for the gaps between the panels. In a gapless construction, the wall insulation consisting of these three layers would have to be approximately 2,3 m thick at an operating temperature of 1100 °C, making this TES unsuitable for use in a detached house. By using polished metal sheets, such as aluminium foil and steel sheet, the insulating effect of the wall insulation can be increased, thus reducing the required wall thickness.

The refractory materials used were able to deliver the expected performance at comparatively low cost, in particular the positioning along the TES brought the desired temperature distribution. To avoid the resulting gaps between the storage core and the insulation, a refractory cast concrete can also be used here, which would also simplify the one-off construction.

However, it is also useful to use a higher scaling for the TES, for example for a housing estate consisting of several houses, since the storage volume increases by a power of 3 and the area to be insulated increases by a power of 2. For this purpose, the CFD simulation generated with the real data can be used to determine the behaviour of the TES for different construction and environmental scenarios. The real TES can then be further developed and compared with the simulated values. In this way, different refractory materials - both shaped and unshaped - can be simulated to efficiently verify suitable materials that offer the best possible performance at a reasonable cost.

## CONCLUSIONS

Through this series of tests, a practical demonstrator has been built which can be used for further development for self-sufficient power supply by the TES. Especially in combination with flow simulation, this goal can be achieved as efficiently as possible.

Although this TES is not yet sufficiently insulated to make this possible, the principle of storing thermal energy in refractory bricks with subsequent storage based purely on radiation seems to be a useful alternative for the important issue of energy management today.

## ABSTRACT

In this study the influence of parameters like heating rate, $N_2$ gas flow and dwell time on the kinetics of the nitridation process were investigated. A combination of *in situ* and *ex situ* methods was used with special focus on the spatial formation of nitride phases. Centerpiece of the experiments was a new thermogravimetric nitridation furnace, capable of firing in $N_2$ atmosphere up to 1500 °C which was built at the Forschungsgemeinschaft Feuerfest e. V. Samples treated in this furnace were analyzed by Raman spectroscopy and scanning electron microscopy (SEM). Both methods provide details on the local formation of nitride phases. SEM analysis was used to determine the morphology of formed phases while Raman spectroscopy is capable of providing spatially resolved mineralogical data. Therefore, it was possible to differentiate between the various nitride phases and silicon nitride polymorphs. With this approach of combined *in situ* and *ex situ* methods, new insights into the formation process of nitride phases within nitride bonded silicon carbides were gained.

## INTRODUCTION

Nitride-bonded silicon carbides (NBSC) are important refractory materials used in various applications. They have high resistance to corrosion and wear and do not react with metal melts, making them an ideal material for the lining in aluminum electrolysis cells [1, 2]. In waste-to-energy plants, NBSC is preferred because of its excellent oxidation resistance and high thermal conductivity [3, 4]. The latter is particularly important for an efficient use of heat exchangers. Typically, the production of NBSC involves the direct nitridation of silicon carbide grains and silicon powder in a controlled nitrogen atmosphere at temperatures up to 1600 °C. This process results in the formation of a composite matrix of different silicon nitride (SN) phases through the highly exothermic reaction:

$$3\ Si_{met} + 2\ N_{2(g)} \rightarrow Si_3N_4 \ [5, 6] \qquad (1)$$
Due to recent crisis, energy prices have increased and there is a growing focus on reducing the environmental impact in almost all industrial sectors. As a result, energy consumption in high-temperature production lines has become a major concern. For the production of NBSC, it is essential to understand the factors that influence the formation of the matrix phases. Parameters such as nitriding temperature, heating rate and $N_2$ gas flow were identified to have a high potential in reducing the carbon footprint and cost of NBSC products. This study aims to investigate the effect of different firing profiles, including varying firing rates and $N_2$ gas flow rates on the silicon conversion and local phase composition. In addition, the influence of the exothermic reaction on these parameters was investigated.

## METHODS

Green bodies were prepared from metallurgical grade silicon powder (98.5 %, FeO: 0.7 %, metallpulver24.com) and different SiC grain sizes (98.5 %, ESK-SiC). For every green body the components were mixed in the ratios given in table 1. Uniaxial pressing was carried out with 300 kN to form cylindric bodies with a height of 50 mm and 50 mm diameter. Included within the pressing mold is a mandrel to later insert a thermocouple into the sample center.

The in-sample thermocouple is part of a set of thermocouples within the newly designed furnace and is intended to provide information on the exothermic heating within a sample during nitriding. A total of four thermocouples are included in the furnace for temperature control (Fig. 1). In addition to the thermocouples, the furnace was equipped with a unit for thermogravimetric (TG) measurements, comprising of a scale and a weighing plate for one cylindric sample. Prior to nitriding, samples were treated at 500 °C for 5 h to allow debinding.

Tab. 1: Standard composition of the green bodies.

| Components | Proportion in Ma.-% | Weigh-in in g |
|---|---|---|
| E-REFSIC98E 0 – 0,06 mm | 10 | 25.0 |
| E-REFSIC98 0 – 0,2 mm | 14 | 35.0 |
| E-REFSIC98 0,2 – 0,5 mm | 16 | 40.0 |
| E-REFSIC98 0,5 – 1 mm | 17 | 42.5 |
| E-REFSIC98 1 – 2 mm | 27 | 67.5 |
| Silicon 45 µm | 16 | 40.0 |
| SUM | **100** | **250.0** |
| Hoechst Wax C | | 1.0 |

Different firing profiles were carried out with heating rates of 1 K/min, 3 K/min and 5 K/min in the nitridation furnace (P1 - P3, Tab. 2). For each nitridation experiment, the heating rate was set to 3 K/min up to 1250 °C and then set to the respective rate. In order to hinder the formation of oxide bearing phases and focus on the formation of silicon nitride, oxygen concentration was kept at $10^{-18}$ % $O_2$ and monitored during the whole process. For P3 at 1 K/min the $N_2$ gas flow rate was varied between 25, 40, 45 and 50 l/h ($N_2$ 99.999 %). The accuracy of the new system was tested in a reproducibility test for which the samples were fired at 3 K/min to 1450 °C and then held at this temperature for 8 h. At the end of a profile, the furnace was switched off and no active cooling of the samples was performed. However, the $N_2$ gas flow was maintained to a temperature of 100 °C. After nitriding, open porosity was determined after DIN EN 993-1 and all samples had an open porosity between 19.6 and 19.8 Vol.-%.

*Fig. 1: Schematic drawing of the test stand used in this study. A weighing unit and multiple encased thermocouples were placed inside the furnace. One of the thermocouples is inserted into the sample.*

The microstructure of the matrix was studied *ex situ* with a SEM running at 15 kV. To identify phases by their morphology SEM

images were taken on the surfaces of sawn samples. In addition, the mineralogical phase composition of the matrix was studied by Raman spectroscopy. For both methods, analyses were conducted at the center and edge of the samples.

Tab. 2: Overview of the different firing profiles with their respective steps and dwell times. Each profile was run at 1, 3 and 5 K/min.

|  | Step 1 [°C] | Dwell time 1 [h] | Step 2 [°C] | Dwell time 2 [h] | Step 3 [°C] | Dwell time 3 [h] |
|---|---|---|---|---|---|---|
| P1 | 1450 | 2 | 1400 | 6 |  |  |
| P2 | 1350 | 4 | 1450 | 4 |  |  |
| P3 | 1350 | 2 | 1400 | 2 | 1450 | 4 |

## RESULTS AND DISCUSSION
### Thermogravimetry and thermochemistry
The final mass gain for all combinations of different heating rates, $N_2$ gas flow settings and firing profiles, ranged from around $9.31 \pm 0.18\,\%$ to $10.00 \pm 0.18\,\%$. This equates to the conversion of approximately 87 to 93 % of the starting silicon. The onset of the nitridation reaction can be observed after 7 to 7.5 h in all experiments, corresponding to a temperature between 1300 and 1350 °C. In all profiles the rate of mass gain begins to slow down rapidly at the end of the last stage and drops to zero when cooling is initiated. After 18 to 19 h no further mass gain is detected in any of the profiles, indicating a complete stop of the nitridation reaction. The highest mass gains were measured for heating rates of 1 K/min and the highest mass gain overall was detected for P1 at 1 K/min. It is noticeable that every increase in temperature causes an increase in the rate of mass gain, whereas a temperature decrease has no influence on the mass gain rate. Furthermore, neither increase nor decrease of the mass gain were observed in experiments varying the nitrogen gas flow (Fig. 2).

Fig. 2: The temperature at the sample center ($T_S$, dashed line) and the absolute mass gain (MG, solid line) are plotted for P3@1 K/min running at different $N_2$ gas flow rates with the furnace temperature ($T_c$) as a solid red line. In addition, the mass gain rate for a gas flow of 50 l/h is depicted as an example.

The temperature measurements at the sample center revealed the strongest exothermic peaks in P1 shortly after the transition from firing to the isothermal stage. Additionally, the other two profiles led to the observation, that smaller temperature steps at lower heating rates decrease the exothermic temperature peaks and at 1 K/min no exothermic peaks were detected at all.

A slight decrease of the sample temperature, indicative of an endothermic reaction, was recorded in all experiments at a temperature of 1400 to 1410 °C. This can be ascribed to the melting point of silicon at 1409 °C and the onset of a silicon melt formation.

## Microstructure
The matrix of all samples is dominated by $\alpha$-$Si_3N_4$ in its 'matte' morphology, while the presence of $\alpha$-$Si_3N_4$ whiskers as well as $\beta$-$Si_3N_4$ prisms depends on the spatial position and firing conditions. It was observed, that a high firing rate reduces the number of whiskers and decreases their size. Whiskers are still present at 5 K/min heating rate, but they appear primarily in larger pores. This is also the case when comparing the sample center and edge. Here, the number of whiskers decreases towards the edge of the sample. At the same time the amount of $\beta$-$Si_3N_4$ prisms increases (Fig. 3). The latter form by a liquid phase or a solid-gas reaction between silicon and nitrogen. Therefore, $\beta$-$Si_3N_4$ is often associated with a high grade of idiomorphism, because crystal growth takes place in the silicon with nitrogen diffusion through the hexagonal crystals [6]. The increased number of these idiomorphic $\beta$-$Si_3N_4$ prisms leads to the conclusion, that higher temperatures are attained at the sample edge and therefore more silicon has already transitioned to a liquid melt phase. The main finding with Raman spectroscopy was a higher amount of residual silicon at higher heating rates, especially at the sample center.

Fig. 3: SEM image of the matrix at the edge position in a sample fired with an $N_2$ gas flow of 45 l/h. $\alpha$-$Si_3N_4$ whiskers are present in larger pore spaces. In addition, $\beta$-$Si_3N_4$ prisms formed in areas where a silicon melt occurred.

## CONCLUSIONS
The $N_2$ gas flow rate has no influence on the overall silicon conversion in NBSC materials. However, lower heating rates increase the silicon conversion and SEM analysis revealed that the number of $\alpha$-$Si_3N_4$ whiskers increases at lower heating rates.

## ABSTRACT

Silicon Carbide (SiC) is a suitable material to be used in thermal exchangers, such as on the boiler walls in waste incinerators. Although SiC raw material is sometimes questioned due to its high carbon footprint and regulations, in the short term, there are no substitutes that can reach the high thermal efficiency and chemical resistance necessary in such applications.

Nowadays, in Japan, because of the lack of skilful bricklaying workers, and in order to reduce the maintenance downtime, castable lining is preferred over ready shaped lining such as bricks and tiles. Because of their high thermal conductivity property high SiC castables bonded with regular calcium aluminate cement require careful temperature control during the drying out process to avoid spalling which could occur because of the rapid water vapor pressure build up inside the castable. On the other hand, silica sol bonding technique gives refractories much higher permeability when heated up above the boiling point of water. Hence this bonding system gives a quick dry out feature to refractories, enabling shorter downtime than cement bonding system. Higher abrasion strength and higher duration than general cement bonded products can also be reached.

This paper reports the development of high SiC content refractories with silica sol binder. Results show that sol-bonded SiC showed a permeability record more than 20 times greater than the one of cement bonded products after drying out at 110 ℃, as a result, spalling was not observed on rapid heating tests. Regarding mechanical properties after sintering, sol-bonded SiC refractory achieved 30 % higher cold crushing strength compared to cement bonded castables.

## INTRODUCTION

Silica sol binder is a water solution of dispersed nanoscale silica particles, the particles are stabilized by pH control to prevent flocculation. Different from sodium silicate, which is commonly used as one of the alternative binders to alumina cement, the sol binder contains little alkaline elements, so it shows high refractoriness at high temperature when used as a binder. Refractory dry mix for sol-bonding does not require alumina cement, thus degradation of the dry mix during storage is less likely. For installation, in order to percolate the silica particles, alkaline powders are used as flocculators. They are mixed with the binder to shift the pH value. Cured strength of sol-bond castables is lower than cement castables because in cement bonded castables there are calcium aluminate hydraulic bonds between the castable particles. In other words, the sol-bonded matrix does not have chemically trapped crystalline water[1].

Hence, it does not need careful temperature control during the

first drying out[2], therefore a rapid drying out curve is applicable at the first heat up after installation. The downtime can then be reduced. For a 350-400mm thick lining, the dry out time can be reduced to about 12 hours, which is around half what is need for cement-bonded system.

Although there are many reports mentioning improvement of strength and usability of sol bonded refractories [3]-[6], discussions for anti-explosiveness used with high thermal conductive materials on rapid heating are very few. This report discusses the rapid heat up and spalling risk reduction of SiC based monolithic materials with silica sol binder. It shows the results of permeability measurement and moisture reduction dependency to drying temperature.

## EXPRIMENTAL

Five mixes are prepared for four types of measurements.

### Mix design

In order to evaluate the spalling risk reduction of silica sol-bonded SiC refractories which have high thermal conductivity, we prepared SiC low cement castables (LCC), bauxite LCC and sol-bonded bauxite as well as sol-bonded SiC. The mixes are compiled in Table 1. In this table, A, B are sol-bonded SiC, C is SiC LCC, D is sol-bonded bauxite and E is bauxite LCC. 0.03 wt% organic fibre is added into the sol-bonded mix, and 0.1 wt% fibre into the LCC mixes. For these five mixes, physical strength measurements, spalling tests and permeability measurements were determined.

### Physical strength

Kneading with either sol binder or water, the mix is casted in cuboid shapes according to JIS specification (40 x 40 x 160 mm$^3$), then cured for 24 hours in 90 %RH environment at 20 °C. After demoulding, the samples are dried out at 110 °C, then cold modulus of rupture (MOR) and cold crushing strength (CCS) is measured.

### Lab-scale explosion test

For this test the Chinese standard YB/T4117-2003 was used. The kneaded mix is casted into 50 mm diameter and 100 mm height cylinder shape, and cured for 24 hours. Then the demoulded sample is put into an electric furnace which is pre-set at 800 °C without dry-out step. The cylinder placed in the hot furnace experiences rapid heat up for 20 minutes. After exposure, inspection of appearance reports whether explosive spalling occurred.

### Permeability measurement

The same size cylinder as for the explosion test is prepared.

Tab. 1: The mixing design for the examination.

|  | A | B | C | D | E |
|---|---|---|---|---|---|
| SiC | 63 | 85 | 61 | 0 | 0 |
| Bauxite | 0 | 0 | 0 | 77 | 77 |

| E | 8 | 17 | 50 | 120 | 2.90 | 2.9 |

585

After demoulding, it is dried out at 200 °C for three hours, then cut into a 50 mm high cylinder. The permeability measurement is performed, following JIS R 2115. The flow rate of a nitrogen gas is recorded when the sample gets 10, 20 and 30 kPa differential pressure. The data is then converted into permeability values.

**Moisture reduction**

The physical properties after drying at 110 °C are described on Table 2. Modulus of rupture values for all samples are between 6 and 9 MPa, and CCS values are almost 50 MPa except for the SiC aggregate cement castable, which showed 90 MPa. The bulk densities (BD) for the SiC aggregate samples are approximately 2.5, and 2.9 for the bauxite ones. The thermal conductivity (TC) at 500 °C, which value depends on bulk density and SiC fraction, are on the right column, bauxite, SiC 60% and SiC 80 % are 3.0, 5.5 and 7.5 at 500 °C respectively.

**RESULTS AND DISCUSSION**

Explosive spalling occurs very fast, due to the surge of vapor pressure. The crack progression speed is related to the MOR. Thus, it is preferable that the MOR after drying at 110 °C is high. Among the samples tested on this set of experiment, MOR values are between 6 and 9 MPa regardless of the bonding system. Figure 1 shows the appearance of the SiC aggregate samples A, B and C after the explosion test. SiC LCC could not withstand this rapid heating and explosive spalling eventually happened. However, no cracks were found on the surfaces of the other four mixes. The explosion risk is strongly related to the balance of the thermal conductivity and the permeability.

Properties for A, B, D after firing at 1200 °C are superior to the conventional LCC C and E, particularly for the MOR results. Nanoscale colloidal silica and reactive alumina form a mullite matrix after firing. The matrix generates high strength for silica sol bonded refractory. In addition, the absence of lime prevents the formation of the low melting point components. Therefore a better abrasion resistance and a longer durability than the cement bonded SiC refractory can be expected at high temperature.

The heat curves for the samples of the explosion tests, in Figure 2, were estimated from the numerical calculation of a two dimensional heat conduction equation for cylindrical coordinates system under Crank-Nicolson Method. The equations are expressed as:

$$\frac{\partial T}{\partial t} = a\left(\frac{\partial^2 T}{\partial r^2} + \frac{\partial^2 T}{\partial z^2}\right) + \frac{Q}{c_p \rho} \tag{1}$$

Fig. 2: Calculated heat curves for three levels of thermal conductivities.

$$T_i^{n+1} = \frac{1}{2(1+c_r+c_z)} \cdot \left\{ c_r \left( \left(1+\frac{\Delta t}{2r_{i,j}}\right) T_{i+1,j}^{n+1} + \left(1-\frac{\Delta t}{2r_{i,j}}\right) T_{i-1,j}^{n+1} \right. \right.$$

$$\left. + \left(1+\frac{\Delta t}{2r_{i,j}}\right) T_{i+1,j}^n + \left(1-\frac{\Delta t}{2r_{i,j}}\right) T_{i-1,j}^n \right) + c_z \left( T_{i,j+1}^{n+1} + T_{i,j-1}^{n+1} \right.$$

$$\left. \left. + T_{i,j+1}^n + T_{i,j-1}^n \right) + 2(1-c_r-c_z)T_{i,j}^n \right\} + 2\frac{\Delta t}{c_p \rho} Q \tag{2}$$

$$a = \lambda/c_p \rho, \ c_r = a\Delta t/\Delta r^2, \ c_z = a\Delta t/\Delta z^2 \tag{3}$$

The differential equation was turned to the equation (2). Coefficients in the equations, $c_p$, $\lambda$, $\rho$, are material constants for heat transfer, $Q$ is radiation heat transportation between the kiln wall and the cylinder surface unit in Watt.

The sample cylinder in the calculation model, put in an electric kiln, receives heat from the kiln wall via radiation, then the heat flux flows inside the sample through conductive heat transfer. For these calculations, vaporization of the moisture and the moisture transfer is not considered. Calculation was done for 2 values of thermal conductivities, to mimic different SiC fractions. For the temperature at the center of the cylinder to reach 95 % of the pre-set furnace temperature (760 °C), it takes only 6.5 minutes for a thermal conductivity of 7.2 W/(m·K). This would correspond to a castable with 80 %SiC. When the thermal conductivity is 3.0

Fig. 1: Appearances of the samples after the explosion test.

Fig. 3: The moisture reduction of the samples after putting for 1 hour at each temperature.

Tab. 3: Results for the explosion test and the permeability measurement.

| | Explosion | Permeability | |
|---|---|---|---|
| | | $(10^{-16}\ m^2)$ | X / C (%) |
| A | No | 78 | 3100 |
| B | No | 53 | 2120 |
| C | Yes | 2.5 | 100 |
| D | No | 150 | 6000 |
| E | No | 2.1 | 84 |

W/(m·K), as for bauxite castable, it would take 13 minutes, which is twice as long. For a thermal conductivity of 5.5 W/(m·K), corresponding to the 60 %SiC castable, an intermediate value of 8.5 minutes is calculated.

These calculations show that the thermal transfer from the surface to the center of the cylinder is slowed down in the bauxite LCC because of the relatively low thermal conductivity. The heating rate is slower compared to SiC contained sample C. The stresses generated by the vapor pressure during the rapid heating does not exceed the MOR of the E sample. On the other hand, the permeability contributes to the explosion avoidance for sol-bonded SiC A and B samples. Their high permeability value is the reason for their explosion resistance, although they have a high thermal conductivity.

On Table 3, the sol bonded refractory showed a very high permeability indenpendant of the type of aggregate. Indeed, after the drying out of samples SiC A, B and bauxite D, the measurement gave 31, 21 and 60 times greater permeability respectively than SiC LCC named C. The residual moisture of these castables formulations after heat treatment can also contribute to the explosion resistance. Figure 3 shows the residual moisture as a function of drying temperature together with the saturation water vapor pressure. For these measurements the same cylinder shapes as for the explosion test were used. They were put in the furnace pre-set at a given temperature for 60 minutes. The water loss is calculated from the sample weight loss, before and after heat treatment. . Below the temperature where vapor pressure begins to surge, almost all moisture has vaporized regardless of the aggregate type. However, after drying at 200 ℃, the LCC sample still has 25 % residual moisture compared to the initial. This residual moisture which comes from crystallized water in the alumina cement hydrates causes explosive spalling of the refractory during rapid heating.

For the sol-bonded lab-scale sample, almost all the moisture is vaporized when the temperature of the body reaches 200 ℃ because there is no crystallised water. Besides, the permeability is over 20 times higher than the one of LCC, which makes it easier for the transfer of the vaporized water from backward. This also applies for industrial scale refractory bodies, of several hundred of kilogram[7].

## CONCLUSIONS

Through this report, we introduced the performance of the silica sol-bonded SiC refractory and its anti-explosiveness in comparison to LCC and to another type of aggregate.
Sol-bonded refractory has over 20 times high permeability compared to LCC, it shows excellent explosion risk reduction at the lab-scale, even if high thermal conductive SiC aggregate is used.

Colloidal silica and reactive alumina form a high strength mullite matrix after firing, and the absence of lime in formula prevents the creation of the low melting point components that may induce poor abrasion resistance and weaken the structure at high temperature.

Hence, this bonding system assures quicker dry out properties for refractories than classic cement-bonding system, enabling short downtime as well as higher durable performance at high temperature, even with high SiC content castable.

## ABSTRACT

Alumina chromium refractories are still amongst the best performing materials for the application in special waste incinerators and other furnaces with for example a high load of alkalies. On the other hand, typically a significant amount of the compounds that contain initially trivalent chromium oxide, turn during application into hexavalent compounds. This requires a special refractory waste treatment to minimize the health and safety risks associated with the water soluble hexavalent Chromium compounds. While for very high temperature fired bricks some Cr-free new matrix compositions have been developed already based on a new in-situ formed mullite-zirconia microstructure, this paper investigates, how such a microstructure can also be employed in aggregates and fillers to enable the formulation of bricks and monolithics without the need for very high pre-sintering temperatures.

In this context, a new synthetic aggregate has been developed. Special focus is given on the different types of raw materials as well as the process conditions necessary to reach the desired characteristics and innovative microstructure. Performance tests in castable formulations have been conducted to verify their behavior in application conditions. It will be shown that this novel sintered aggregate keeps a kind of microstructural memory of its original raw materials which is very beneficial for its thermomechanical behavior compared to a standard zirconia mullite aggregate produced through the electrofusion route.

## INTRODUCTION

Althought the alumina chromium refractories still remain amongst the highest performing materials for the application in special waste incinerators and other furnaces with for example a high load of alkalies [1], the drawbacks linked to the necessary special treatment of refractory wastes due to the presence of water-soluble Cr VI motivate more and more the search for alternative Cr-free solutions. In particular, new zirconia-mullite based materials, obtained by electro-fusion or sintering, seem to have a high potential in this role as shown by Bouchetou et al. [2], Chotard et al. [3] and Rendtorff et al. [4], regarding the thermal shock resistance and/or corrosion tests.

The present paper deals with the synthesis at laboratory scale of sintered zirconia-mullite (SZM) materials dedicated to be used as aggregates in refractories. The effect of those SZM materials will be evaluated in terms of thermal shock resistance (TSR) and slag corrosion resistance of SZM-based refractories.

## MATERIALS AND METHODS

The raw materials and their characteristics are described in the following tables (Tab. 1). The zircon flour and alumina (smelter grade) materials were from external sources, while the andalusite (Kerphalite KA) was from internal Imerys SA materials. Samples of coarse materials were previously ground down to under 100 µm prior to analysis, either for the chemical composition measured by X-ray fluorescence (XRF) with the Panalytical Zetium device on fused beads, or for the X-ray diffraction (XRD) performed with the diffractometer Bruker D8 Advance equiped with Detector Lynxeye XE-T, using Cu radiation and analysis within the 2θ range of 5-80°. The mineralogical composition was quantified with the software Topas R V6. The particle size distribution (PSD) was determined by the laser granulometer Malvern Mastersizer 3000 using the Fraunhofer model and powder dispersion pressure of 3 bar.

Tab. 1: Chemical composition and fineness of the raw materials.

| Raw materials | SiO$_2$ (wt%) | Al$_2$O$_3$ (wt%) | ZrO$_2$ (wt%) | Fe$_2$O$_3$ (wt%) | Total (wt%) | Fineness D$_{90}$ (µm) |
|---|---|---|---|---|---|---|
| Zircon flour | 32.5 | 0.8 | 66 | 0.1 | 99.4 | 4.8 |
| Alumina | 0.1 | 99.7 | 0 | 0 | 99.8 | 100 |
| Andalusite | 38.3 | 59.8 | 0 | 0.8 | 98.9 | 90 |

## SYNTHESIS OF SZM MATERIALS

The sintered zirconia-mullite materials have been synthesized by sintering a raw material powder mix containing zircon flour, alumina and andalusite. The ratio of the raw material components was chosen to achieve a total weigth ratio (Al$_2$O$_3$/SiO$_2$) close to that of the 3:2 mullite, so that the mullite formation may be maximized either from andalusite mullitisation or as secondary mullite from the reaction between silica and alumina. The raw mix of materials was prepared following two different processes prior to calcination. On the one hand, a wet process consisted of milling the raw materials in a jar mill with a certain quantity of water to obtain a fluid slurry. Afterwards, the obtained final slurry was cast into parallelepipedic steel molds (2x2x10 cm$^3$) and dried for 24 hours in an oven at 110°C before demolding. On the other hand, the mix of raw materials was dry-milled and was submitted to granulation in an Eirich mixer for 60 minutes. During this mixing, water was progressively added in order to form granules of around 1 cm diameter. Those granules were then dried in an oven at 110°C for 24 hours.

The dried materials from the two preparation processes were then placed in alumina saggars and calcined in an electric muffle furnace Nabertherm HT 128-17 at the same very high temperature. The SZM materials (SZM-1 from wet milling process and SZM-2 from granulation process) thus obtained were characterized regarding the bulk density (d) and open porosity (OP) which were determined by water immersion according to Archimedes' principle method, and the microstructural observations by Scanning Electron Microscopy (SEM) coupled with elemental analysis by Energy Dispersive Spectroscopy (EDS) on polished surface sections.

## RESULTS

### Sintered zircon-mullite materials characteristics

Tab. 2: Mineralogical composition, density and open porosity of SZM materials. m-ZrO$_2$ and t-ZrO$_2$ stand for monoclinic and tetragonal zirconia respectively.

| SZM materials | Zircon (wt%) | Mullite (wt%) | m-ZrO$_2$ (wt%) | t-ZrO$_2$ (wt%) | α-Al$_2$O$_3$ (wt%) | d (g/cm$^3$) | OP (%) |
|---|---|---|---|---|---|---|---|
| SZM-1 Wet milling | traces | 80.4 | 18.3 | 1.2 | 0 | 3.21 | 6.1 |
| SZM-2 Granulation | traces | 80.6 | 18.2 | 1.0 | traces | 3.11 | 8.4 |

It is to note the amorphous phases were not considered in the quantification of the mineralogical composition by the Rietveld method shown in Tab. 2. Nevertheless, the quantities found were not far from the values theoretically expected as shown below.

Indeed, it can be observed that $Al_2O_3$ and $SiO_2$ have been almost completely combined during the calcination, leading to a maximum content of mullite. As the mullite quantified by the Rietveld method was considered as the 3:2 mullite (3 $Al_2O_3$ . 2 $SiO_2$), its theoretical weight ratio ($Al_2O_3/SiO_2$) equals to 2.55, quite close to that of the recipe which is 2.69 calculated from the chemical composition of raw materials and their respective proportions in the recipe. So, the content of $Al_2O_3$ of the recipe is slightly in excess in comparison to the needed quantity of $SiO_2$ with respect to the composition of 3:2 mullite. Likewise, the zircon has been nearly totally decomposed to $SiO_2$ and $ZrO_2$ during the heat treatment, and $SiO_2$ reacted with $Al_2O_3$ to form Mullite whereas $ZrO_2$ remained as m-$ZrO_2$ mainly. Finally, andalusite and zircon have been quasi completely decomposed to form mullite and zirconia, leaving a very low quantity of residual silica as a potential amorphous phase.

According to Tab. 2 the two types of SZM materials have similar mineralogical compositions but with a slight difference in density and open porosity.

Fig. 1: SEM microstructure of (a) SZM-1 and (b) SZM-2 materials

Fig. 2: SEM microstructure of (a) SZM-1 and (b) SZM-2 materials

The SEM images of Fig. 1 and Fig. 2 show an example of microstructure of SZM-1 and SZM-2 materials after calcination at 1700°C. Both types of microstructures exhibit a dispsersion of zirconia grains (small white grains) in a matrix of mullite (grey parts), with pores in black. In both cases, the zirconia grains appeared smaller than 4 µm. However, it can be observed that the SZM-1 shows a more homogeneous dispersion of zirconia grains and a lower porosity with smaller pores than in SZM-2.

**Corrosion and thermal shock tests**
The two sintered zirconia-mullite materials previously obtained (SZM-1 and SZM-2) have been sized in different grades in order to be used as aggregates in refractory castables for thermal shock and slag corrosion tests.

The castable compositions shown in Tab. 3 are the two reference formulations which contain tabular alumina aggregates and differ by the grade of fine zircon sand ($ZrSiO4$). In total, 65 wt% of different grades of tabular alumina were replaced with the SZM materials as shown in Tab. 4, and the combination of the remaining alumina and zircon sand ($ZrSiO_4$) is expected to form in-situ mullite and zirconia.

Prior to thermal shock and corrosion tests, a pre-calcination at 1600°C was applied to the specimen according to the following thermal treatment profile after 24 hours drying at 110°C. The heating up was from 110°C to 500°C at 100°C/h, from 500°C to 1600°C at 300°C/h with a holding time of 6 hours. The cooling down was from 1600°C to 110°C at 300°C/h and then the specimens were exposed to ambient conditions.

Fig. 3: Examples of specimen of SZM-based castables dedicated to the corrosion test.

The SZM-based castables were also compared to two commercial alumina-chromium bricks, A and B. The characteristics of the different materials are shown in Tab. 5 and Tab. 6.

Tab. 5: Phase composition of commercial products. Mull stands for mullite and Am stands for amorphous phase.

| Comm. product | Phase composition (wt%) | | | | |
|---|---|---|---|---|---|
| | α-Al$_2$O$_3$ | (Al,Cr)$_2$O$_3$ | Mull | Am. | Eskolaite_Cr$_2$O$_3$ |

For the dynamic corrosion test, a synthetic slag has been made in laboratory according to an average composition of real slags from incinerator of municipal wastes (Tab. 7).

Tab. 7: Slag composition in weight percent

| Al$_2$O$_3$ | CaO | SiO$_2$ | MgO | Fe$_2$O$_3$ | SO$_3$ | Na$_2$O | TiO$_2$ | P$_2$O$_5$ | K$_2$O | Cl | Tot. |
|---|---|---|---|---|---|---|---|---|---|---|---|
| 11.2 | 32.1 | 34.0 | 2.3 | 4.3 | 2.5 | 3.8 | 1.6 | 4.7 | 0.9 | 2.7 | 99.9 |

The corrosion was performed with a dynamic Finger test consisting of immersing 115x25x25 mm$^3$ specimen into fused slag at 1350°C

while rotating for 2 hours. The slag resistance was evaluated by the erosion size (width variation along the length of specimen after corrosion test) and penetration degree (visual examination of cross sections).

Fig. 4: Visual aspect of specimen after corrosion test, the up part shows the whole samples and the bottom part their cross-section.

The thermal shock test was performed on specimen of 160x40x(25~30) mm$^3$ at 950°C for 30 minutes and at 1, 3, 5, 7, 9 cycling times with 5 minutes air quenching followed by Young's modulus (E-Mod) determination by impulse excitation of vibration for E-Mod residual retention rate. For the modulus of rupture (CMOR) after thermal shock, the samples of 160x40x40mm$^3$ were submitted to 950°C for 30 minutes and 5 continuous cycling times with 5 minutes air quenching and evaluated by CMOR for residual retention rate.

The evaluation of erosion size and anti-penetration is much subjected to uncertainty and must be confirmed by microstructure analysis by SEM-EDS techniques. However, the values of Tab. 8 indicate that the SZM-based specimen have underwent the most important erosion, but had also the best anti-penetration.

Tab. 8: Width variation and visual examination of specimen after corrosion tests

*Fig. 5: Young's modulus as a function of thermal shock cycle*

*Fig. 6: Young's modulus residual retention rate after thermal shocks*

It is noted that the B-specimen has shown the highest Young's modulus before thermal shock (Fig. 5), but also the most important loss of this modulus after each thermal shock cycling (Fig. 6). A remarkable performance of SZM-based specimen can be observed with the fact that their loss of Young's modulus is lower than that of the other samples from the first thermal shock, and that this elastic modulus remained stable along the thermal shock cycles.

Tab. 9: Mechanical strength and residual strength after 5 thermal shocks.

| | Before thermal shock CCS (MPa) | Before thermal shock CMOR (MPa) | After 5 thermal shock CMOR (MPa) | Residual CMOR rate (%) |
|---|---|---|---|---|
| **A** | 176 | 11.4 | 9.8 | 86% |
| **B** | >280 (*) | 40.4 | 6.6 | 16% |
| **SZM-1** | 121 | 19.5 | 15.3 | 78% |
| **SZM-2** | 125 | 17 | 19.8 | 116% (**) |
| **Ref 1** | 99 | 9.9 | 9.3 | 94% |
| **Ref 2** | 88 | 7.4 | 7.6 | 102% (**) |

(*) In Tab. 9, the cold compressive strength (CCS) of the specimen was higher than the value of the maximum limit of the device.
(**) The ratio between the modulus of rupture before and after the thermal shock is higher than 100% due to the uncertainty of the measure. In that case, the ratio may be considered equivalent to 100%.

The results show that the SZM-based formulations are only slightly impacted by the thermal shock cycles (Fig. 6, Tab. 9), indicating that their microstructure can cope very well with thermomechanical stresses preventing macroscopic damages.

**CONCLUSIONS**

Sintered zirconia-mullite (SZM) materials have been synthesized via two different processes regarding the raw materials preparation, either by wet milling or by granulation of fine andalusite, alumina and zircon sand. Both SZM materials exhibited a similar microstructure containing fine grains of zirconia well dispersed in mullite matrix. In addition, quantitative XRD has shown that the starting raw materials have been quasi completely reacted and combined during the high temperature calcination process, leading to a nearly maximum quantity of mullite and zirconia with traces of remaining uncombined materials. When submitted to thermal shock and corrosion tests, the castables containing SZM aggregates have shown high thermomechanical performances. In particular, a remarkable performance of SZM-based castables could be observed with the fact that their loss of Young's modulus is lower than that of the other samples from the first thermal shock, and that this elastic modulus remained stable along the thermal shock cycles.

Further characterizations on post-mortem samples will be conducted to investigate the phase composition and the texture of microstructure as a consequence of thermal shock cycles and of slag corrosion exposure.

# OXIDATION BEHAVIORS AND MECHANISMS OF SIC REFRACTORY MATERIALS USED IN MUNICIPAL WASTE INCINERATORS CONTAINING ANTI-OXIDIZING ADDITIVES

C. Lang*, S. Abdelouhab, F. Delobel, P. Pilate
BCRC-INISMa, Belgian Ceramic Research Center, Mons, Belgium

**ABSTRACT**
An oxidation test, based on the ASTM C863-83 standard was developed, allowing a sequential follow-up of the oxidation by mass variation measurement. An oxide bonded SiC material, mixed with different boron-based additives and a nitride-bonded SiC material (commercial tile) were tested in this testing device. The characterizations before and after oxidation (mass variation, C-content analysis, open porosity) allowed for the mechanism identification responsible of the material oxidation behaviour. The comparison of oxidation resistance between the samples tested are discussed based on the adjuvant and the observed oxidation behaviour, in comparison with the reference material. Some additives enhanced the oxidation resistance, whilst being easy to prepare, making them interesting for an industrial upscaling.

## INTRODUCTION

Nowadays, the incineration process of municipal wastes with energy recovery is both a way to reduce waste volumes and a way to produce energy. Waste sorting and management lead to an increase in their calorific value, as well as an increase in the combustion temperature in the furnaces. The combination of high temperature, ashes and corrosive gases induces serious oxidative and corrosive conditions. Therefore, the steel tubes of the boilers need to be protected with refractory materials [1, 2, 3, 4, 5]. Silicon carbide (SiC) shaped materials (bricks or tiles) are mainly used and fixed to the metallic boiler walls with steel anchors. The main advantages of using SiC products for this process are the high thermal conductivity of SiC, associated to the low thermal expansion and the high corrosion resistance of this material. Even with these properties, the harsh conditions encountered in the furnaces justify the ongoing research for new solutions to improve the durability of the linings and the SiC oxidation resistance.

It is well known that the nitride bonded SiC presents better resistance to oxidation and corrosion than oxide bonded SiC, but these materials need firing under nitrogen atmosphere thus leading to more expensive production costs [6]. Their use can only be justified in the higher temperature area of the furnaces. Oxide bonded materials are preferred in the remaining part at lower temperature and with less active corrosion. However, the oxidation of SiC to $SiO_2$ leads to some disorders due to the associated expansion.

In this context, the aim of this work was to incorporate some anti-oxidizing additives in the oxide bonded phase, in order to improve the material oxidation resistance. Boron based additives ($B_2O_3$ or $B_4C$) were selected. Indeed, the literature reveals that for some materials (for example cutting tools made of SiC) [7] boron-based compounds can be used as sintering additives to obtain a higher density after firing [8, 9, 10] and therefore a lower porosity [11] of the material due to a liquid sintering at lower temperature. In addition, $B_4C$ addition is also well-known acting as an anti-oxidizing agent in carbon containing refractory materials by oxidizing first, therefore preventing the material from early oxidation [12].

The oxidation performances of the new compositions developed and tested in this study has been compared to those of a nitride bonded SiC.

## MATERIALS AND METHODS

### Materials

*Nitride bonded SiC tile (Si3N SiC):*

For the establishment of the oxidation behaviour of nitride bonded SiC material, the commercial material used in this study is a REFRAX plus material supplied by Saint Gobain (France).

*Oxide-bonded SiC raw material composition:*
For the evaluation of the corrosion resistance of oxide bonded SiC material containing boron based anti-oxidizing additives, a commercial SiC reference mixture was supplied by Fire Technic SA.
The boron-based additives used were: $B_2O_3$ (Merck) and $B_4C$ (grade HD15, Höganäs). The contents added in the starting mixture were 0.5 wt% or 1.0 wt% for $B_4C$ and 1.0 wt% for $B_2O_3$ with respect to the weight of the starting mixture.

### Sample preparation

All samples were prepared by mixing the SiC reference mixture powder with the selected additive compound. Boron based additives were directly incorporated in the starting composition of the commercial oxide bonded SiC composition for an easier further industrial implementation without process production modification. The samples were prepared by filling a cylindrical mould (50 mm diameter 50 mm height), followed by uniaxial pressing (RT, 2 min, 200 kN) in the mould. Finally, the cylindrical shaped samples were fired at 1400 °C for 4h.
The sample identifications and their composition are presented in table 1.

*Tab. 1 : Description of the samples*

| Sample name | Composition |
|---|---|
| Ref SiC | Reference SiC, oxide bond |
| Si3N SiC | SiC, Nitride bond $Si_3N_4$ (commercial tile) |
| SiC05B4C | SiC, oxide bond + 0.5 % $B_4C$ |
| SiC1B4C | SiC, oxide bond + 1.0 % $B_4C$ |
| SiC1B2O3 | SiC, oxide bond + 1.0 % $B_2O_3$ |

The pressed and fired samples were machined in 2.5×2.5×2.5 cm³ cubes for oxidation tests.

### Characterization method

Density/porosity
The density and the porosity were obtained according to the standards EN 993-1 (Archimedes' principle), for samples before and after oxidation.

C-analysis
Samples of materials before and after oxidation were finely ground before chemical analyses (≤5µm). Carbon content was determined using LECO spectrometer for the calculi of silicon carbide contents.

Mass variation
The samples were weighted before and after oxidation for each 100 h cycle, the mass variation ($m_v$) was calculated based on the initial mass before oxidation ($m_i$) and the final mass ($m_o$) after 100 h oxidation cycles:

$$m_v(\%) = 100 \times \left(\frac{m_o - m_i}{m_i}\right)$$

### Oxidation tests

For the evaluation of the oxidation and corrosion tendencies, a vertical tubular furnace was used (figure 1). The working temperature was 1000 °C. Each oxidation test was conducted for 500 h under oxidative atmosphere (5 cycles of 100 h). For that, a

pump linked to a water tank allows water injection in the bottom of the furnace. In this case, the ASTM C863-83 standard was followed leading to 32 kg.m$^{-3}$.h$^{-1}$ of water flow in the furnace.

As a mass variation occurs during the oxidation of SiC into $SiO_2$ [6] (mass variation directly linked to SiC oxidation), the oxidation was followed by measuring the mass variation of the samples after 100 h oxidation cycles.

*Fig. 1: oxidation setup*

## RESULTS
### Oxidation tests
The results obtained during oxidation tests on reference samples and boron-containing samples are reported on figure 2.

*Fig. 2: Oxidation results*: **Si3N SiC**, **Ref SiC**, **SiC1B2O3**, **SiC05B4C**, **SiC1B4C** *based on mass variation*

First, the Ref SiC oxidizes slowly in a nearly linear way as it is shown through the mass gain curve figure 2.

Regarding $Si_3N_4$-bonded SiC, $B_4C$ and $B_2O_3$ containing samples, the oxidation profile can be divided in two stages. During the first cycle (100 h), a high oxidation rate is observed, linked to a high mass gain. Then, during the other cycles, the mass variation decreases. The curve becomes nearly linear with a lower mass gain indicating a lower oxidation rate.

The oxidation rate was estimated from the slope of the mass variation in the linear zone (from 200 h to 500 h oxidation) and is presented table 2.

*Tab. 2: Mass gain slope*

| Sample | Mass gain slope (×1000) wt% / h |
|---|---|
| Ref SiC | 1.3 |
| Si3N SiC | 0.6 |
| SiC1B2O3 | 1.6 |
| SiC05B4C | 1.2 |
| SiC1B4C | 0.7 |

The different samples can be ranked according to their oxidation rate, from higher to lower oxidation rate:

SiC1B2O3 > Ref SiC ≈ SiC05B4C > SiC1B4C ≈ Si3N SiC

### Open porosity
Figure 3 reports the comparison between open porosities (%) before and after oxidation (500h). The porosity variation is calculated in % relative to the initial porosity (before oxidation) of each sample.

*Fig. 3: Open porosities before and after oxidation*: **Si3N SiC**, **Ref SiC**, **SiC1B2O3**, **SiC05B4C**, **SiC1B4C** *and porosity variation compared to initial porosity before oxidation*

First by comparing the samples before oxidation, it appears that the porosity is similar for oxide bonded reference SiC and $Si_3N_4$ bonded SiC, and higher for the sample containing $B_2O_3$. The porosity is lower for $B_4C$ containing samples, indicating a better densification during firing due to the presence of $B_4C$ [8, 9, 10, 11]. Except for the Ref SiC, where the porosity after oxidation is similar to that before oxidation, for all other samples the porosity decreases after oxidation, indicating a pore closure phenomenon which takes place during oxidation.

### C-Analysis
C-analysis allows to calculate the amount of SiC in the samples before and after oxidation during 500h (figure 4).

*Fig. 4: SiC contents before and after oxidation:* **Ref SiC**, **SiC1B2O3**, **SiC1B4C**, **SiC05B4C**

First, it is important to notice that the initial SiC content (before oxidation) is higher for samples containing additives than for the Ref SiC. During sample preparation, the firing at 1400 °C was performed under air, and some small part of the SiC easily accessible could have been oxidized during this process. The additives ($B_2O_3$ and $B_4C$) already have a protective effect on SiC during the first heating of samples (the firing step) and play a role in decreasing SiC oxidation during firing, leading to higher SiC content after firing.

It appears that for all samples, the SiC amount decreases after oxidation test, indicating an oxidation of SiC to $SiO_2$.

## DISCUSSION
First, as mentioned before, looking at the oxidation results (figure 2) of reference samples, it appears that the Ref SiC oxidizes in a

593

linear way whereas the oxidation profile of SI3N SiC sample is divided in two stages with a higher oxidation rate during the first 100 h and then a lower oxidation rate indicated by the slope of the curve in the time range 200 h – 500 h.

Also as mentioned in the result section, for Ref SiC sample, the open porosity after oxidation is similar to that before oxidation, with only a slight variation: 7% loss of porosity. For Si3N SiC sample, the open porosity after oxidation is very low compared to that before oxidation with a 51 % loss of porosity (figure 3). This could be explained by the preferential oxidation of $Si_3N_4$ phase (bonding phase, located in the matrix) to $Si_2ON_2$, leading to pore closure during the first hours of oxidation [13, 14]. This pore closure limits the gas access in the sample, thus limiting the SiC coarse grain oxidation beyond 100 h of test leading to a low oxidation rate, $0.6.10^{-3}$ wt%/h that is the smallest rate observed in this study (table 2).

The SiC1B2O3 sample presents a similar oxidation profile as the Si3N SiC sample, with two stages. The open porosity is also lower after oxidation test than before. These results indicate a similar oxidation behaviour as that of nitride bonded material, with a pore closure during test preventing from gas penetration and thus a further SiC coarse grain oxidation. However, the oxidation mechanism of SiC1B2O3 can differ in the first 100 h from Si3N SiC. Indeed, the $B_2O_3$ present in the composition could react with silica coming from the SiC oxidation [15] during the first 100 h of the test to form a borosilicate viscous phase filling then the pores. With the enrichment in silica of the borosilicate phase while the SiC oxidizes in $SiO_2$, this phase becomes more and more viscous [16, 17]. At the end, the viscous glassy phase may slow down the oxidation rate with the porosity closure and the decrease in oxygen diffusion in the material microstructure as the viscosity of the borosilicate phase increases [18].

For SiC05B4C and SiC1B4C, the oxidation is still divided in two stages, with a higher oxidation rate in the first stage. Nevertheless, the oxidation rate of the first stage is less important than for previous samples (Si3N SiC and SiC1B2O3). The B4C is an anti-oxidizing additive, meaning that it first oxidizes to $B_2O_3$ and thus partially prevents the SiC from oxidation. Then, as for the SiC1B2O3, the $B_2O_3$ that is formed can oxidize the SiC to $SiO_2$ and produce the viscous borosilicate phase leading to pore closure as the viscous phase filled them. The borosilicate phase is enriched in $SiO_2$ as the SiC oxidizes, increasing the viscosity. As before, the closure of the porosity and the increase in the borosilicate phase viscosity slows down the penetration of gases and leads to a decrease in the oxidation rate during the second phase. It appears that the lower B4C content (0.5 % instead of 1%, respectively for samples SiC05B4C and SiC1B4C) leads to the same mechanisms but less marked with a higher mass gain slope in the second stage of oxidation, related to a higher porosity after 500 h under oxidation. This may be related to the lower amount of glassy borosilicate phase formed because of the lower amount of B4C. The SiC05B4C sample is therefore less resistant to the oxidation than the SiC1B4C one.

The SiC oxidized calculated from C-analysis (in %, related to initial SiC content) and the total mass gain are presented in table 3.

*Tab. 3: % of oxidized SiC related to initial SiC (before oxidation) and mass gain after 500h under oxidation*

| Sample | SiC oxidation (%) | Total mass gain (%) |
|---|---|---|
| Ref SiC | 0.7 | 0.8 |
| SiC1B2O3 | 10.8 | 2.2 |
| SiC1B4C | 5.2 | 1.1 |
| SiC05B4C | 7.5 | 1.6 |

When the samples are ranked from least to most oxidized regarding SiC loss in C-analysis: Ref SiC > SiC1B4C > SiC05B4C > SiCB2O3. It corresponds to the total mass gain after oxidation (figure 2 and table 3). By comparing this result with the oxidation curves, it is clear that the C-analysis does not take into account the

oxidation rate occurring during the second stage (figure 2), but only reflects the oxidized SiC after the whole test (500h under oxidation). The effective oxidation resistance should be better described only by the mass gain in second stage of oxidation and an extension of the trial would lead to an inversion of the trends observed for C-analysis and directly linked to the oxidation rates (mass gain in second stage of oxidation).

The SiC1B2O3 sample presents a high amount of initial SiC but also the highest loss of SiC (SiC oxidation, table 3), in accordance with the high mass gain during the first stage of oxidation (figure 2). The SiC05B4C and SiC1B4C also present a higher initial SiC content compared to Ref SiC, and a higher SiC loss (table 3) that is also correlated to the first stage of oxidation. Their SiC oxidation is much lower than for SiC1B2O3 sample and can be due to the protection and oxidation mechanism previously described: first oxidation of B4C to $B_2O_3$ preventing an early SiC oxidation then SiC oxidation by $B_2O_3$ progressively formed and closing the porosity by the viscous glassy borosilicate phase thus decreasing oxidation rate. In the end, the oxidation resistance can be estimated here from the oxidation rates obtained from mass gain (table 2). The sample containing 1 % $B_2O_3$ seems to have a higher oxidation rate than the Ref SiC, attributed to the additional oxidation of SiC due to the presence of $B_2O_3$. On the opposite, the B4C seems to have a positive impact on SiC oxidation, and the sample containing 1% B4C presents an oxidation rate very close to that of Si3N SiC sample (respectively mass gain slopes of 0.7 and 0.6).

**CONCLUSIONS**

This work sought to improve the oxidation resistance of oxide bonded SiC materials through the incorporation, in the composition, of some additives such as boron compounds.

The whole results showed that different mechanisms are implicated in SiC oxidation in the presence of different boron additives. This study showed the presence of a two stages mechanism for SiC oxidation in the presence of boron additives as for nitride bonded SiC material. The first stage concerns the formation of a glassy borosilicate phase, that leads to close the porosity, decreasing the oxidation rate in stage two.

Based on the slopes of second oxidation stage and on the low SiC oxidation, the sample SiC1B4C containing 1 % B4C seems to present the most interesting tendencies. This additive helps closing the porosity through the progressive formation of the glassy borosilicate phase during the first hours of oxidation and also the B4C oxidation preventing of an early SiC oxidation, leading to a high decrease in the oxidation rate and thus protecting the SiC from further oxidation. The oxidation rate measured with this additive is close to that for Silicon nitride bonded materials. Trials with content higher than 1 wt% of B4C should be performed to determine an optimum adding value of B4C as anti-oxidizing agent for oxide bonded SiC refractory materials used for lining of waste incinerator furnaces.

# DEVELOPMENT OF HIGH CHROME OXIDE GASIFIER REFRACTORIES – ONE STEP AHEAD TOWARDS CARBON NEUTRALITY

J. P. Nayak, B. Ghosh, R. Adhikary, H. Nagata, S. Sengupta, P. B. Panda

TRL Krosaki Refractories Ltd., Jharsuguda, Odisha, India

## ABSTRACT

Shaped refractory making and its uses, both are high energy-intensive one. Manufacturing of refractory products involve a large section of raw materials; most of the refractory raw materials require a large capacity of energy for their production, as it is not possible to use as such and needed at least crushing and screening, which often requires thermal processing. Based on an application; different type of refractory products manufactured by refractory makers, which are required to process at different temperature ranges by using fossil fuel mainly. As a result, refractory industry also contributing environmental burden up to some extent apart from other manufacturing industries, although percentage is very less. Now, the refractory industries are increasingly attentive and motivated to promote the functionalities which is much needed to support carbon neutrality program. In this context, present work describes the development of high chrome oxide ($Cr_2O_3$) gasifier refractory product, $Cr_2O_3$ content is more than 85.0%, which has been fired at lower temperature i.e., 1450 to 1550 ºC compared to chrome based shaped refractory products generally sintered at high temperature i.e., >1650 ºC. By the developmental process; manufacturing process and firing temperature has been optimized. Chemical analysis, physical properties, and thermal shock resistance of the product has been evaluated. Slag corrosion resistance of the developed product has been also carried out by using slag of gasifier run with feed stock of pet coke + coal.

Key words: Refractory, Chrome, gasifier, environment, carbon neutrality, corrosion

## INTRODUCTION

Coal gasification is a process of producing syngas - a mixture of CO, $CO_2$, $H_2$ and water vapour from coal and water in presence of air/oxygen [1].

$$3C \text{ (Coal)} + O_2 + H_2O \longrightarrow H_2 + 3CO + H_2O \longrightarrow CO_2 + H_2$$
While coal gasification itself can be an efficient way to produce energy, it does have implications for carbon footprint. It also helps to reduce carbon footprint when combined with carbon capture and storage technologies. So, the need to reduce greenhouse gases emision to the environment become more intense for sustainable energy solutions for all kind of manufacturing industries. To achieve carbon neutrality $CO_2$ must be reduced as much as possible and for industries those are dealing with very high temperature processing like refractory inducstries, their role is very significant here. Gasifications, an advanced thermomechanical conversion process, offers the potential to transform carbonaceous feedstocks like coal, tar, petcoke into valuable products such as syngas, hydrogen and biofuels. $CO_2$ is generated during gasification as minority process by-product [2]. Gasifiers with high-performance refractories can operate at higher temperatures, which improves energy efficiency. Higher temperatures enable more complete carbon conversion and enhance the overall process effuciency, reducing carbon footprint per unit of energy generated. Gasifiers suffer a lot of problems which limit their wide use due to degradation of working lining refractory of the inner walls of gasifier. Lining loss is due to the severe gasification environment involving high temperature, high pressure, reducing environment, and both physical and chemical attack by impurities in the carbon feedstock [2]. Due to operational severity of gasifiers, high chrome oxide refractory has been chosen because of its excellent intrinsic properties like corrosion resistance, thermal shock resistance, and thermomechanical strength.

This article mainly focuses on the develpment of high chrome oxide gasifier refractory body sintered at low temperature compared to in general sintering temperature of $Cr_2O_3$-Corundum shaped refractory, which is an innovative approcah to address the challenges associated with gasification technology and emission of greenhouse gases. Developed product plays a crucial role in supporting sustainable and environmentally friendly industrial processes as well as towards carbon neutrality aspect.

## EXPERIMENTAL STUDY

This study mainly discusses the development of low temperature fired high chrome oxide bricks for coal/coke gassifier reactor application. Developed product is resulting similar or little bit better properties compared to bricks fired at high temperature (> 1700 ºC). As a result energy consumtion in low temperature fired bricks is less, thus emision of greenhouse gases are also less to the environment.

The main raw materials used to develop the high chrome oxide bricks were synthetic chrome corrundum grains and chrome oxide powder along with special additive and binders. A series of recipes i.e. trial 1 (T-1), trial 2 (T-2), and trial 3 (T-3) were formulated, as tabulated in Table 1 using said raw materials in varying proportions to manufacture the bricks.

Tab. 1: Batch composition of bricks.

| Raw Materials (wt.%) | T-1 | T-2 | T-3 |
|---|---|---|---|
| Synthetic Chrome Corrundum (1) | 25 | 30 | 35 |
| Synthetic Chrome Corrundum (2) | 60 | 55 | 50 |
| Chrome Oxide | 15 | 15 | 15 |
| Additive | 1.7 | 1.7 | 1.7 |
| Binders | 2 | 2 | 2 |

The mixes were made in high intensity mixer machine and bricks were given into perticular shape by using high capacity hydraulic press. After drying at 110°C for 24 hours, dried bricks were fired in tunnel kiln at two different temperature i.e., >1700°C with 5 hours soaking i.e., High Temperaure Fired (HTF), and >1450°C with 6 hours soaking i.e., Low Temperature Fired (LTF).

## CHARACTERIZATION OF PRODUCTS

Fired bricks were characterised to evaluate the apparent porosity (AP), bulk density (BD), cold crushing strength (CCS), refractoriness under load ($t_a$) according to DIN standard. Hot modulus of rupture (HMoR), and permanent linear change (PLC) of developed bricks also tested at 1400 °C (soaking 30 minutes) and 1500 °C (soaking 180 minutes) respectively. Reversible thermal expansion (RTE) behaviour of brick samples also checked at 1500 °C with Dilatometer. Thermal shock resistance (TSR) of brick samples were estimated by adopting DIN method (at 950°C by water quenching). Slag Corrosion test has been carried out by using rotary drum slag corrosion test method at 1550°C with 1 hour soaking. Coal/coke gassifier slag sample was used during slag corrosion test. Corrosion test samples were further analysed by using X-ray diffraction (XRD) technique to know the phases developed in the interface area of reafractory body after corrosion test, and to understand the reaction mechanism between slag and refractory mass; microstructural study and elemental analysis were being performed by using scanning electron microscopy (SEM) and energy dispersive X-ray analysis (EDAX).

## RESULTS AND DISCUSSION

Chemical and physical properties analysis of three trials have been evaluated and summarized in Table 2 and 3 respectively.

Tab. 2: Chemical analysis of the fired brick samples.

| Constituents (wt.%) | T-1 | | T-2 | | T-3 | |
|---|---|---|---|---|---|---|
| | .>1700°C | .>1450°C | .>1700°C | .>1450°C | .>1700°C | .>1450°C |
| $Cr_2O_3$ | 88.65 | 88.53 | 89.39 | 89.27 | 89.38 | 89.28 |
| $Al_2O_3$ | 6.21 | 6.23 | 6.33 | 6.34 | 6.33 | 6.35 |
| $SiO_2$ | 0.39 | 0.40 | 0.27 | 0.28 | 0.27 | 0.27 |
| $Fe_2O_3$ | 0.32 | 0.32 | 0.33 | 0.35 | 0.35 | 0.35 |
| $TiO_2$ | 1.32 | 1.37 | 1.31 | 1.36 | 1.29 | 1.34 |
| CaO | 0.10 | 0.10 | 0.11 | 0.12 | 0.10 | 0.10 |
| MgO | 2.01 | 2.01 | 2.02 | 2.01 | 2.01 | 2.0 |
| $Na_2O$ | 0.11 | 0.12 | 0.06 | 0.07 | 0.06 | 0.07 |
| $K_2O$ | 0.01 | 0.01 | 0.01 | 0.01 | 0.01 | 0.01 |

Tab. 3: Physical properties analysis of the fired brick samples.

| Properties | T-1 | | T-2 | | T-3 | |
|---|---|---|---|---|---|---|
| | >1700°C | >1450°C | >1700°C | >1450°C | >1700°C | >1450°C |
| AP (%) | 18.1 | 17.7 | 18.0 | 17.3 | 16.3 | 15.7 |
| | 17.9 | 17.8 | 17.8 | 17.7 | 16.7 | 16.0 |
| BD (g/cc) | 4.01 | 4.03 | 4.02 | 4.05 | 4.04 | 4.08 |
| | 4.02 | 4.04 | 4.01 | 4.06 | 4.05 | 4.10 |
| CCS (Mpa) | 647 | 687 | 655 | 707 | 723 | 779 |
| | 635 | 703 | 678 | 717 | 737 | 763 |

From the chemical analysis, it is concluded that all samples are resulting similar chemical purity, but physical properties of T-3 bricks are better than others. Thus, further high temperature studies were performed by considering T-3 brick samples only, and test results are tabulated in Table 4.

Tab. 4: High temperature properties of T-3 brick samples.

| Properties | Unit | T-3 | |
|---|---|---|---|
| | | .>1700°C | .>1450°C |
| RUL($t_a$) | °C | 1740+ | 1740+ |
| HMOR at 1400°C | MPa | 3.1, 3.2 | 3.1, 3.3 |
| PLC at 1500°C/3 hrs. | % | +0.81 | +0.79 |
| RTE at 1000°C | % | 1.23 | 1.35 |

From the test results mentioned in Table 2, 3 and 4, it is concluded that both temperature fired bricks of T-3 are giving better results as compared to other two trials. It may be due to selection of materials with proper granulometry; T-3 gives significant improved results compared to others. Phase analysis of T-3 brick samples has been performed to understand the reason being of attaining the improved properties. Fig.1 (a) and (b) depicts the XRD pattern of high chrome bricks fired at high and low temperature respectively. Both HTF and LTF bricks are resulting similar type of XRD pattern, and dominant phase is only Eskolite.

Fig. 1: XRD Pattern of high chrome brick (a) HTF, (b) LTF.

Due to the severe and harsh application conditions of coal gasifier reactor, alumina chrome refractory has been choosen because of its excellent slag corrosion resistance and thermal shock resistance. Rotary drum slag corrosion test method was adopted to check the corrosion resistance of high chrome bricks. In this study, a hexagon was made with T-3 brick samples. Six samples were considered, where three from LTF (Sample no. 1, 2, 3) and rest three samples (Sample no. 4, 5, 6) were from HTF bricks. Slag was collected from a reputed coal gasifier industry for slag corrosion test and analysis of slag is summarized in Table 5.

Tab. 5: Chemical composition of gasifier slag.

| Components | Wt. (%) |
|---|---|
| $Al_2O_3$ | 12.79 |
| $SiO_2$ | 17.02 |
| $Fe_2O_3$ | 6.53 |
| CaO | 10.89 |
| MgO | 0.79 |
| $Na_2O + K_2O$ | 0.90 |
| NiO | 3.08 |
| $V_2O_5$ | 38.75 |
| $SO_3$ | 6.15 |

Slag corrosion study detail has been described sequentitally in Fig.2. Hexagon builted with the fired bricks as per schematic design and lined in rotary drum furnace, after then corrosion test was conducted. After completion of test, hexagon structure was dismentled, and individual brick sample pieces were sliced down to estimate the slag corrosion percentage.

*Fig. 2: Rotary slag corrosion test: from making of hexagon to getting slicing part of individual tested brick sample specimen.*

Slag corrosion test indicates that low temperature fired brick of T-3 is resulting better slag corrosion resistance due to formation of thicker interfacial area/band in between refractory body and attacking slag. Interfacial area is mainly dominated by the presence of vanadium-chromium (V-Cr) bearing spinel along with nickel, as confirmed by XRD analysis in Fig. 3. Formation of V-Cr spinel is more in LTF brick which enhances slag penetration resistance and limiting the ingress of corrosive slag components to the refractory matrix. Whereas in HTF high chrome brick interface band area as well as spinel formation is less compared to LTF high chrome brick, as a result penetration of slag is more. Slag corrosion test result is shown in Table-6.

Tab. 6: Slag corrosion test results.

| Sample ID | Sample No | % of Slag Corrosion (Avg.) |
|---|---|---|
| Low temperature fired high chrome brick | 1 | 5.41 |
| | 2 | 5.49 |
| | 3 | 5.43 |
| High temperature fired high chrome brick | 4 | 6.49 |
| | 5 | 6.51 |
| | 6 | 6.44 |

Porosity is a critical factor influencing both spalling and corrosion resistance. It is seen that LTF bricks are resulting little bit lower

porosity compared to HTF bricks. A low-porosity refractory material provides fewer pathways for the ingress of corrosive substances, such as gases or liquids, thereby improving corrosion resistance. On the other hand the reduced porosity minimizes the presence of voids or trapped pockets of gas, which can lead to spalling under thermal cycling conditions.

Fig. 3: XRD Pattern of interface portion of LTF high chrome brick sample after slag corrosion test.

Typical failure mechanisms found in gasifiers having a gas or liquid feedstock include thermal expansion or irreversible creep deformation, which occurs during rapid thermal cycling and leads to surface spalling or joint failure [3]. To estimate the potential of spalling resistance of developed bricks, thermal shosk resistance (TSR) test has been performed, and condition of tested brick sample specimen has been shown in Fig. 4. Both the samples are showing similar type of characteristics but it has been observed that LTF brick sample is resulting better TSR property as compared to HTF brick although having porosity slightly lesser than HTF one. This has happened may be due to rigidityness of HTF brick sample compared to LTF brick, since HTF bricks have been fired at quite high temperature. As a result, HTF test samples spalled after 15th cycle whereas, complete spalling occured after 17th cycle for LTF brick sample. High-temperature firing can induce significant thermal stress within the refractory material due to the large difference in temperature between the firing process and subsequent operational conditions. This thermal stress can promote crack initiation, propagation, and subsequently spalling. In contrast, low temperature firing minimizes the thermal stress generated, leading to improved resistance against spalling.

Fig. 4: Status of HTF and LTF brick samples after TSR test.

On the other aspect, during high-temperature firing, certain refractory materials may undergo undesired phase transformations, which can negatively affect their performance. By employing a low-temperature firing process, the phase transformations can be controlled, resulting in a more stable crystal structure within the refractory body. This results in better bonding between the refractory grains, leading to increased resistance against spalling,. The finer microstructure also hinders the penetration of corrosive agents into the material, enhancing its corrosion resistance.

From the above studies, it is clearly evidensed that low temperature fired brick is better as compared to high temeperature fired brick in terms of thermal shock resistance as well as slag corrosion resistance.

Fig. 5 represents the micrograph of interface area of HTF brick sample after corrosion test. Three different zones called refractory body (R), slag portion area (S), and slag/refractory interaface area separated by yellow lines in between R and S are being clearly distinguished from Fig. 5 (a) and (b). Magnifying view of interface area is shown in Fig. 5 (c) and (d). It is found that refarctory aggregates are sevely attacked by slag materials, and micro cracks are also developed within the aggregates.

Fig. 5: Microstructure of HTF high chrome brick sample after corrosion test (a) interface portion of test sample, (b) magnifying view of interface area, (c) and (d) further magnifying view of interface area.

It is understood from the SEM images of HTF brick sample that slag materials have penetrated into the refractory mass through grain boundary channel, and/or through voids network as shown in Fig. 6. It may be assumed that such type of phenomena might be enhancing the structural spalling of refractory body during application.

Fig. 6: slag penetrated into the refractory mass through grain boundary channel of HTF brick.

Fig.7 depicts the interface area of LTF brick sample after corrosion test mainly. Wide band of interface area between refractory mass and slag is being found, which is widener than interface area of HTF brick sample. Said widened interface area is mostly populated with V-Cr spinel material along with nickel, as confirmed from XRD analysis (previously described) and EDAX analysis of interface area as shown in Fig.8.

Fig. 7: Magnifying view of interface area and grain boundary of LTF brick sample after corrosion test.

Fig. 8 depicts EDAX analysis of R, S, and slag/refractory interaface area, wherein, R consists of chrome (major) and alumina (minor) along with some amount of magnesia. The slag (S) mainly consists of different elements like vanadium, iron, nickel, magnesium, sodium, silicon etc.

*Fig. 8: EDAX analysis of R, S, and slag/refractory interface area.*

It can be corelated from slag corrosion test result with XRD, and SEM analysis that due to presence of more amount of V-Cr bearing spinel crystal in the interface area of LTF brick sample; better slag corrosion resistance resulted by LTF brick sample compared to HTF one. Spinel crystals are acting as protecting agent against slag components, as a result slag infiltration followed by penetration suppressed.

Summerarlly, it has been concluded that LTF high chrome containg brick is exhibiting not only good physical and chemical properties than HTF brick, but also resulting better TSR and slag corrosion rsistance property, which are much essential and awaited intrinsic property of gassifier refractory to achieve desired performance during application. By the process of low temperature firing of high chrome bricks, less fuel consumption is required, as a result less carbaneous gases emitted into atmosphere – which is directly accelerating carbon neutrality toward a sustainable future.

**CONCLUSIONS**
Developed brick exhibits exceptional slag corrosion resistance, and thermal shock resistance, which are desired to achieve better performance in gassifier reactor application. Development of low temperature fired high chrome refractories applicable for gasifier application is a significant step towards achieving carbon neutrality

and sustainable energy production. Firing at low temperature consumes lesser energy, which contributes towards lesser carbon emission into atmosphere.

# PREMATURE REFRACTORY LINING INTEGRITY DETERIORATION IN A SYN-GAS REFORMING FURNACE

Manabendra Maity
Saudi Basic Industries Corporation (SABIC)
Kingdom of Saudi Arabia

## ABSTRACT

Reforming furnaces are the heart of synthesis gas (syn-gas) production processes in hydrogen, ammonia, and methanol plants. Revamping and modifications of these furnaces are ongoing strategies as part of the continuous improvement of aging plants. Revamping aged plants provide opportunities to enhance plant reliability, production capacity, energy, and operational efficiencies including complying with best practices and environmental regulations. Often, the conventional burners of furnaces are upgraded for higher firing capacity to add additional thermal energy and to improve combustion efficiencies and heat distributions inside the furnace. Also, in many cases, the quality of fuel and service condition of the furnace are changed significantly.

Refractory linings of furnaces are designed considering certain operating parameters and performances. Changes in operating conditions from the original design limitations including the replacement of the burner with a different flame size and/or increased heat release or any other significant modifications may negatively affect the performance and life of the existing refractory linings and structures. A premature refractory lining degradation occurred in a petrochemical plant within a short period of time after a major revamp that included the replacement of burners of a reforming furnace. Investigation revealed that the old refractory system was not compatible with the revamped operating conditions of the furnace. Therefore, the adequacy and limitations of the existing refractory systems should be carefully assessed in order to avoid any post-revamp reliability and performance uncertainties.

This paper discusses the potential refractory problems associated with furnace revamping. Mitigation measures are also discussed.

Keywords: Reformer, refractory, lining, burner, failure

## INTRODUCTION
### Reforming furnace
Main function of a reforming furnace is to convert a mixer hydrocarbon feedstock (e.g., natural gas) and steam into a mixture of $H_2$ and CO with the ratio varying depending on the desired final products [1-3]. This gas mixture of $H_2$ and CO is usually known as synthesis gas (syn-gas). Syn-gases have a wide range of applications including ammonia and methanol production, liquid fuel production in gas to liquid (GTL) plants, hydrogen production for the oil refining, iron ore reduction in steel productions, etc. Thus, reforming furnace is an integral part of many industries. The reforming reactions of hydrocarbon feedstocks usually take place in pressurized catalyst-filled alloy tubes disposed of vertically inside the furnace that operates at high temperatures in the range of 950°C to 1100°C. A reforming furnace could be used as a standalone syn-gas production unit or in combination with other reforming process units such as adiabatic pre-reforming, heat exchange reforming, auto thermal reforming, or secondary reforming. Reforming furnace is typically known as a hydrogen reformer when it is exclusively used for the production of hydrogen. It is known as a primary reformer in an ammonia or methanol plant when used in combination with a secondary reformer or auto-thermal reformer. Reforming furnace is one of the most complex and energy-intensive equipment to design, built, operate and maintain. Size of a reforming furnace can vary widely and plant capacity is typically in the range of 1000 to 5000 MT per day. A wide variety of proprietary reforming furnace designs and shapes are available. The main furnace is a large refractory-lined box (known as radiant chamber) containing hundreds of tubes disposed of vertically. A furnace is equipped with a large number of burners to supply the required heat for the endothermic steam reforming reaction of hydrocarbon feedstocks inside the tubes. The burners can be placed in different places- on the roof, on the floor, on levelled terraces on the walls, or on the walls. A rectangular shaped furnace with top-fired and side-fired types is most common. Fig. 1 shows a typical top-fired reformer. The heat from the hot flue gases leaving the radiant chamber is recovered in furnace convection box and flue-gas heat-recovery system to pre-heat the hydrocarbon feedstock, pre-heat combustion air, generate steam, and superheat steam and for other process requirements. The cooled flue gas after maximum possible heat recovery leaves the convection and waste heat recovery section and is vented to the atmosphere through the stack at 100-200°C. The reformed process syn-gas leaving from the catalyst tubes (at about 800°C to 900°C) is further processed in several downstream process units depending on the plant configuration and desired end products.

Fig. 1: Typical top-fired reforming furnace.

Syn-gas process plants including reforming furnaces usually operate continuously at the best possible efficiency for 3 to 4 years or more without a shutdown. Refractory lining design, material selection, installation and maintenance practices of a specific furnace are typically decided based on its design and operating parameters and performance objectives. It is expected that refractory linings and structures will continuously provide thermal protection and should not be the cause of an unplanned shutdown. Typical service life of radiant wall lining is around 10 to 15 years for such furnaces. However, life of the lining and its performance could vary significantly depending on the initial lining design, quality of installed refractories, installation workmanship, furnaces operation, and refractory repair & maintenance practices.

### Furnace revamp and upgradation
Many process plants are more than 25-30 years old. Such plants can't often continue yielding desired throughput, reliability, run-length, fuel efficiency and pollutant emission limits. Revamping or retrofitting the existing plant including the furnace is a good opportunity to make the plant economical and fit for continuing operation with improved reliability through the use of new

technologies. Therefore, during the long life-cycle of a process plant, often several changes are made in a plant in order to enhance the production capacity, reliability, risks, and environmental, health and safety (EHS) issues. However, changes made to equipment, process technology, operation variables, burner systems, quality and type of fuels could impact the integrity, reliability and life of existing refractory systems and associated structures. The consequences of such changes could be immediate or accelerated degradation that could occur over time resulting in reduced life, potential unplanned shutdown incidents and high maintenance costs. For example, furnace burner retrofitting from conventional to ultra-low NOx burners could cause problems associated with high heat-flux, flame instability and potential flame impingement on walls [4-5]. Relatively higher heat-flux, flame dimensions and possible impingement on refractory wall and tube could cause overheating and accelerated damage. Similarly, substituting alternate dirty fuels (e.g., waste gases and fuels with relatively high S, Na, and V content) in place of clean fuels could accelerate both high-temperature and low- temperature corrosion (e.g., acid gas dew point corrosion) and deterioration of refractory and metallic components.

## Management of change (MOC)

Regulatory codes and standards on process safety management (PSM) and asset integrity management require hydrocarbon and petrochemical plants to develop and implement an effective management of change (MOC) process in order to ensure that the potential risks associated with significant changes in an operating asset are carefully evaluated and controlled prior to implementation of the changes. While MOC requirements for implementing important changes and modifications are well integrated with plant integrity management programs, refractory integrity-related issues are often overlooked or misunderstood. Often significant changes are made assuming that such changes would not impact the existing refractory material and lining systems. However, premature refractory failures could take place directly or indirectly related to inadequate implementation of the MOC program. Incidents of accelerated refractory deterioration and unusual failures have been reported in the industries due to process and hardware changes in the furnaces without an effective MOC process to check the adequacy of existing refractories for the changed conditions. Following such incidents, the plants could require unplanned shutdowns for several days to restore the integrity of refractory and associated components.

In this article, a case history of an unusual post-revamp refractory deterioration of a reformer furnace of an ammonia plant is presented including remedial measures suggested for preventing recurrence of similar incidents.

## CASE STUDY
### Background information

Primary reformer of an ammonia plant was in service for more than 28 years. The Reformer is top-fired box type with process tubes arranged vertically in numbers of rows in the radiant section. Burners are fixed on the roof in multiple rows, with process tubes located between each burner row. The outermost rows of burners are located close to the side wall. Natural gas is used as fuel. Heat is radiated on the process tubes, both from the high-temperature refractory surfaces and directly from the flame. This is illustrated in Fig. 1 with the rows of process tubes identified as the vertical lines. The tunnels made of refractory bricks on the floor of radiant chamber collect hot gas and divert towards the convection section. The refractory linings of radiant box sidewalls consist of insulating fire brick and insulating board. Roof lining consists of ceramic fiber module and blanket. There were no incidents of major problems or failure of refractory lining except for usual aging. Overall, the original lining system performed well before revamping.

## Furnace revamp and burner retrofitting

Revamp and reliability improvement of the ammonia plant necessitated a change of the reformer furnace heat duty and burner retrofitting. The existing reformer was retained but burner types and heat duties were upgraded. All the burners were replaced and upgraded from conventional to relatively higher-capacity ultra-low NOx types. An MOC had been performed for tubes and associated structural supports to check their suitability and fitness for service for the changed heat duty and service conditions. However, a detailed adequacy check of the existing refractory for the changed service was overlooked. The refractory design and lining system of the reformer remained the same.

## Post-revamp refractory performance

Following the start-up of the plant, new burners were able to increase the heat duty for enhanced plant capacity, meet the reduced NOx emissions limit, and improve thermal energy efficiency. However, the furnace casing temperature was found to be relatively higher, particularly at the upper side walls. Higher casing temperatures and localized hotspot problems were mainly restricted to areas adjacent to burners. In-service visual inspection of the radiant box through peep-doors showed flames interactions and roll into adjacent refractory walls. Also, inspection through peep-doors indicated refractory deterioration locally around the burners. The hotspot problems were a major concern for the safe operation of the plant. Therefore, once the problems were noticed, some of the side row burners were switched off and the remaining side burners were operated with reduced firing load to restrict further deterioration of refractory and steel structures. Also, external steam cooling was provided locally on steel casing to control the hotspot temperature and continue plant operation safely till the next shutdown.

The nature of refractory damage was unusual as the same refractory system had performed satisfactorily for more than 28 years before the furnace revamp. Therefore, an investigation was performed to identify the possible causes of the problems. The findings and causes of deterioration are briefly discussed.

*Fig. 2: Deteriorated refractory wall.*

*Fig. 3: Deteriorated refractory around burners.*

An on-site inspection of the lining during shutdown revealed considerable deterioration of hot face insulating brick with severe shrinkage, cracks, and deformation. The deterioration was mainly restricted to the upper walls only and more severe around the burners as shown in Fig. 2. Bricks were found to be either displaced

or fallen locally and the back-up insulating board and brick hooks (anchors) were exposed, Fig.3. The lower brick walls and roof linings were found to be in satisfactory condition.

## DISCUSSION
**Burner retrofitting and potential impact on refractory integrity**
Burner locations, heat flux, flame shape (flame length and diameter), peak flame temperature, and flame stability could significantly impact the performance of refractory and tubes. Usually, radiant box outlet flue gas temperature is monitored to infer reformer internal temperature and operating severity. However, the radiant box outlet temperature usually does not reflect localized temperature variations within the box. Radiant box temperature could vary significantly at different regions depending on burner location, design, operation and heat release profiles. In the case of a top-fired reformer, the flue gas temperature is relatively higher at the upper half of the radiant box. As a result, the upper wall could be subjected to higher thermal exposure. Further, the outer row burners of a top-fired furnace are located very close to the side wall. Localized flame impingement on the refractory wall and/or higher heat flux could potentially raise the temperature of the wall above 1300$^0$C. In the original design, natural draft burners were used. The burner flames were compact and short which avoided damage to the refractory wall due to flame impingement. Therefore, no problem was experienced and the refractory performed satisfactorily. However, total heat release (heat flux) of burners and flame dimension has increased significantly after the burner revamp. Usually, a low NOx burner has a flame that is relatively longer and larger in cross-sectional area and volume than the flame in a standard conventional burner. Also, the flame of a low NOx burner is relatively less stable than a conventional burner. The risk of elongated flame is potential impingement and overheating of refractory wall. Further, operational upset tends to increase the flame length in low NOx burners, thereby increasing the chance of flame impingement [4-5] and flame rollover on the wall, Fig.4. Even though there is no flame impingement, the burners located adjacent to the walls, causes very high heat flux and overheating of wall locally.

Computational fluid dynamics (CFD) modelling and simulation allow performing detailed combustion analysis of burners to study the temperature profiles, flue gas flow pattern, flame impingement issues, heat flux distribution over radiant tubes and refractory [6]. The flame patterns and potential flame interactions were investigated through CFD analysis of the furnace radiant box to evaluate the performance before and after a furnace revamp. CFD analysis confirmed relatively higher heat flux on the refractory wall around the burner. The localized temperature of the wall is hotter than the surroundings by more than 100$^0$C. The overheating resulted in accelerated deterioration of refractory wall locally.

*Fig. 4: Flame impingement on wall and associated damage.*

## CORRECTIVE MEASURES
The nature of localized damage of lining suggests that the original refractory lining around the burner is not suitable for the changed operating conditions with the new burners. Therefore, the refractory design and anchor metallurgy was upgraded for all four walls. An optimum combination of a compatible superior grade insulating brick, insulating board and micro-porous material was used to enhance the performances without changing the total lining thickness, casing temperature and heat losses. Also, burner operations of outer rows, left and right sides of Fig. 1, were readjusted and fine-tuned to reduce firing load and improve flame stability. The problems were resolved after the successful implementation of the above changes.

## FINAL REMARKS
Furnace revamp and optimization efforts are often focused on capacity and efficiency improvement. However, improvement steps taken could result in subsequent issues that negatively impact the safety and reliability of critical components including the refractory system. Premature deterioration of refractory lining of a reforming furnace was investigated. Investigation revealed that the existing refractory lining around the burners was not suitable for the revamped operating conditions. The changes in burner design have resulted in relatively higher flame dimensions, heat flux and heat radiation. The refractory lining was subjected to high levels of heating from the intense radiation of high-capacity burners. Higher heat flux and potential flame impingement on the adjacent wall caused localized overheating and accelerated deterioration of refractory and components. Based on this investigation, modified refractory designs for the walls have been implemented to resolve the problems. The following suggestions are made in general:

- Furnace revamping and associated changes in operating temperature, thermal load and other critical parameters can have a negative effect on the life of the refractory linings and structures. Therefore, suitability and validation of fitness for service of the existing refractory system for revamped conditions should be analyzed carefully considering the changed service conditions.
- Refractory around the burners of fired furnaces can become hot locally due to the proximity of the flame. Major changes in burner design may require a refractory material upgrade and design modification of the entire lining and / or locally around the burners. A higher design margin for refractory materials and associated components around the burners should be considered.

# REFRACTORY LINING CONDITION ASSESSMENT AND INTEGRITY MANAGEMENT OF HYDROCARBON PROCESS FURNACES AND REACTORS

Manabendra Maity
Saudi Basic Industries Corporation (SABIC)
Kingdom of Saudi Arabia

## ABSTRACT

Fired heaters, furnaces, reformers, reactors, incinerators, and boilers are amongst the most expensive and essential assets in the hydrocarbon process industries including oil-gas refineries, petrochemicals, fertilizers, and allied industries. Refractory linings and components play a significant role for managing the structural integrity, process safety, reliability and profitability of these high temperature assets. There are several factors over the life-cycle that affects the performances of refractory systems. The complex service conditions and operational upsets often make them vulnerable to risk of premature failure. Refractory performance left unchecked, could cause serious impact on reliability and run-length. The consequences of undetected refractory degradation or failure could be catastrophic.

Over the years, the qualities of refractory materials, design, installation and maintenance practices have been enhanced progressively with operational experiences and technological developments. Despite advances in refractory integrity management practices, premature failures still occur. Many of these problems could have been mitigated by following a systematic on-stream and off-line inspection and monitoring program in order to timely detecting the faults, predicting degradation of refractory and take corrective measures before loss of integrity or functional capability beyond the safety margins. Standards and codes for refractory inspection and maintenance are very few or non-existent. Further, each individual process furnace is unique to its operational environment and performance demand. Therefore, individual strategies should be formulated for a more proactive and tailored approach towards refractory integrity management backed by experience and driven by appropriate technologies and techniques.

This paper discusses the important aspects of refractory lining and structural inspection, performance monitoring, and the integrity management best practices that serves to increase reliability for the furnaces and vessels in hydrocarbon process industries.

## INTRODUCTION

### Process furnaces and reactors

Hydrocarbon and petrochemical industries typically involve processing of gaseous, liquid and solid feedstocks at elevated temperature and/or pressure within a broad range of fired heaters, furnaces, reformers, pressure vessel reactors, fluid catalytic and fixed bed reactors, carbon-black reactors, gasifiers, coke calciner, dryers, incinerators, oxidizers, boilers, hot gas transfer piping, and a host of other assets (hereinafter called furnaces). Operating conditions and process dynamics of furnaces typically range from hot-oxidizing atmospheres to processes that contain hot acidic & alkali gases or gases with entrained solid particles or extremely reducing conditions or highly corrosive and erosive slags, molten salts, and ashes. Typical operating temperatures in furnaces could be as low as 250°C to as high as 1950°C. Many of these assets are pressure vessels, operated at pressures as high as 8MPa or more. Safety and reliability is top priority for construction, operation and maintenance of these assets.

### Refractory linings, structures and components (RLSC)

Furnace casings and structures are usually made of carbon steel or alloy steel and designed based on several codes including ASME, API, etc. Objectives of the refractory linings are to protect the casing against thermal-mechanical-physical-chemical stresses and associated degradation. Also, the lining provides thermal insulation and reduces heat losses from the furnace. Refractory functions could be completely different between the furnaces and between the various zones of the same furnace. Therefore, a proper understanding of the purpose of the refractory is important for both the design and material selection, and also for subsequent maintenance and repair decisions. For example, fired heaters are designed to have substantial insulating capability in their linings, while others (e.g., Fluid catalytic cracking unit-FCCU) designed to withstand the extremely severe erosion caused by the flowing catalyst. Thus, several different refractory lining designs range from 25mm to 450mm thick or more are utilized depending on the operating severity and performance demands. Varieties of refractory materials are used like, brick, monolithics, ceramic fiber, insualting boards, etc. Also, there are many other internal structures and functional components made of refractory materials like catalyst support structures, domes, flue gas tunnels in syn-gas reformers, partition walls, bridge walls, ceramic ferrules, etc. Integrity and performance of these structures and components are equally important for a trouble free operation.

Process plants typically operate continuously for 2 to 5 years or more between planned maintenance shutdowns. Furnace outage frequency and refractory maintenance is accordingly combined with outage of upstream and downstream equipment. Life of refractory should not be a barrier in continuous plant operation. Therefore, refractory linings and structures must be fit for service and maintain their structural and functional performance over required levels to meet specific demands during its lifetime. This can be achieved both with adequate reliable design, construction and maintenance practices based on the concept of life-cycle management.

### Refractory failure and consequences

RLSC are susceptible to ageing and degradation by several mechanisms including overheating, melting, shrinkage, chemical wear, thinning due to corrosion, abrasion & erosion, thermal shock, cracking, thermo-mechanical stresses, creep, acid dew point corrosion, etc. Also, many of the refractory failures could be accelerated as a result of refractory design deficiencies, poor material quality, inadequate anchoring, installation quality deficiencies, operational upsets, and inadequate maintenance practices. Combined effect of many of these factors could give rise to susceptibility to an accelerated deterioration and early failure. Deteriorations of refractory lining can be continuous (e.g., corrosion or erosion) or discontinuous (e.g., cracking or spalling). Also, deterioration could differ by zones within the same furnace.

When a lining deteriorates or fails, the metallic containment structure could be exposed to service conditions and potentially overheated creating local hotspots. At high temperature, metallic structures are prone to several damage mechanisms including metallurgical degradation, thermal fatigue, creep, deformation, corrosion, sulfidation, metal dusting, hydrogen attack, reheat cracking, etc. In case of pressure vessels, the combined effect of high temperature and pressure can reduce the overall load carrying capacity due to lower yield strength of the region resulting from overheating. A ruptured vessel can be extremely dangerous, leading to potential loss of containment, leaks, fires, and even explosions. In general, once the lining integrity is lost, through-wall damage may not take very long time, Fig.1. Also, a deteriorated lining can reduce process thermal insulation efficiency and increase fuel costs and associated NOx emissions.

Further, furnaces in process plants are rarely built with a backup or stand-by equipment. Therefore, an unusual incident and unplanned shutdown in a plant can cost millions of dollars per day in lost production. For example, a FCC unit in oil refinery processes several hundred thousand barrels of crude oil a day. An unplanned FCC unit shutdown could be a very expensive incident and may lead to local fuel shortages. In case of an integrated complex chemical plant (e.g., refinery and petrochemical unit), the consequential impact of unplanned downtime could be serious on associated upstream or downstream operating units.

A permanent damage to the containment structure may take several weeks to repair and restore the integrity. In many cases, the refractory repair and replacement costs of a furnace could be insignificant compared to the cost of unscheduled stoppage. The magnitude of impact (in terms of safety, cost and time) of failure incident could vary significantly depending on whether the problem is identified and mitigated on time before major damage. Consequently, RLSC requires periodic inspection, assessment, maintenance and repair.

*Fig. 1: Refractory deterioration leading to shell overheating and puncture in a vessel.*

Many refractory failure and unplanned shutdown incidents have been reported in different process industries. Investigations revealed that such incidents could have been avoided, if there had been an effective refractory integrity management program including inspection maintenance for timely identification of the problems and implementation of corrective measures. This paper describes the importance of inspection and condition monitoring of RLSC in particular, in-service monitoring and typical approaches to assess refractory fitness for continued service.

**REFRACTORY INSPECTION AND ASSESSMENT**
Once a furnace is commissioned and placed into service, the RLSC integrity and performance should be monitored by periodic in-service inspection to detect any signs of emerging degradation and failure [1-3]. Also, RLSC should be inspected and repaired at each scheduled shutdown. Inspection and maintenance requirements for each specific equipment item should be included in a customized preventive and predictive maintenance program. Assessment can be made by condition-based and performance-based concept.

**In-service inspection and monitoring practices**
A variety of traditional and state-of-the-art non-destructive tests (NDT) and techniques could be utilized for assessment of condition of equipment and refractory integrity when the plant is in-service. Typical benefits of in-service assessment of refractory condition include but are not limited to
- Timely identification of anomalies, operational deviations and potential problems before they become major issues;
- Catastrophic lining failure, extent of damage to main containment structure, unplanned downtime and associated risks can be proactively prevented and / or reduced by effective mitigation measures and / or by a safe shutdown;
- Monitor ageing and degradation, damage progression, trending and decide fitness for continued service and assess remaining service life, reducing uncertainties;

- Plant run-length can be extended by interim mitigation measures(e.g., hot spot temperature control by steam sparging);
- Proactively schedule and prioritize maintenance rather than reacting to a catastrophic failure;
- Allow advanced shutdown scoping, planning, resourcing, and refractory spare management.

Common in-service inspection and monitoring practices include:
- Furnace casing temperature measurement and trending: Periodic monitoring of furnace casing temperatures could identify the onset of potential problems and provide an early indication of refractory damage and/ or any other abnormalities. Typical tools include: Infrared thermography (Fig.2), thermo-indicating paint (Fig.2), skin thermocouple (Fig.3).

*Fig.2: Localized hotspot: Thermography view (left) and thermo-indicating paint discoloration (blue to white).*

*Fig.3: Skin thermocouple.*          *Fig. 4: Internal thermocouple.*
- Visual inspection of casing (paint burning, deformation, corrosion, cracks, and leaks caused due to overheating): Once abnormalities detected; affected area could be closely inspected and monitored by thermography or other techniques.
- Interior refractory wall-temperature measurements can be done through peepholes of fired heaters and furnaces (e.g., infrared spot pyrometer, infrared borescope and thermocouples, Fig.5).
- Infrared radiation pyrometer, contact thermocouples and IR emission sensors are commonly used tools to measure the internal temperature of thermal reactor of sulphur recovery unit (SRU), incinerators, etc. Also, thermocouples could be embedded at specified locations in the refractory wall to monitor temperature profile at any cross-section of the lining, Fig.4.

*Fig.5: Interior refractory wall-temperature measurements (wall overheated and caused accelerated deterioration of fiber lining).*

- Visual inspection of fired furnaces interior through peep-doors to check flame patterns, flame impingement on walls, broken, missing or displaced refractory (Fig.6 & 7).
- Ultrasonic thickness (UT) measurement of casing at suspected areas where erosion (Fig.8) or corrosion could occur due to refractory damage (e.g., FCC unit in oil refinery).
- Furnace operation and control: A well-established integrity operating windows (IOW) program would allow monitoring

604

key parameters (e.g., temperature, pressure, heating & cooling rate, burner malfunctioning, and operational upset) those have direct effect on refractory damage mechanisms. Periodic monitoring of major deviations of critical operating parameters could provide early sign of potential refractory problems so that the possible corrective measures could be initiated.

*Fig.6: Peep-doors.*

*Fig.7:-Internal view.*

*Fig. 8: FCCU Refractory deterioration leading to erosion of casing plate and through hole.*

- For water jacketed refractory lined vessels, water flow rate, deviations in water outlet temperature through jacket and steaming can be monitored to monitor lining integrity.

Also, a wide variety of advanced NDT inspection techniques, such as acoustic emission testing, impact-echo methods, ultrasonic, radiography, and microwave based techniques, optical and laser techniques are aviable. However, most of these methods have limitations and requires specific skills to perform and asses refractory integrity.

Frequency of in-service inspections is usually decided for each specific equipment based on the several factors including asset criticality, industry best practices, past experiences, severity of operation, existing or chronic problems or new problems, etc.

**Inspection & assessment during shutdown**
During a plant shutdown, a thorough internal inspection of refractory systems should be performed, especially at locations where thermography indicated elevated temperatures. This inspection helps in validating findings of in-service inspection. Inspection involves combination of activities including visual inspection, dimensional measurement, hammer test, photographing, sample testing, and engineering analyses. The integrity is assessed for general condition including existing or developing visible unusual damage, signs of any forms of deterioration, defects or deviations, crack, gap, shrinkage, leak, erosion, corrosion, thickness profile, discoloration, detachment or dislodgement, sagging, deformation, bowing, bulging, leaning structures, out of plane offsets, movement-out of plumb, instabilities that indicate a compromised structural integrity of the refractory systems, anchors, supports, etc. Where access is limited, borescopes can be used to perform the inspection.

**Refractory repair, replacement or alteration**
Fitness-for-service, repair or relining decision of RLSC should be made based on inspection findings, engineering assessment and analyses of useful data, and past experiences. It is important to address weaknesses with a scientific approach instead of "replace in-

kind" practices. Potential root causes, contributing factors and mode of failure of premature and chronic problems should be identified and ascertained in order to prevent reoccurrences. Interim and long term mitigation plan could be planned and implemented based on identified risks.

Inspection and maintenance records including all major findings and descriptions, operating history, basic data, field notes, pictures, sample test reports, failure investigation reports, location of the repairs, follow-up tasks, expected repair for next shutdown etc. should be maintained. These periodic inspection and maintenance records typically form the basis of scheduled maintenance programs.

**FINAL REMARKS**
An effective life-cycle and integrity management of furnaces and associated refractory systems is essential to ensure their fitness for service during the long campaign cycle. A typical refractory integrity management program involves several requirements including periodic in-service inspection, monitoring, surveillance, preventive and corrective maintenance. It is necessary to develop real-time diagnosis tools with capabilities of generating early warnings of hotspots or potential deteriorations. Each furnace and associated refractory system is unique with respect to its design, operational severity and performance requirements. Therefore, a customized refractory integrity monitoring program should be tailored to the specific equipment to suit the specific process condition and service. The plan should include what, how, where and when the inspection must be conducted and the what, how, where and when the appropriate action must be undertaken to address the concerns that may affect safety, reliability, and productivity.

# MICROPOROUS CALCIUM SILICATE HYDRATE–BASED THERMAL INSULATORS: A CRITICAL REVIEW

Rafael Salomão, Leandro Fernandes

São Carlos School of Engineering, Materials Engineering Department, University of São Paulo, São Carlos, Brazil

## ABSTRACT

Calcium silicate hydrate (CSH) is a synthetic microporous material used as a thermal insulator due to its low thermal conductivity, chemical resistance, and competitive costs. The production of porous CSH structures requires the hydrothermal dissolution of sources of CaO and $SiO_2$ and the precipitation of needle-like whiskers of Xonotlite ($Ca_6Si_6O_{17}(OH)_2$). The flocculated CSH paste is shaped by press-filtering and dried. Typical industrial applications of porous CSH involve thermal insulation between 300-1000ºC, as pre-shaped boards or pipe-covering in petrochemical units, non-ferrous metals casting operations, and steam-powered electric power plants. In civil construction, thin boards comprise fireproofing doors and roofs, and, in cold regions, reduce the loss of heat through external walls. This paper addresses a review of the technical and scientific literature on microporous CSH, focusing on the processing, microstructure, and properties of thermal insulation at high temperatures.

## ENERGY CONSUMPTION IN INDUSTRIAL PROCESSES

Three groups of human activities, namely transportation of people and goods, acclimatization and agriculture, and heating-based industrial processes are responsible for the greatest consumption of energy [1]. Together, they spent approximately 30,000-40,000 EJ of energy and generated over 500 million tons of $CO_2$ per year in the past decade (Fig. 1) [2]. One-third of this energy amount and approximately one-quarter of the $CO_2$ emissions originated in industrial operations that employ heat to produce or modify raw materials and goods (Fig. 2) [1]. Although most of their energy consumption is necessary, inevitably, all processes show a certain degree of unnecessary heat exchange and thermal losses. The use of thermal insulators based on microporous ceramics is a well-known strategy to improve thermal efficiency [3,4].

*Fig. 1: Word energy consumption and $CO_2$ emissions [2].*

*Fig. 2: Temperature ranges found in industrial processes [3].*

Towards reductions in undesired heat exchange, microporous ceramics combine the high refractoriness of ceramic matrixes with a large fraction of thin pores (0.5-5 μm diameter) [5-7]. The lack of a permeable connection amongst them hinders the heat transfer by air convection. Moreover, they are very effective in scattering thermal waves (phonons and photons) whose mean free path and wavelength are similar to their average diameter and inter-pore distance [8,9]. Consequently, microporous ceramics such as calcium silicate hydrate (CSH) show very low thermal conductivity in a wide range of temperatures (Figs. 3-4), as well as enough strength to support compression loads [10].

*Fig. 3: Thermal conductivity of porous materials [3,8,9].*

*Fig. 4: Thermal conductivity of microporous ceramics [3,4,10].*

## CALCIUM SILICATE HYDRATES INSULATORS (CSHI)

CSHI consists of structures of very low relative density (< 10 %) containing intermeshed 1-5 μm length by 50-100 nm diameter whiskers of xonotlite ($Ca_6Si_6O_{17}(OH)_2$) and tobermorite ($Ca_5Si_6O_{16}(OH)_2$) around 1-5 μm diameter pores (Fig. 5) [4,11,12].

*Fig. 5: Microstructure of a CSH insulator (fracture surface) [4,10]*

The fabrication of CSHI structures begins with the production of an aqueous mixture of finely grounded raw materials and recycled shavings that will behave as templates for the growth of crystal nuclei [11]. Other elements such as foaming agents, inert filers, and fibrous reinforcement can be added at this step [13]. Intensive paddle mixers produce slurries containing 10-25 wt% of solids that are thickened by vacuum filtering and then pressed or extruded. Those shaping steps increase the solid content in the suspension to up to 70-80 wt% and define the geometry of the product. The humid compacts remain in autoclaves at 160-250ºC for up to 10 h. Under hydrothermal conditions, both hydroxylation and dissolution of CaO rapidly increase the suspensions' pH (Eq. 1), favoring the dissolution of silica into silicilic acid (Eq. 2) [15]. Because amorphous silica sources usually show higher chemical reactivity in comparison to crystalline ones, the replacement of micronized quartz with diatomaceous earth, for instance, reduces the total hydrothermal time-temperature schedule [15,16].

$$CaO + H_2O \rightarrow CaOH^+ + OH^- \rightarrow Ca + 2OH^- \qquad (1)$$
$$SiO_2 + OH^- \rightarrow (HSiO_3)^- \qquad (2)$$
When the concentration of ions in the solution reaches the saturation point, calcium silicate hydrates are formed (Eq. 3) and begin to precipitate as weak agglomerates of elongated thin crystals.

$$xCa^{2+} + y(HSiO_3)^- + z(OH)^- \rightarrow xCaO.ySiO_2.zH_2O \qquad (3)$$
where $2 \leq x \leq 6$, $1 \leq y \leq 6$, and $1 \leq z \leq 5$. Such compounds that crystallize as needle-like whiskers belong to the Xonotlite and Tobermorite mineral family, whose ideal chemical formulas are $Ca_6Si_6O_{17}(OH)_2$ and $(Ca_5Si_6O_{16}(OH)_2)$, respectively [15]. Variations in the initial solid-water and CaO-SiO$_2$ ratios affect both formation and development of the CSH structure. As an example, higher contents of SiO$_2$ require longer autoclave times and produce longer and more rigid whiskers due to the lower mobility of the ions in the solution [12,15,17]. After cooling, the autoclaved structure is dried and trimmed in specific dimensions.

## APPLICATIONS OF CSHI
Different from other microporous ceramics that require thermal treatments at high temperatures to trigger pore formation [18], CSHI became fully functional soon after the evaporation of the remaining free-water. Moreover, exposures to temperatures above 350ºC lead to the dehydroxylation of CSI, even further increasing the total pore content of the structure [11,19]. Depending on the Xonotlite-Tobermorite ratio, the final composition can be a mixture of high refractoriness calcium silicates (Alite, $Ca_3SiO_5$, $T_M$=2150ºC; Belite, $Ca_2SiO_4$, $T_M$=2130ºC; $CaSiO_3$, Wollastonite, $T_M$=1544ºC) that withstand long-term working temperatures of up to 1100ºC [15]. Due to such excellent thermal insulation properties, mechanical strength, and chemical stability, CSHI finds a wide range of industrial applications. For instance, civil, marine, offshore, and automotive construction uses CSHI sheets for thermal insulation of walls, roofs, and floors, as well as for fire-resistant and soundproofing partitions [10,17]. Regarding high-temperature applications, glass fiber-reinforced CSH boards line the outer surface of urban waste incinerators (300-500ºC), primary aluminum smelters and runners (700-800ºC), pipes at petrochemical units (600-800ºC), and rotary cement kilns (700-1100ºC) [4-6,10].

## FUTURE DEVELOPMENTS
The major challenge for CSHI production is to reduce the time-temperatures employed in hydrothermal reactors [19]. The use of raw materials, which are more reactive due to their finer particles and higher specific surface area, would reduce both maximum temperature and pressure inside the vessels. On the other hand, the production of stable hetero-dispersions under such conditions would require the careful use of surfactant agents and powerful mixers.

CSHI are promising materials for reducing the carbon footprint of industrial processes not only due to their high energy-saving potential but also because of the possibility of being fully produced from biomass-based raw materials. Dried avian eggshell, for instance, contains approximately 92 wt% of calcium carbonate, which can be converted into CaO or Ca(OH)$_2$ at low calcination temperatures (720-800ºC) [20]. Similarly, the ashes of rice husks, currently employed as fuel for boilers furnaces, contain 98 wt% of amorphous SiO$_2$ [21]. Besides adjustments of processes and formulations to the intrinsic variability of natural products, the selective pick-up of such materials is another challenge.

# LIFE CYCLE ENVIRONMENTAL AND COST ASSESSMENT OF LADLE REFRACTORIES MANAGEMENT ACCORDING TO CIRCULAR ECONOMY CRITERIA

Ivan Muñoz, 2.-0 LCA consultants, Barcelona, Spain. E-mail: ivan.munoz@lca.net.com
Aintzane Soto, SIDENOR I+D, Basauri, Spain

**ABSTRACT**

Management of ladle refractories by a steel factory in Spain melting 1 million tonnes of steel scrap per year, is assessed by means of life cycle assessment (LCA) and life cycle costing (LCC). The case study addresses two situations, namely before and after implementing circular economy strategies. Such strategies include reduction of refractory waste generated in the ladles by optimising the ladle life, increasing amounts of worn bricks that can be reused in the production process or for other purposes, and increasing the amounts of waste refractories that can be recovered as secondary raw materials through recycling. The LCA and LCC studies consider the entire life cycle of refractory products and addressed a set of 14 environmental indicators, while the LCC is expressed in €. The results show both environmental and economic benefits by adopting the developed strategies. Life cycle costs are reduced by approximately 1 million €/year, while GHG emissions are reduced by 2,000 tonnes $CO_2$-eq/year.

## 1. BACKGROUND AND GOAL

Every year close to 20 million tonnes of spent refractory waste materials need to be managed globally, of which it is estimated that around 70% is landfilled and 30% recycled, the latter either as a secondary refractory raw material or in other applications such as roadbed aggregates [1]. However, management practices differ widely from country to country. In Spain, landfilling still constitutes a widespread practice [2], which constitutes the least preferred option from a waste hierarchy and sustainability perspective, due to the loss of potentially useful materials. In this paper we present the application of life cycle assessment (LCA) and life cycle costing (LCC) to the management of ladle refractories by a steel factory in Spain, melting 1 million tonnes of steel scrap per year.

## 2. The E-CO-ladleBrick PROJECT

This research was carried out as part of the EU RFCS-funded E-CO-LadleBrick project, aiming at implementing the environmental model of the 4R (reduce, reuse, remanufacture and recycle) to the management of refractories in the European steel sector. The developed strategies within the project, implemented in the above-mentioned steel factory in Spain, include:

- Reduction of refractory waste by optimising the ladle life
- Increasing amounts of worn bricks that can be reused internally at the factory
- Increasing waste recovery through off-site recycling
- Completely avoiding refractory waste landfilling

Table 1 below summarizes the ladle management achievements as a result of project E-CO-LadleBrick, when the situations before project (2018) and after project (2022) are compared.

Tab. 1: Key performance indicators for ladle management as a result of implementing E-CO-LadleBrick in a steel factory melting 1 million tonnes steel scrap per year.

| Reduction in refractory consumption | Additional waste refractories reused internally | Additional waste refractories valorised externally | Reduction in refractories sent to landfill |
|---|---|---|---|
| 237 tonne/year | 262 tonne/year | 228 tonne/year | 653 tonne/year |

## 3. Applying LCA and LCC

The LCA applied consequential inventory modelling principles (multifunctionality dealt with by substitution, constrained suppliers excluded), which is consistent with the ISO 14040 and ISO 14044 standards. The study included the entire life cycle of refractory products: mining of minerals, processing to obtain refractory raw materials, manufacturing of finished products, use phase and management as waste. Inventories (mass and energy balances) were built for production of 12 different raw materials and 17 finished shaped and unshaped products (see Fig.1). Data were also collected from the steel manufacturer in terms of refractories consumption, waste collection and treatment. As background database, the EXIOBASE v3 (https://simapro.com/products/exiobase-database/) was used in the LCA software SimaPro. The advantage of using an input-output based database as EXIOBASE is its high level of completeness, as well as the ability to cover processes in different countries with country-specific data. The main limitation of such a database, namely the level of aggregation of activities, is managed by disaggregating them whenever necessary, using process-specific data from other sources. In terms of environmental impact metrics, the LCA addressed a set of 14 environmental indicators by means of the Stepwise method developed by 2.-0 LCA consultants.

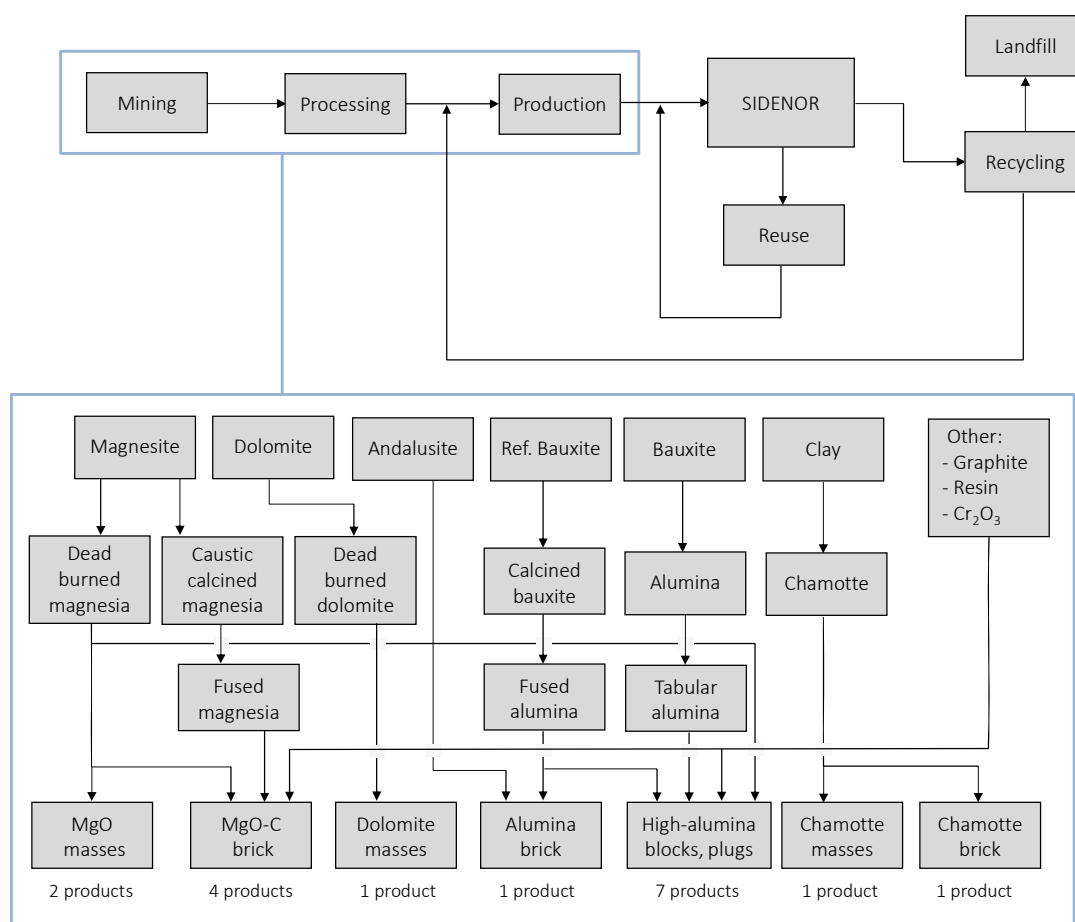
In parallel, LCC was applied following the principles by [3] and [4], where LCC is defined as an assessment of all costs associated with the life cycle of a product that are directly covered by any one or more of the actors in the product life cycle (supplier, producer, user/consumer and waste manager. This LCC approach addresses only 'internal' costs, that is, costs for which a price is paid by a particular actor in the supply chain. Costs and benefits must be taken into account even if the decision maker, in this case the steel factory, is not directly responsible for them. The calculation of the LCC was performed based on a wide variety of data sources, such as actual prices of refractories and estimated costs and benefits for waste collection, reuse, recycling and disposal.


*Fig. 1: Boundaries of the LCA study.*

**Results: LCA**

Table 2 shows the impact assessment results for annual ladle management before and after E-CO-LadleBrick project implementation, for the 14 indicators included. Each indicator is expressed in different units and therefore they cannot be compared to one another. Besides the absolute scores for each scenario, the last column shows the reduction in impact score, expressed in percentages. The results clearly show a lower impact after project implementation, with reductions in impact that range from 19% in aquatic eutrophication (water pollution by nutrients) to 79% in mineral extraction.

Tab. 2: Life cycle impact assessment results before and after E-CO-LadleBrick implementation in a steel factory melting 1 million tonnes steel scrap per year. Indicators in physical units according to the Stepwise method.

| Indicator | Units[a] | Before E-CO-LadleBrick | After E-CO-LadleBrick | E-CO-LadleBrick reduction (%) |
|---|---|---|---|---|
| **Human toxicity, carcinogenic effects** | kg $C_2H_3Cl$-eq emitted to air/year | 246,502 | 192,576 | 22% |
| **Human toxicity, non-carcinogenic effects** | kg $C_2H_3Cl$-eq emitted to air/year | 34,688 | 26,428 | 24% |
| **Particulate pollution** | kg $PM_{2.5}$-eq/year | 15,281 | 12,375 | 19% |
| **Ecotoxicity, aquatic** | kg TEG-eq emitted to water/year | 15,903,823 | 12,583,435 | 21% |
| **Ecotoxicity, terrestrial** | kg TEG-eq emitted to soil/year | 34,576,994 | 27,606,864 | 20% |
| **Nature occupation** | PDF·$m^2$a/year | 122,869 | 101,571 | 17% |
| **Greenhouse-gas emissions** | kg $CO_2$-eq/year | 10,550,041 | 8,499,345 | 19% |
| **Acidification** | $m^2$ UES/year | 782,915 | 610,942 | 22% |
| **Eutrophication, aquatic** | kg $NO_3$-eq/year | 7,356 | 6,052 | 18% |
| **Eutrophication, terrestrial** | $m^2$ UES/year | 818,079 | 647,722 | 21% |
| **Respiratory organic effects on humans** | person·ppm·hour/year | 11,558 | 9,104 | 21% |
| **Photochemical ozone effects, vegetation** | $m^2$·ppm·hour/year | 106,912,340 | 84,109,634 | 21% |
| **Non-renewable energy demand** | MJ primary/year | 85,963,291 | 69,344,681 | 19% |
| **Mineral extraction** | MJ extra/year | 81,614 | 17,483 | 79% |

[a] $C_2H_3Cl$: chloroethylene; $PM_{2.5}$: fine particulates measuring 2.5 microns or less in width; TEG-eq: triethylene glycol; PDF: potentially disappeared fraction of species; $CO_2$: carbon dioxide; UES: unprotected ecosystem; $NO_3$: nitrate; ppm: parts per million; MJ: megajoule; eq: equivalents.

Fig. 2 below shows how emissions of greenhouse gases (GHG), measured in tonne $CO_2$-eq/year, are distributed across the life cycle of refractories, from production to waste management. The graph shows values with a positive sign, interpreted as emissions, as well as values with a negative sign, interpreted as emission savings or avoided emissions.
*Fig. 2– Life cycle GHG emissions for ladle refractory management before and after E-CO-LadleBrick implementation in a steel factory melting 1 million tonnes steel scrap per year.*

Fig. 2 shows that the major share of emissions is associated with refractory production (including the entire chain of mining and processing of raw materials into finished products), which justifies the E-CO-LadleBrick strategy of maximizing a ladle's useful life, thus reducing the consumption of refractories. This alone achieves a reduction in GHG emissions of 4%. Fig. 2 also shows how crucial waste management is. Reuse and recycling notably increase after project implementation, leading to the avoidance of emissions associated to producing new raw materials and final products. Altogether, reuse and recycling achieve a reduction in GHG emissions of 14%. Finally, the avoidance of landfilling after project implementation also contributes to the GHG reduction, by 1%. Overall, the life cycle GHG emission reduction is 19%.

**Results: LCC**
The results of the LCC study are shown in Table 3 below, where instead of showing the before project/after project situations separately, we show only the difference between these two situations. Results with negative values imply a benefit, that is, a cost reduction as a result of implementing E-CO-LadleBrick. The total LCC shows a negative value, indicating a benefit, that is, a lower cost after project implementation.

*Tab. 3: Life cycle costing results, in €/year: difference between before and after implementing E-CO-LadleBrick in a steel factory melting 1 million tonnes steel scrap per year.*

| Cost item | Cost, € |
|---|---|
| Refractory supply | -610,648 |
| Ladle reparation | -548 |
| Ladle demolition | -823 |
| Waste collection | 10,444 |
| Waste transport | -7,655 |
| Waste treatment | -40,869 |
| Substituted raw materials | -135,897 |
| Substituted refractories | -269,659 |
| **Total** | **-1,055,656** |

It can be seen that total annual life cycle costs are reduced by about 1 million € thanks to the implementation of E-CO-LadleBrick. All items in Tab. register cost reductions, with the exception of waste collection, where an increase is registered. This is mainly due to the increase in collection efforts for bricks destined for internal reuse in the factory. The volume of such bricks increases substantially, thus incurring in higher costs for manual sorting and internal transport. This cost increase is, however, largely compensated by the resulting avoided cost of purchasing new bricks, estimated at more than 269,000 €. Overall, the biggest cost reduction is associated to a reduced supply of refractories, thanks to the optimization of their useful life as a result of the prediction model developed in the project. These savings are estimated at 610,000 €. The second most important cost reduction is due to brick reuse, estimated, as already mentioned, at 269,000 €. Recycling also leads to substantial benefits, through avoided raw material production. Altogether, avoided raw materials amount to savings close to 136,000 €.

**Conclusions**
The main outcome of this parallel LCA and LCC study is that circular economy strategies such as the ones developed in the E-CO-LadleBrick lead to a reduction in life cycle impacts and costs associated to ladle refractory management. Even though this is only one case study in a single factory, the overall conclusions are likely to be valid for the general refractories sector.

Morgan Advanced Materials, Bromborough, UK

## ABSTRACT

Legislation and market forces are necessitating an increasing range of products to declare their environmental impact, reverberating down the supply chain. This paper discusses the cradle-to-gate Life Cycle Assessment (LCA) for insulating refractories, including the challenges of obtaining accurate raw material data and attributing Scope 1 and Scope 2 emissions to individual products. Insulating refractory products reduce the amount of carbon emissions from thermal processes, a methodology of differentiating between best-in-class and consumer grades is presented. This utilises heat flow models, and fuel carbon intensity calculations over the full expected lifetime of a refractory lining.

## DRIVING FORCES FOR MEASURING CARBON FOOTPRINT THROUGH LIFE CYCLE ASSESSMENT

According to the United Nations Intergovernmental Panel on Climate Change (UN IPCC), climate change is causing global temperatures to increase[1], resulting in rising sea levels, and more frequent extreme weather events. The principal cause of global warming is the rise in man-made greenhouse gas (GHG) emissions.

Legislation is pushing the need to measure and declare an increasingly detailed amount of environmental impact data. Over the past several years and in many jurisdictions, there has been the requirement that the company's annual directors report must contain energy use and greenhouse gas emissions[2,3]. Recently, the EU introduced the Carbon Border Adjustment Mechanism (CBAM)[4] , which is a tool to put a fair price on the carbon emitted during the production of carbon-intensive goods that are entering the EU, and to encourage cleaner industrial production in non-EU countries. The CBAM will initially apply to imports of certain goods and selected precursors whose production is carbon intensive and at the most significant risk of carbon leakage: cement, iron and steel, aluminium, fertilisers, electricity, and hydrogen. These and other legislations are requiring companies to track, in detail, their Scope 1 (direct), Scope 2 (indirect energy emissions) and, increasingly Scope 3 (other indirect) environmental emissions. Knowledge of the environmental impact of raw materials and components is required for the accurate calculation of Scope 3.

As stakeholders' opinions shift towards a more vital environmental consciousness, it becomes critical for companies to prioritise sustainability against the three pillars of: environmental, social and governance (ESG). Therefore, a company cannot solely focus on one pillar (e.g., focusing on governance goals solely while disregarding environmental impact). Doing so may be profitable in the short term but detrimental to the company's long-term viability as regulatory penalties, investor or other stakeholder interests and public opinion can negatively impact the company. By contrast, every company will have an environmental footprint, and there is a limit to reducing the impact of that footprint before the price becomes so large that it impacts the governance pillar. As public concern grows, more customers ask about industries GHG emissions as part of the manufacturing process and request information on products' environmental impacts.

The above factors are driving the need for the measurement and declaration of the environmental impact of their products. Refractories are no exception to this. In fact, their influential role in the production of carbon intense goods mentioned in CBAM, put them in a group of high interest materials. The process for measuring the environmental impact of a product is called Life Cycle Assessment.

## LIFE CYCLE ASSESSMENT PROCESS

Life Cycle Assessment (LCA) is a systematically analyses the environmental impacts across a product's life[5]. The beginning of a refractory materials life is mineral extraction at many separate mines, followed by transportation and a first round of manufacturing steps. These intermediate products then undergo more transportation and get used by the refractory producer as raw materials in further manufacturing steps. When the product reaches the end user, it may have gone through numerous manufacturing and transportation stages. The product is then used, maintained, and eventually recycled or disposed of. The summation of the environmental impact, in numerous categories, across all these steps comprises the LCA.

A complete assessment of manufacturing a product, its use and recycling are referred to as "cradle-to-cradle" see Figure 1. An assessment including manufacturing and use, but not recycling is called "cradle-to-grave". An assessment of only the manufacturing level is called a "cradle-to-gate" assessment. Cradle-to-gate refers to all environmental impacts associated with a product until it leaves the refractory manufacturer's site; it includes the impact of:
- Raw materials
- Transportation of raw materials from the last manufacturing / processing site
- Manufacturing impacts

Environmental impact encompasses many categories, including, but not limited to: climate change ($CO_2e$) -often referred to as carbon footprint, ozone depletion, acidification, and resource use, to name a few out of more than 20 categories usually tracked.

To ensure uniformity in approach and comparison between manufacturers and industries, numerous standards cover the process such as ISO 140406, ISO 140447, EN 15804+A28.

*Fig. 1: the LCA process*

## LIFE CYCLE ASSESSMENT FOR REFRACTORIES

Below, a Cradle-to-Gate Life Cycle Assessment is discussed on materials from Morgan Thermal Ceramics. The Cradle-to-Gate method is selected because it is currently problematic for a manufacturer to predict use and disposal / recycling due to the myriad uses of each refractory, the high impact of various applications in different use environments (eg. Glass, Iron & Steel, Energy production, Petrochemicals, Ceramics.) on lifetime and variability in end of life due to contamination. As more industries adopt LCA, this will resolve by the integration of multiple assessments. The order and detail of the steps below are not intended to be instructional or comprehensive. Instead they are intended to highlight some of the important considerations and challenges experienced with specific reference to refractories.

### Software to calculate, analyse and present LCA

Multiple companies offer software and support for calculating Life Cycle Assessment. Most of these integrate databases of the environmental impact of standard raw materials, packaging, transportation, water usage, waste disposal and Scope 1 and Scope 2 emissions. The user interface guides the entry of data in the categories mentioned below and automatically generates a Life Cycle Assessment. Often the software has tools to help the user understand which materials or process steps have the largest impact. In the below assessment, Ecochain Helix[6] cloud-based LCA software tool was used, with integrated Ecoinvent v6.3 database. The quality and accuracy of the software output is highly dependent on the input's quality and accuracy; careful verification is required to avoid inappropriate selection of raw materials or order of magnitude errors in mass or energy allocations. To ensure sufficient LCA quality, adherence to the previously mentioned standards[6,7,8] is imperative.

### Raw Material Environmental Impact.

In the best-case scenario, the raw material suppliers can provide a Cradle-to-Gate LCA on each raw material. Currently for the specialist minerals grades used in refractory production, such information is quite rare. An alternative is using a standard materials database, such as Ecoinvent V6.3. Whilst these are very large and powerful, it is not always easy to identify the most appropriate entry. Common materials, such as Alumina, have many entries, some with similar descriptions and maybe none exactly matching to a specialist grade used in refractories. Where no close match can be found, read across from analogous product, or the combination of a base material with a process step can be used, e.g. a calcination step could be combined with a standard Alumina to yield the environmental impact data for calcined alumina. More complexity can result where the raw material is from a recycled source or is a by-product of another process. Detailed rules for considering these are available in relevant standards and texts[5,8]. For some refractories such as castables (see below), the raw materials constitute the majority of the finished product's environmental impact; therefore, errors in the supplier data can be very significant in the accuracy of Cradle-to-Gate LCA.

### Environmental impact of transportation.

In a cradle-to-gate LCA, the manufacturer must include the impact of all materials being transported to their site and waste removed. This will vary by distance and type / efficiency of vehicle used, e.g. truck type, size, Euro emissions rating and loading factor. The most accurate data for this would come from a LCA that had been carried out on that type of Vehicle (giving climate change potential per km per kg of material transported). Where this is not available, standard databases can provide relevant data. Generally, transportation is only a small component of refractory production, this is due to the high packing density of raw materials and the relatively high energy intensity of extraction and manufacturing steps.

### Emissions from energy used in manufacturing

It is required to consider both direct emissions, Scope 1, e.g. from burning natural gas, fuel oil, diesel etc. and Scope 2, where the energy is used on-site, but the emissions are made elsewhere, e.g. electricity. For Scope 1, it should be noted that in the calculation of the LCA, the environmental impact will be higher than that for just fuel combustion. This is because it is also necessary to include the fuel's life cycle, including its extraction, refining and transportation. This data can be taken from a supplier who has performed an LCA, or from a standard database. For Scope 2, many electricity suppliers do provide the carbon intensity of the supplied power (calculated through LCA). Although databases do have standard entries by geographic region, these are of limited use as each energy supplier will have its own, ever-changing mix of electricity sources, some with higher or lower environmental

impact. Even where a manufactures electricity comes from a 100% renewable source, the LCA will need to considered contributions from the manufacture of the production unit, its operation and electricity transmission etc.

### Emissions from process releases

Many processes in refractory manufacturing may lead to direct process emissions, such as $CO_2$ from calcination of carbonates. These need to be accurately calculated and included in the LCA. Other factory and office releases such as refrigerants, have a very high environmental impact by mass, so the amount used on a site needs careful monitoring and allocation. Waste and water leaving the site are also environmental emissions and need to be accounted.

### Allocation of resources to products

Presuming a manufacturing facility has multiple production lines and products, it is necessary to map all raw material and energy use onto those lines and products. Where there is metering and logging on each process, this can be a relatively simple task of data enquiry. A system for fair allocation will be required where metering covers multiple processes or lines.

### Calculation and reporting of LCA.

Once the raw materials have been identified, the transportation distances and methods measured, the energy sources identified, and each allocated to a process and product, then the LCA can be calculated. This is a mathematical process of ratioing the environmental impact of each input by the amount used to manufacture the product. Often it is easiest to calculate the LCA of a product in environmental impact per kg manufactured. However, end users may often work in terms of per unit area or unit volume of insulation or per box or bag of product purchased. When interpreting a LCA, paying attention to the reporting unit is important.

### COMPARISON OF THE OUTPUT OF A LCA ON FIBRE BLANKET, INSULATING FIRE BRICK (IFB) AND LIGHTWEIGHT CASTABLE

A LCA will report on many environmental impact categories. The most reported and compared is climate change ($CO_2e$) [EN15804+A2], often called carbon footprint. Figure 2 shows the relative climate change $CO_2e$ for 3 typical refractory products as calculated by Ecochain Helix software[9] (the actual values are not revealed as they are not yet verified for publication). The breakdown shows the contribution of raw materials, transportation, and manufacturing. This breakdown and their subcomponents are useful information for targeting improvements in environmental impact of products. It should be noted that this is at the manufacturer's level; at the supplier level, the raw materials themselves could be again subdivided into these 3 categories; this data is not carried through to the final assessment.

Differences in Carbon Footprint of Products

*Fig. 2: relative climate change impact of various refractories as calculated by LCA (Cradle-to-Gate).*

Figure 2 shows that per kg of product, Fibre blankets are accountable for about half the $CO_2e$ emissions compared to an Insulating Fire Brick (IFB), the major difference being the large Scope 1 emissions in firing the IFB compared to the Scope 2 electricity used in melting raw materials for fibres. The Castable has little energy input in manufacturing with the major contributor being the raw materials (although at the supplier level, manufacturing, transport and process emissions would have contributed most of their cradle-to-gate LCA).

When considering the effect of manufacturing location on LCA, typically the contribution from Scope 1 emissions will typically be very stable around the world, barring any variations in process efficiency. Hence the carbon footprint for an IFB from Europe will be largely similar to one from America. This is not necessarily the case for Scope 2 emissions; a fibre blanket from a country with predominantly green electricity may have a significantly lower carbon footprint than one from a country generating electricity from mostly fossil fuels.

## IMPACT OF REFRACTORY SELECTION ON PROCESS EFFICIENCY AND CARBON EMISSIONS

The selection of grade, quality, and thickness of an insulating refractory lining will greatly influence the efficiency of any high-temperature process and hence the environmental impact of any product manufactured by that process. Heat flow calculation, combined with the fuel cost and carbon footprint can demonstrate the payback of a lining selection, both financially and environmentally. Figure 3 compares three options for insulation on the walls of an ethylene cracker operating at 1250°C. Originally "Consumer grade" fibre refractories were installed; the customer was not happy with the heat loss; this is shown in the "Existing Lining" scenario. Two alternative systems were proposed, to prove performance, the customer chose to have both installed in different regions of the walls. System 1 comprises best in class Pyro-Bloc®[10] fibre modules and Superwool® Plus fibre blankets[11]. System 2 comprises the Pyro-Bloc with ultra low thermal conductivity WDS microporous board[12] replacing the fibre blanket. Figure 3 shows for each scenario a thermal image scan of the outside casing, and a thermal calculation using Morgan Heat Flow[13] calculator.

Using the supplier data for the "Consumer grade" refractory, the outside casing was calculated to have a temperature of 123°C and a heat loss of 1400W/$m^2$. In actuality, the thermal imaging showed the temperature, and hence heat loss to be even higher. With System 1, the casing was calculated to have a temperature of 104°C and a heat loss of 1041W/$m^2$, this was found to be accurate within measurement error. For system 2, the casing was calculated to have a temperature of 82°C and a heat loss of 663W/$m^2$, again the thermal imaging demonstrated the accuracy of the calculation.

Figure 4 shows a lifetime performance comparison of the three linings using, Thermal Efficiency and $CO_2$ Emissions (TECE) calculator software[14]. This calculates financial and environmental impacts over a 16 year life and gives a payback period in comparison to the existing lining. Typical market prices for the refractory, natural gas and carbon credits are used, as shown in the figure.

The TECE predicts that over the lifetime of the ethylene cracker wall lining (700$m^2$), the use of Pyro-Bloc and WDS instead of "Consumer grade" refractories would save 13,000 tons of $CO_2$ emissions and €3.9 Million in natural gas and carbon credits (based on 0.04€/kWh for natural gas and €85/ ton of $CO_2$). The upgrade in lining would have a payback period of 6 months. A future revision to the TECE, will take the carbon footprint from LCA (once available) and calculate a carbon payback time.

## CONCLUSIONS

Legislation and customer demand increasingly require all products, including refractories, to declare their environmental impact. The method for calculating this is through Life Cycle Assessment (LCA), for which there are defined standards. For refractories, there are complexities in calculation resulting from the use of specialist raw materials, which may not have had LCA performed upon them and for which it is not easy to identify analogous materials in standard databases. Where uncertainty exists in material flow and facility metering, emissions from manufacturing may be hard to map. The scope 2 emissions of electricity used in production can be location dependent; hence the LCA for refractory products consuming a large proportion of electricity in manufacture may vary by geography. A LCA both informs consumers about the environmental impact of a product and the manufacturer about which components have the largest influence on emissions. Thermal heat flow calculations combined with the cost and environmental impact of fuels can be used to demonstrate the payback time of additional high-quality insulation. Once LCAs are available on refractory materials, the environmental payback times can also be calculated

## ABSTRACT

Organizations are now integrating life cycle thinking tools and techniques into decision-making to enable an analysis of the environmental impacts associated with all stages of a product's life. In this context, mining has been questioned by the widespread consensus that reducing resource consumption is a requirement for sustainable development. On the other side, it is clear that, due to dissipation, virgin raw materials will always be needed, and that circular economy thinking should integrate the mining industry and not oppose it. From this emerges the concern of resource depletion and the abiotic depletion potential (ADP) comes therefore as an attempt to assess the risk of depletion within life cycle assessment (LCA) methodology. However, when it comes to mineral resources, a lot of general assumptions are made, and the specificities of each element are often neglected. By attempting to include anthropogenic stocks in the calculations, some authors also neglect the singularities of each product. LCA has proven to be a powerful tool and its successful application within the refractory industry depends on collaboration between organisations in order to fill the numerous lacks of data availability and to overcome the challenges ahead. This paper is part of a PhD project that aims to build a database of magnesia production, from the mine to the kiln, to support LCA as well as to discuss resource depletion within the methodology and to account for the benefits and challenges of refractory recycling, focusing on magnesia bricks.

## INTRODUCTION

The Circular Economy (CE) concept is increasingly gaining ground in academia and industry. Sustainability is the key word of our times and is leading the trend to increase circularity throughout all the stages of the production processes (Fig. 1). To achieve such a bold goal, it is important to know well and have a systemic vision of the whole life cycle, from the raw materials to the end-of-life (EoL), accounting for the origin of the main dissipative flows and environmental impacts.

Fig. 1: Representation of a product life cycle, Source: EIT Raw Materials

Life Cycle Assessment (LCA) has gained relevance in many industrial sectors as a sustainability tool. The methodology is used in different maturity levels within the industries, but it is generally recent. It is a powerful tool to get a better picture of the whole production chain and to help decision-making and redesigning of a product or process. Knowledge has advanced through the development of scientifically valid life cycle inventory (LCI) databases and models (e.g., EcoInvent), but some industrial sectors have still no significant or reliable inputs. Therefore, this is an open field with plenty of opportunities to be developed and intensive work will be required to face the challenges that will come with it.

The refractory industry is not out of it, but the LCA of refractory products is still in its infancy. Refractory linings are required in a lot of high-temperature production processes (metals, glass, cement, etc.). Therefore, refractories are part of the production of many essential materials for the civilization. Additionally, refractories have a significant $CO_2$ footprint, especially due to the calcination of magnesite ($MgCO_3$) to produce magnesia ($MgO$), one of the main raw materials (Eq. 1). Furthermore, the harsh corrosive conditions to which refractories are often exposed during their service life result in high dissipation rates, which affects circularity.

$$MgCO_{3(s)} \rightarrow MgO_{(s)} + CO_{2(g)} \tag{1}$$

LCI databases have been created but seem still inconsistent and/or incomplete that professionals prefer not to use them and trust on their internal data, even though it may not represent a global extent. Additionally, relevant stakeholders are still not interested in overall environmental data, which limits the added value of LCA. Instead, customers are increasingly interested in Product Carbon Footprint (PCF) due to the growing pressure to decarbonise their whole value chain. Despite the given lack of interest in full environmental assessments, it can be expected that regulations can encompass an overall environmental impact of products in the near future. Therefore, given the importance of the refractory industry and the significant environmental impacts associated with it, efforts should be made to promote the use of LCA tools to provide a better picture and support decision-making towards sustainability.

## REFRACTORY INDUSTRY: A SPECIAL CHALLENGE

Refractories present a major challenge to LCA practitioners due to their complexity. There is a wide variety of refractory products with distinct compositions and production processes. Unlike ordinary clay bricks, refractories have a wide range of raw materials between aggregates, binders, and additives. RHI Magnesita, the global leader in refractories manufacturing, uses more than 6,000 raw materials from many types of sources to produce more than 200,000 different refractory products. This is the order of magnitude of the challenge that needs to be addressed.

Moreover, very often some steps of the production chain are neglected or poorly documented in the literature. For example, it is common to find simplified representations of the production chain of magnesia from magnesite that obliterate the mineral processing step right after mining. The availability of high-quality data is fundamental for the assertiveness of the LCA study and therefore, industrials should think more collaboratively to fill the lacks that actual databases have. In the complex context that the refractory industry presents, only collective and centralized efforts would produce satisfactory results.

## RAW MATERIALS SOURCING

Given that dissipation is inevitable in every step of a production process, many industries are often concerned about supply risk

since virgin raw materials will always be necessary to feed the loop. Getting to know the production process and its required inputs is a first step that, followed by a detailed study of the raw materials sources, can give a more accurate scenario to help strategic decisions. Abiotic Depletion Potential (ADP) is a method within LCA that aims to account for the risk of depletion of elements with characterisation factors based on the ratio of the annual extraction rate (DR) to the square of the assumed stock (R) of a given element [22]. Antimony was chosen arbitrarily as a reference element to make a normalization of the results as shown in Equation 2.

$$ADP_i = \frac{DR_i / (R_i)^2}{DR_{ref} / (R_{ref})^2}$$

(2)

Despite the simple calculation, the determination of the assumed stocks can be challenging, especially in the case of diverse potential sources and uses of the same element. In addition, since the methodology focuses on the very long run, an estimation of stocks should also consider a technological development that could make available some sources that are currently unavailable due to technical and economic constraints. To do so, there is no objective answer, and this subject is still an open discussion among experts.

Given that there may be more than one source and/or functional mineral of a given element, crustal content seems to be the best base for the calculation, since it refers to the element. Additionally, crustal content is the only reliable and stable base to estimate the stocks [3]. Regardless of the criteria used to determine the stocks in a long-term perspective, very often authors generalize it for different elements (e.g., same crustal depth). This is not geologically reasonable since different elements may have distinct origins, with different types of mineralization, varying the size, shape, and depth of the deposits. The generalization is also not economically supported, since elements may also have different values, not being able to afford the same extraction/processing costs. It is inconceivable to expect companies to dig as deep for limestone as they do for gold, due to the discrepant added values between these commodities. In the same way, it is unimaginable to find bauxite as deep as we find copper, given the differences in the geogenesis of these mineralisations.

Moreover, crustal content may mislead if applied disregarding the cut-off grade, i.e., the minimum concentration that allows the processing of a given element with the actual technology. Still, as ADP refers to a very long-term, technological development should be expected, enabling deeper mining and processing of poorer ores. Finally, economic, geological and technological constraints must be considered in the analysis.

**A closer look into Magnesia**

Due to its high melting point (2800°C), magnesia is one of the most important refractory aggregates. Mainly used in steelmaking, magnesia is obtained from the calcination of magnesite in most cases (Eq. 1). Developed countries without commercial magnesite resources typically produce magnesia from seawater, brines, or evaporitic deposits, which are common sources for the production of magnesium metal [19]. Magnesia produced from these sources is often called "synthetic magnesia", and "natural magnesia" is commonly the name given to the one obtained from magnesite. The concentration of magnesium in seawater is 1290 ppm [4] and high-purity magnesia can be obtained from it, but with significantly higher costs. Synthetic magnesia production requires up to twice the energy needed in natural magnesia production [18].

The share of synthetic magnesia in the global magnesia production capacity has decreased due to the tough competition with the Chinese market resulting in closures and a significant decrease in synthetic magnesia production capacity. However, due to the return of market growth, substantial investments were made in 2010, resulting in synthetic magnesia production capacity increasing, but remained a minor part of the share with magnesite source [19].

Figure 2 shows the global production capacity share between natural and synthetic magnesia in 2001 and 2013. Experts estimate that synthetic magnesia may represent around 10% of the actual global magnesia production capacity.

*Fig. 2: Global production capacity of Natural and Synthetic magnesia, 2001 and 2013 [19]*

With the increasing urgency of tackling climate change, alternatives to natural magnesia with a lower $CO_2$ footprint should now receive more attention. Besides seawater and brines, it has been shown to be possible to produce magnesia from Mg-bearing minerals either by mineral digestion followed by brucite ($Mg(OH)_2$) precipitation and further calcination [21] or by carbonation [11]. These processes are highly energy intensive and present higher $CO_2$ footprint than the natural magnesia mainly due to the available energy sources. Therefore, fostering green energy production could enable the production of magnesia from alternative sources with considerably lower $CO_2$ footprint. Combined with that, improvements are needed to achieve a production scale that would meet the industrial demand and increase the market share of synthetic magnesia.

**Anthropogenic Stocks**

With the growing stimulus to establish an industry that follows the principles of circular economy, it is important not to disregard anthropogenic stocks when evaluating resource depletion. Elements are not always used or dissipated, they can often still be available to be reused through recycling, which is also true for refractories. Therefore, Schneider et. al. (2015) [20] suggested that the ADP assessment should be broadened to encompass anthropogenic stocks in the calculation. The authors made no differentiation between the elements and a general dissipation rate was used. This is problematic because, in addition to the different behaviour of distinct elements, the same element may be used in multiple ways within the anthroposphere, resulting in multiple dissipation rates for the same element. That gives an idea of how complex the estimation of anthropogenic stocks can be.

Moreover, a point that must be highlighted is that not all the elements within the anthroposphere are available for eventual recycling due to long-term use. Consequently, occupation-in-use should be taken into account when trying to measure anthropogenic stocks [1].

Last but not least, in some cases the anthropogenic stocks may not be relevant because they may represent a minor part of the total stocks in the calculation of ADP. Thus, estimating the anthropogenic stocks to include in the ADP calculation may not be worthwhile for elements with high natural stocks and/or dissipation rates. Otherwise, it may be relevant in case of more scarce elements and/or with high recyclability.

**RECYCLING**

During the use phase, around 30-40 wt.% of the refractory is consumed [13], indicating that up to 35 million tons of spent refractories are generated every year from the 50 million produced [12]. The fact that refractories are corroded and dissipated during the use phase shows that primary raw materials will always be needed in the refractory industry because even with refractories completely made of recycled raw materials in a closed loop, the losses during the use phase would make it impossible to keep the production without using virgin raw materials.

Due to the abundance of virgin raw materials, in the past, recycling received little attention in refractories manufacturing. Added to this, the low disposal costs of the, largely inert, spent refractories was another reason to keep the refractories recycling out of focus. Instead, a lot of progress was made in the refractory consumption per ton of product. In the steel industry, refractory consumption has declined from 25-30 kg of refractory per ton of steel in the 1970s to 8 kg/t today in US and Japan [2]. Such progress could be seen also in other industries as the production of cement, which decreased the relative refractory consumption from more than 2 kg per ton of cement clinker to on average 0,9 kg/t [5].

With the increasing landfilling costs and environmental concerns, recycling has risen as a strategic alternative to guide the refractory industry towards a circular economy. Spent refractories have been largely used in open-loop recycling applications such as roadbed aggregates [2] and slag conditioners in the steel industry [8]. In these applications, the value of the recycled material is limited to the cost of the replaced material, which is much cheaper than refractories.

However, closed-loop recycling is still limited to an average of 7% of refractory raw material demand [15]. Recently, RHI Magnesita has increased the global recycling rate to 10.5% in 2022 [16]. Studies showed that the production with 20% of recycled refractories as raw material is achievable in the manufacturing of LC series [9]. Remanufactured MgO-C bricks containing up to 30% of recycled material were found to have almost the same properties and durability as low-grade MgO-C brick [13]. More recently, Kunanz et al. (2022) [10] reported a successful implementation of high recycling containing magnesia-carbon brick in steel ladles. The newly developed brick contains 87 wt.% of recycled material and reduced the long-term average consumption from 0.21 kg/tonne steel to 0.13 kg/tonne steel, a reduction of 38% of refractory material use.

The substitution of virgin raw materials for recycled spent refractories leads to a considerable reduction in the carbon footprint since the thermal treatment of magnesite and dolomite includes the most $CO_2$-intensive processes. The production of dead burned magnesia (DBM) and dead burned Doloma (DBD) is responsible for around 85% of RHI Magnesita's scope 1 emissions. In 2020, the production of DBM and DBD generated approximately 1.8 million tons of $CO_2$ scope 1 emissions, of which 60% were geogenic and 40% were fuel-based [17]. A standard magnesia-carbon brick has a $CO_2$ footprint of 3.95 tonne $CO_2$/tonne bricks, while an 87% recycled content magnesia-carbon brick has only 0.55 tonne $CO_2$/tonne bricks, an expressive reduction of 85% [10].

Nevertheless, refractories recycling can be challenging. During their lifetime, the refractories undergo some modifications in their physical and chemical properties, especially in their exposed surface, due to the usually hard operating conditions. Refractories may then have some inclusions of slag or metals and then, the content of CaO, $Fe_2O_3$ and $SiO_2$ also increases in the spent magnesia-based refractories used in steelmaking. Therefore, this increase can also be seen in recycled refractories [7]. The presence of these impurities typically leads to a decrease in durability because of melt formation between Ca/Si and Mg/Al [6]. Furthermore, recycled refractories aggregates tend to present higher porosity and lower density than virgin raw materials, which affects their physicomechanical properties and limits the amount of recycled refractory aggregates that can be introduced into the refractory mix [7].

In addition, as most of the furnaces use more than one type of refractory product, it becomes difficult to separate the different refractories when removing the spent lining and in most of cases they are indiscriminately mixed into a pile. Therefore, processing spent refractories to improve refractory recycling faces the challenge of sorting different types of refractories. The state-of-the-art recycling plant for refractory waste includes, therefore, a pre-sorting step, in which the different types of refractories are separated. This stage is usually done manually, and even after this sorting process different types of refractory materials are often mixed and contaminated with pieces of iron metal and slag [6]. This step is highly error-prone due to the presence of dust and other contaminants that limit the visual identification and because it is dependent on the operator's expertise [7].

Besides the lack of efficiency and objectivity of the manual pre-sorting of spent refractories, the dusty environment and the hostile working conditions are other concerns. Therefore, there is a strong demand for automation in the pre-sorting step within the industry to improve accuracy and speed as well as the working conditions. Some systems have been developed based on colour sorting, however, it is hindered by the dust layers as well as the similar appearance of chemically distinct refractories. In the last years, sorting systems were developed using LIBS (Laser Induced Breakdown Spectroscopy), which uses a pulsed laser to ablate the surface of a material, typically penetrating around 100 µm deep into the sample, eliminating then, most of the surface interference caused by dust [7].

The European project REFRASORT successfully developed a LIBS system that aims to separate the main refractory types used in the steel industry, such as MgO-C with and without antioxidants, carbon-bonded doloma, fired doloma, bauxite, andalusite and chamotte [14]. A test was carried out using the REFRASORT demonstrator (Figure 3) with 30 t of mixed magnesia, doloma and alumina-based spent refractories [7]. The accuracy was validated by analysis of the output fractions and the sorted fractions achieved the targeted contents, being the only exception a slightly higher $SiO_2$ content in the doloma fraction.

*Fig. 3: REFRASORT demonstrator system [7]*

Recycling is one of the best strategies to reduce carbon emissions within the refractory industry and therefore it is one of the priorities of many refractory producers. The increasing environmental concern may motivate customers to push the refractory industry to develop green alternatives. In this context, some kind of sustainability certification of refractories will be of interest, since refractory consumers will be concerned about the global environmental impacts the products have. LCA is the right tool to produce that kind of summary and enable a more conscient consumption.

**CONCLUSIONS**

LCA is an important tool that can contribute to a better understanding of a whole production process in terms of supply and environmental impacts. It is a powerful method to enable a systemic vision and therefore to identify the main bottlenecks in the environmental performance of a product, allowing the eco-designing. By giving the big picture of a product, LCA can help industries to know their products and processes well enabling a more assertive decision-making towards sustainability.

However, it has been proven challenging to implement LCA within the refractory industry. There is still low reliability in the few databases created and the high complexity and variability of refractory products pose difficulties. To accomplish such a tough goal, collaborative efforts would be necessary between raw materials suppliers, refractory producers, and end users since data availability is still of concern.

Moreover, there is a lack of interest in LCA data from relevant stakeholders, which limits the added value of such assessments. Instead, PCF is increasingly in demand as companies come under small but growing pressure to decarbonise their entire value chain. Thus, from a regulatory perspective, linking taxation with the whole environmental footprint could be a possibility in the near future to push the industries to reduce overall environmental impacts, and then the refractory industry should be prepared to overcome this challenge, possibly by implementing LCA analysis.

In terms of supply, there is evidence that the ADP should be reviewed to assess the risk of depletion of raw materials more accurately. Every element should be addressed individually, accounting for its specificities, and avoiding generalisations. The assumed stocks have been a concept under discussion and hard to determine, given the subjectiveness of envisioning economic and technological conditions in a very long-term perspective added to the complexity of geological analysis. Alternative sources should be considered to avoid supply shortages and, in the case of magnesia, can offer the environmental advantage of avoiding high $CO_2$ emissions by producing synthetic magnesia instead of natural magnesia. The inclusion of anthropogenic stocks in the calculation of ADP seems to be relevant since recycling has been fostered in many industries. However, some improvements are still needed to do this coherently.

Recycling has proven to be an effective strategy to reduce the carbon footprint of refractories and to make the refractory industry more sustainable and circular. A lot of progress has been done in the past few years and an overall recycling input rate of 10.5% was achieved in 2022 at RHI Magnesita. Magnesia-carbon bricks made with 87 wt.% of recycled material proved to be functional, reducing the PCF by 85%. Many projects have been developed to improve the recycling of refractories and the LIBS technique delivered good results in sorting different spent bricks. Recycling seems to be the way to revolutionise the refractory industry towards sustainability.

## OUTLOOK

This paper is part of a PhD thesis, within the CESAREF consortium, entitled *"Documenting the Upstream of Refractories Manufacturing to Support LCA"*. Since one of the challenges of implementing LCA within the refractory industry is the lack of availability of good quality data, the main goal of this project is to build a better knowledge about the production of refractory raw materials, more specifically, magnesia production. A description of the current and alternative production routes will be accompanied by an inventory of the main inputs and outputs of the production processes ($CO_2$ emissions, energy consumption, etc.). Parallelly, the project aims to discuss resource depletion within LCA, reviewing the ADP methodology and making an analysis focusing on magnesium. Finally, accounting for the benefits and challenges of magnesia bricks recycling with eco-design recommendations is another goal.

## ABSTRACT

Refractory solutions go beyond thermal management during the secondary refining of liquid steel. For instance, refractory bubbling devices might be applied in the ladle to homogenise the molten bath (chemically and thermally) and to induce the floating of non-metallic inclusions to the slag phase. These inclusions are typically ceramic phases and have many origins along the steelmaking, e.g., the deoxidation step, the re-entrainment of slag and the erosion of refractories. Their effect on the mechanical properties of steels may be detrimental based on the severity of the processing step and the stresses during the application. To illustrate, inclusions could lead metallic axles to an early fatigue failure by acting as stress concentrators under cyclic loading. Therefore, the design of high-performance ceramic plugs and the production of cleaner steel grades rely on understanding the fundamentals of non-metallic inclusions captured by the gas bubbles. From a thermodynamic point of view, this attachment changes the system's energy related to the interfacial energies among the phases, which can drive the system to a meta-stable configuration where the detachment of the particle is unlikely, mainly for non-wettable particles. Thus, this work uses a thermodynamic model to discuss the influence of the particle's wettability on its removal rate and efficiency. Besides, it analyses the design of a flotation water model to conduct physical simulations assessing the theoretical calculations. Based on the results, suggestions are proposed to improve the removal of non-metallic inclusions during the secondary metallurgy of steels.

## INTRODUCTION

The removal of non-metallic inclusions (NMI) is one of the goals for the secondary refining of steels and is conducted by injecting inert gases through porous bubblers either in the ladle or in the tundish. From a macroscopical point of view, the bubble plume interacts with the molten metal to capture inclusions, carrying them to the slag layer. If properly adjusted (i.e., in chemical and rheological aspects), this top molten layer irreversibly dissolves the NMI, positively contributing to the cleanliness of the molten bath [1]. On the other hand, understanding the underlying microscopical mechanisms allows one to tune the process parameters and increase the removal rate and efficiency of the bubble-induced flotation which might also lead to the development of porous bubblers [2]. In this sense, the literature describes three mechanisms by which inclusions interact with bubbles: (A) they can be attached to the gas bubble's surface, (B) captured in the bubble wake region and/or (C) dragged by the flow pattern induced by the bubble plume, as represented in Fig. 1 [3,4]. It is worth noting that only mechanism "A" relies on a three-phase contact among the inclusion, gas bubble and liquid medium. Thus, it may become relevant to investigate the interface tensions and their influence on the attachment step.

Fig. 1: Mechanisms involved in the bubble-induced flotation of particles in liquid media.

The thermodynamics of particle attachment has been previously investigated by the authors in a former paper [5] that could be summarised as depicted in Fig. 2. From the moment when the bubble-particle collision takes place, the three-phase contact line defines an angle for the particle on the bubble's surface ($\theta$). By increasing this angle, the particle moves towards the bubble, facing an energy barrier to its attachment ($\Delta E_a$). Thus, the magnitude of this energy barrier can be related to the easiness of capturing the inclusion. Once overcome, the system seeks a local minimum energy point, corresponding to the stable contact angle ($\theta_e$). In some cases, typically for liquidphobic inclusions, this point also corresponds to a global minimum, so the detachment of the inclusion back to the liquid phase is unlikely. If it was to occur, the particle would need enough energy to overcome a detachment barrier ($\Delta E_d$), which is higher than the attachment one ($\Delta E_a$) when the attachment represents a lowering in the system energy (i.e., $\Delta E_{att} < 0$). Instead, the detachment barrier is lower than the attachment one for liquidphilic particles, as $\Delta E_{att} > 0$. Then, the particle could still be attached to the bubble surface, though in a metastable condition as it does not represent a global minimum energy point.

Fig. 2: Typical energy curve for the particle attachment [5].

Therefore, this work presents the design of experiments on a water model to assess the flotation of hydrophobic and hydrophilic particles. The particle concentration was measured timewise and the decay due to particle removal was exponentially fitted to get insights about the removal rate and process efficiency. The results suggest that bubble injection speeds up the flotation of hydrophobic particles and increases the removal efficiency.

## METHODS

Aiming at investigating the induced flotation of inclusions with different wettabilities, two grades of particles with similar size distributions were selected. Potters Q-Cel 7014 and 3M Glass Bubbles K-20 were employed as hydrophobic and hydrophilic particles, respectively. Both are spherical glass hollow spheres, with a density lower than the water one, as presented in Tab. 1. However, as the particle density is directly related to the ratio between its glass thickness layer and the hollow bulk, one could expect that smaller particles have a higher density, approaching the solid glass one. Thus, the particles were dispersed on a 3:2 water-isopropanol solution and wet-sieved down to 75 μm. The particles (as received) and the obtained suspensions were characterised in a Malvern

Panalytical Mastersizer 2000 to get their size distribution, coupled with a Hydro 2000S sample dispersion unit. In these analyses, the solvent phase was ethanol 96% v/v for the hydrophobic particle and deionized water for the hydrophilic particle. All samples were analysed according to Fraunhofer's theory of light scattering. Besides, SEM micrographs were obtained in a TESCAN MIRA electron microscopy under high vacuum, with an acceleration voltage of 25kV, a working distance of 15 µm, and a beam current of 300 pA. Samples were coated with a 10nm layer of AuPd alloy.

Tab. 1: Glass particles employed in the flotation experiments.

| Particle | Wettability | Density [g/cm³] |
|---|---|---|
| 3M Glass Bubbles K-20 | hydrophilic | 0.20 |
| Potters Q-Cel 7014 | hydrophobic | 0.14 |

The water model consisted of a 1000x400x40mm³ vessel with acrylic walls to allow the visualisation of the experiments, as illustrated in Fig. 3. The system is filled in with softened tap water and has a pump to recirculate the aqueous suspension and homogenise the concentration of particles. During the experiments, the pump is kept at 900 rpm, corresponding to a recirculating flow of 21 L/min or a velocity of roughly 22 mm/s when considering the model's cross-section. Besides, a porous bubbler was installed at the centre of the model's base, where compressed air was blown to generate bubbles of roughly 1.1 mm.

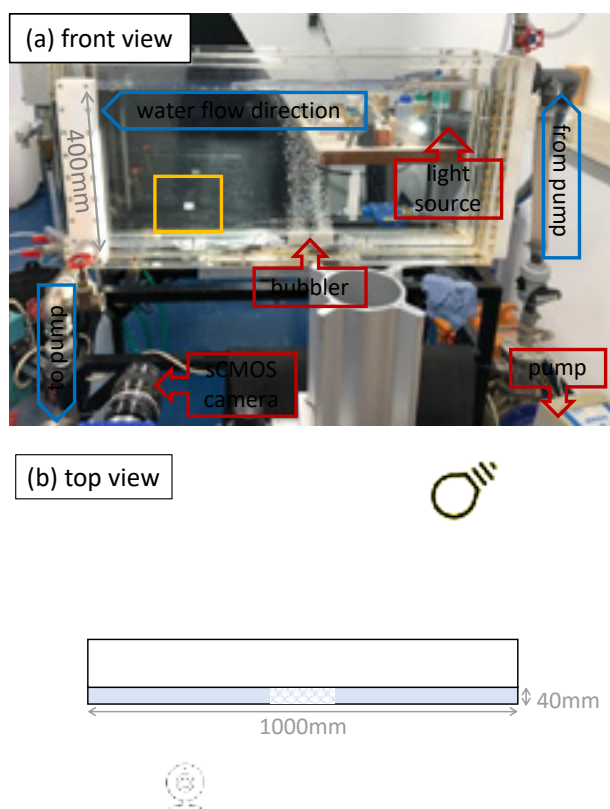

Fig. 3: Water model's (a) front view - highlighting the recirculation path (in blue), the various apparatus (in red) and the field of view (in yellow) - and (b) top view – illustrating the light scattering system.

The concentration of particles was indirectly measured by a light scattering technique, as represented in Fig. 3b. The system had been previously calibrated within the analysed range (700-9000 counts). A 250-watt tungsten-halogen lamp, located in the back part of the model, was used as a source of collimated light. The light rays are scattered by the particle and collected by a scientific CMOS camera (LaVision Imager) in front of the model, at 1 Hz. Each frame has 2160x2560 pixels, is 16-bit deep, and corresponds to a 1 ms exposure

time. The camera has a Nikon 55mm lens installed at full aperture (f/2.8).

Before starting the experiments, 80 mL of particle suspension was injected close to the water outflow, and the model was homogenised for 5 minutes. Then, the natural flotation of particles was recorded for 10 minutes and fitted by an exponential decay function ($I(t) = I_\delta \cdot \exp(TS^{-1} \cdot t) + I_\infty$), where TS stands for "time scale" and represents the mean lifetime of particles in suspension. Next, compressed air was injected through a porous bubbler at 100 NL/min, and the induced flotation of particles was recorded for 25 minutes and mathematically adjusted. Finally, particles were filtered out, and the system's background with bubbles was measured.

## RESULTS AND DISCUSSION

### Suspension characterisation
The hydrophilic and hydrophobic particle grades were characterised by their size distribution before and after the wet-sieving procedure, resulting in a suspension of fine particles. The results of size distribution are presented in Fig. 4 and summarised in Tab. 2. Based on the results, one can notice the similarity of size distribution between the hydrophilic and hydrophobic grades. It is also possible to infer that the sieving procedure not merely removed particles above 75 µm but generated a new distribution of smaller particles. For the hydrophilic grade, the values of $d_{10}$, $d_{50}$ and $d_{90}$ were cut down by two-thirds whereas these values decreased by roughly a half for the hydrophobic one.

Tab. 2: Particles diameters measured from their size distribution before and after the wet-sieving procedure.

| Sample | | $d_{10}$ [µm] | $d_{50}$ [µm] | $d_{90}$ [µm] |
|---|---|---|---|---|
| as received | 3M K-20 | 21.6 | 51.1 | 100 |
| | Potters 7014 | 20.2 | 57.6 | 114 |
| in suspension | 3M K-20 | 14.2 | 34.2 | 66.1 |
| | Potters 7014 | 10.1 | 28.5 | 64.3 |

Fig. 4: Particle size distribution obtained by a Malvern analyser before and after the wet-sieving procedure.

The particles and their suspensions were also analysed by electron microscopy and the micrographs are presented in Fig. 5 a-d. The images show that the particles are perfectly round, and few fragments and debris are observed in the samples before sieving. There is a noticeable decrease in particle size after wet-sieving and preparing the suspensions, which confirms the results of Fig. 4. However, broken particles were also among the sieved fraction that was suspended, and the debris would tend to sediment during the experiments.

**Flotation experiments of hydrophobic and hydrophilic particles**

The sieved suspension of hydrophobic particles was employed in the flotation experiment, and the results are shown in Fig. 6, which presents the average pixel intensity in the obtained images as a function of time. The highest intensity in the beginning represents that more light rays were scattered by the particles, due to their higher concentration. After the homogenisation step, the average intensity of pixels (4640 counts) is taken as 100% for the concentration of particles. The first decay in Fig. 6 represents the particles' natural flotation (NF), as no gas bubbles were being injected into the system. The exponential fitting shows that particle concentration tends to 3127 counts at an infinite time, corresponding to a removal efficiency of 40.4 % (Eff. NF). When bubbles were injected into the system, the flotation speeded up as the TS parameter was reduced from 607 to 138 seconds. Besides the 3.4 times faster removal, the efficiency increased to 49.0 % (Eff. N&IF) when the mechanisms of induced flotation were coupled by the bubble plume.

Fig. 6: Intensity of scattered light as a function of time for the flotation experiment of hydrophobic particles. The 100% concentration and the efficiencies are highlighted.

Even though the experiment with hydrophobic particles highlighted the higher removal rate and efficiency when bubbles were injected, it is not possible to correlate these results with individual mechanisms of induced flotation, as pointed out in Fig. 1. Thus, the same experiment was carried out with the sieved suspension of hydrophilic particles and the results are presented in Fig. 7. Under these conditions, the average intensity of 5089 counts was obtained after the system homogenisation and taken as the 100% concentration of particles. During the natural flotation step, the exponential fitting led to a TS parameter of 687 seconds and an efficiency of 56.5 %.

In contrast to the previous experiment, the injection of bubbles initially led to an increase in the average intensity, as highlighted in Fig. 7. This effect might be related to the re-entrainment of particles from the top surface of the system as the bubble plume locally increases the instability of this layer. After 10 minutes, the removal and the re-entrainment of particles came to a stable condition, and the results were fitted by an exponential decay equation. Although the removal rate decreased 2.4 times, with TS going from 607 to 2351 seconds, the efficiency was still higher when induced flotation mechanisms were coupled (64.5 %). However, these results were affected by the instability of the water model's top layer and do not represent the behaviour of a slag phase, in which inclusions could be dissolved when reaching the metal-slag interface.
*Fig. 7: Intensity of scattered light as a function of time for the flotation experiment of hydrophilic particles, highlighting the particle re-entrainment after bubble injection starts.*

The instability of the floated particles layer at the water model's top region may be related to the thermodynamics of capturing particles at liquid-gas interfaces. As shown in Fig. 8, the change in energy due to the attachment depends on the macroscopic contact angle ($\theta_{slg}$) among the solid, liquid and gas phases, defining three scenarios:

– Non-wettable particles (90° or higher) show a negative $\Delta E_{att}$, causing the detachment barrier to be higher than the attachment one ($\Delta E_a < \Delta E_d$). Thus, particles are stable at the liquid-gas interface, as in the experiment with hydrophobic particles (Fig. 6);

– Slightly wettable particles (around 60°) can still be attached to the liquid-gas interface because a local minimum energy point is observed beyond the attachment barrier. However, it represents a meta-stable condition as $\Delta E_{att}$ is positive (and $\Delta E_d < \Delta E_a$), causing the particle to easily detach and return to the liquid phase;

– Highly wettable particles (30° or lower) do not even have a metastable condition of attachment, and the energy components ($\Delta E_{att}$, $\Delta E_d$ and $\Delta E_a$) are not applicable.

*Fig. 8: Change in energy caused due to the attachment of a particle at a liquid-gas interface as a function of its position for different values of macroscopic contact angles ($\theta_{slg}$).*

Considering that the hydrophilic grade of particles (3M Glass Bubbles K-20) was made of soda-lime-borosilicate glass, one could expect a low macroscopic contact angle in contact with aqueous solutions and, therefore, a condition close to the third scenario – where particles are not stable at the liquid-gas interface. Thus, the naturally floated particles remained at the model's top surface merely because of their low density (compared to the water phase) and re-entrained the system when the bubble plume was started, increasing the turbulence of the top layer. On the other hand, the additional

flotation mechanisms - related to either the particles captured by the bubble wake region or by the induced flow pattern – would still be activated, which explains the higher efficiency of removal when bubbles were injected (Fig. 7). Therefore, changes in the system to remove the floated particles right after reaching the top layer would be required for future experiments so that it suitably acts as a slag layer.

**CONCLUSIONS**

This work studied the flotation behaviour of hydrophobic and hydrophilic hollow glass particles by conducting experiments on a water model and measuring the particle concentration by a light scattering technique. Particles were pre-dispersed in an isopropanol-water solution and wet-sieved to generate inclusion-like suspensions. The natural flotation of both particles presented a similar removal rate. When 1.1 mm bubbles were injected, the removal rate for hydrophobic particles increased by 3.4 times, and the removal efficiency improved from 40.4 to 49.0 %. Conversely, the naturally floated hydrophilic particles re-entrained from the model's top region as bubbles were injected, and no conclusions could be drawn about the contribution of the bubble plume to the removal rate and efficiency. Such an effect was expected as these particles are highly wet by the liquid and not captured by the liquid-gas interface due to their low contact angle.

## ABSTRACT

Contact with molten slags is one of the key reasons for chemical wear of refractory materials used in the metallurgical industry. Computational thermodynamics and equilibrium simulations offer a fast method to estimate the driving force for chemical wear in situations in which refractory material is in contact with reactive fluids such as slags. The purpose of this study was to estimate the possible wear mechanisms based on thermodynamic simulations executed with commercial thermochemistry software FactSage and its databases. Interactions between different refractory materials and slags with compositions corresponding stainless steelmaking and flash smelting slags (both copper and nickel matte production) were studied. Based on the results of these simulations, the driving forces for direct and indirect dissolution, formation of new solid phases as well as other forms of chemical interaction were estimated. The results of the simulations were compared with the analyses of industrial samples as well as results of the laboratory experiments. Based on the results of the simulations, it is possible to predict the chemical wear of refractory materials caused by slags.

## INTRODUCTION

Depending on the conditions, the wear of the refractory materials in pyrometallurgical processes is caused by different combinations of thermal, mechanical and chemical stresses. In order to estimate the durability of different materials under different conditions, it is necessary to know the wear mechanisms caused by the stresses mentioned above. Although the characterization of materials either tested in laboratory experiments or used in actual processes can provide more reliable information on the behavior of materials, the computational simulation tools can offer a faster, cheaper, safer and more reproducible way to predict the possible wear mechanisms of different materials.

With a focus on the chemical stresses caused by molten slags, the wear mechanisms can be roughly divided into three categories: (1) direct dissolution, (2) indirect dissolution and (3) formation of new (solid) phases on the slag/refractory-interface. In the third mechanism the refractory material is not worn by the chemical reaction itself, but the formation of new phases may cause mechanical stresses which, in turn, can cause wear of the material.

The aim of this research was to estimate, whether the chemical wear mechanism caused by molten slags can be predicted from the results of thermodynamic simulations made with a commercial thermochemistry software (FactSage) and its databases. For this purpose, the simulation results were compared with the results of laboratory experiments as well as *post mortem* analyses of industrially used refractory materials.

## METHODS

Thermodynamic simulations were made for refractory-slag-systems in which the total composition of the system varied from 100% refractory material to 100% slag. Thermochemical software FactSage (version 8.0) and its FactPS, FToxid and FSstel databases were used in the simulations. As a result, thermodynamically stable phases for different refractory/slag-ratios in given conditions (*i.e.* temperature and pressure corresponding the conditions in chosen industrial processes) were obtained. These results illustrate what can happen when different portions of refractory material and molten slag are in contact with each other. For example, if the proportion of molten oxide phase in equilibrium is larger than its initial proportion, there is a driving force for dissolution. On the other hand, the existence of solid phases not present in the unused refractory material indicate the possibility for the formation of solid product layers on the slag/refractory-interface.

The studied refractory/slag-systems are shown in Table 1, whereas the chemical compositions of the considered refractory materials and slags are shown in Tables 2 and 3. The highest simulation temperatures were chosen to correspond the temperatures in studied industrial processes, whereas the lower temperatures simulate the conditions inside the refractory materials close to the interface. Atmospheric pressure was chosen for all studies except for the system, in which refractory/slag-interactions in steel ladle vacuum treatment were simulated. Magnesia-carbon-refractories with two different C-contents were studied: (1) one with lower carbon content for the chrome converter system and (2) one with higher carbon content for the steel ladle vacuum treatment system. The numbers (1) and (2) in Tables 1 and 2 indicate these two different materials. Three refractory materials studied in the flash smelting furnace systems were identical for both copper and nickel production systems.

Validation was made by comparing the simulation results with the results of the laboratory experiments (crucible tests) executed for similar systems as well as with the characterisation of used industrial refractory materials.

Tab. 1: Refractory/slag-systems studied in this research.

| Process | Refractories (main components) | Slag compositions | T (°C) | p (kPa) |
|---|---|---|---|---|
| Chrome Converter (CRC) (Stainless steelmaking) | MgO-C (1) $Al_2O_3$-$SiO_2$ | Corresponding industrial CRC-slag (3 different basicities; CRC1-3) | 1400-1650 | 101 |
| Flash Smelting Furnace (FSF) (Production of copper matte) | MgO-$Cr_2O_3$ $Al_2O_3$-$Cr_2O_3$ SiC-$Al_2O_3$ | Corresponding industrial FSF-slag in copper production (FSF1) | 1100-1350 | 101 |
| Flash Smelting Furnace (FSF) (Production of nickel matte) | MgO-$Cr_2O_3$ $Al_2O_3$-$Cr_2O_3$ SiC-$Al_2O_3$ | Corresponding industrial FSF-slag in nickel production (FSF2) | 1100-1400 | 101 |
| Vacuum Tank Degassing (VTD) (Steelmaking) * | MgO-C (2) MgO-$Al_2O_3$ | Corresponding ladle slag in steelmaking (reduced/unreduced; VTD1-2) | 1550-1700 | 101 / 0.7 |

* Simulations for the VTD-system were executed with an earlier version of the FactSage (7.2) and the results have been presented in [1].

Tab. 2: Normalized refractory compositions (in weight-%) studied in this research. Compositions of VTD-refractories taken from [1].

| Refr. | MgO | SiO₂ | Fe₂O₃ | CaO | Al₂O₃ | TiO₂ | Cr₂O₃ | K₂O | ZrO₂ | P₂O₅ | SiC | C |

## RESULTS AND DISCUSSION

A few examples of the results of thermodynamic simulations are shown in Figure 1. The examples in Figure 1 have been chosen to represent different kind of potential wear mechanisms. A more comprehensive summary of potential wear mechanisms for different slag/refractory-systems is shown in Table 4.

Results of the MgO-C (1) / CRC1 -system at 1650 °C (presented in Figure 1(a)) illustrate a system in which the phases existing in thermodynamic equilibrium correspond almost exactly with the initial phases. This represents a more or less "ideal" situation, in which there is no driving force for either dissolution (direct or indirect) or formation of new solid phases in the refractory/slag-interface. Small stability area of spinel solid solution in the lower right-hand corner of the Figure 1(a) indicates, that the slag is not homogeneously molten at 1650 °C.

Results of the MgO-C (2) / CRC3 -system at 1650 °C (presented in Figure 1(b)) illustrate a system in which the phases existing in thermodynamic equilibrium still correspond rather well with the initial phases, but in in which the stability area of the molten slag is larger in comparison to the situation presented in Figure 1(a). For instance, a system consisting of 50% of slag and 50% of refractory material has an equilibrium composition with approximately 40% of solid phases. This difference indicates the driving force for the dissolution of refractory material in these conditions. The lack of new solid phases (*i.e.* phases not existing in the initial system) suggests that the dissolution would be direct.

Results of the Al₂O₃-SiO₂ / CRC2 -system at 1650 °C (presented in Figure 1(c)) illustrate an example in which the driving force for the chemical wear of the refractory material is much larger than in the situations presented in Figures 1(a) and 1(b). A very large stability area of the molten slag phase indicates a strong driving force for the dissolution. If a smaller amount of molten slag is assumed to be in equilibrium with the refractory material (situation shown in the left-hand side of the Figure 1(c)), there is a driving force for direct dissolution of the corundum phase. If the amount of molten slag is increased, a new phase (spinel solid solution) is formed and dissolution is likely to occur indirectly. In addition to this severe chemical instability in studied conditions, it is also seen from Figure 1(c) that this refractory material does not have a sufficient thermal resistance at 1650 °C either, since the stability area of the molten slag extends all the way to the system consisting of 100% refractory material. According to the thermodynamic simulations, approximately one third of the material would melt at 1650 °C even when it is not in contact with slag at all.

Results of the MgO-Cr₂O₃ / FSF1 -system at 1350 °C (presented in Figure 1(d)) illustrate a system in which the stability region of the molten slag phase is smaller in comparison to previous three examples, but which contains a relatively large stability area for a new solid phase (olivine) in addition to the solid phases already existing in the original refractory material (spinel and monoxide). Similar to the system presented in Figure 1(a), there is no driving force for dissolution in this system, but unlike in Figure 1(a), the occurence of the olivine phase indicates a clear driving force for the interactions between the refractory material and molten slag. Instead of dissolution, a solid olivine phase is formed due to this reaction. From the perspective of refractory durability, this new phase could act as a protective layer (forming autogeneous lining) when formed on the interface, or it could cause mechanical stresses when formed in the pores of the refractory material.

Results of the Al₂O₃-Cr₂O₃ / FSF2 -system at 1400 °C (presented in Figure 1(e)) illustrates a system which also contains a large stability area for a new solid phase (in this case spinel) in addition to the solid phases existing in the original material (in this case corundum and ZrSiO₄). The magnitude of the molten slag phase stability region indicates that there is only a very small driving force for dissolution. A comparison of Figures 1(d) and 1(e) reveals that the major difference between these systems is related to the location of the stability region of the new phase. In the MgO-Cr₂O₃ / FSF1 -system (Figure 1(d)) this stability region of olivine decreases the size of the molten slag stability region, where as in the Al₂O₃-Cr₂O₃ / FSF2 -system (Figure 1(e)) the formation of the new phase (spinel in this case) decreases the size of the solid corundum stability region. This difference could indicate that in the MgO-Cr₂O₃ / FSF1 -system the forming olivine phase is more likely to form on the refractory/slag-interface (*i.e.* grow outwards), whereas in the Al₂O₃-Cr₂O₃ / FSF2 -system the forming spinel phase is likely to form inside the refractory material (*i.e.* grow inwards) as the original corundum phase reacts into spinel as a consequence of interaction with the molten slag.

Results of the SiC-Al₂O₃ / FSF1 -system at 1350 °C (presented in Figure 1(f)) illustrate a system with clear driving forces for various chemical reactions between the refractory material and molten slag. Even though there is no significant driving force for the dissolution in this system, the high reactivity makes the system very unstable for refractory purposes. It is seen from Figure 1(f) that the refractory material acts as a reductant and hence the conditions are reducing enough for oxidic iron (in the slag) to be reduced into metallic iron. Depending on how much carbon is dissolved into this metal phase, it may exist in either solid or liquid form, both of which are quite likely to cause severe stresses to the refractory materials. As FeO-content of the molten slag is decreased due to reduction of iron, some solid SiO₂ (not existing in the original refractory material) also precipitates as the slag composition changes and the solubility of SiO₂ is eventually exceeded. This formation of new solid phase may cause mechanical stresses if formed inside the refractory material. Furthermore, it is also possible for small amounts of gaseous reaction

products to form in the refractory/slag-interactions making the system even more reactive.

Examples of the results concerning steel ladle vacuum treatment system are not included in Figure 1, but the results of this case can be found in more detail in our previous paper [1] and the main results concerning these systems are also summarized in Table 4.

Phases described as "Others" in Figure 1 refer to phases, which exist in small quantities (between 0 and 2 wt-% of the total systems studied in this research) in the results of thermodynamic simulations, but which were estimated not to exist in real systems. The occurence

of these phases in the simulation results is mainly due to the lack of certain components in the used models. For instance, if a system is defined to contain small amounts of certain components which are likely to be dissolved in *e.g.* molten slag or some solid solution, but for which there is no thermochemical data available in the models used to describe these solutions, the results show these components as separate phases. However, these phases are included in the results shown in Figure 1 (especially 1(a) and 1(b)) in order to ensure that the total size of the system remains constant.

Tab. 4: Summary of conclusions based on the results of thermodynamic simulations. Systems also shown in Figure 1 are marked in **bold**.

| *Refractory* | *Slag* | *Potential wear mechanism* | *Observations concerning validation* |
|---|---|---|---|
| **MgO-C (1)** | **CRC1** | No driving force for chemical wear. | No dissolution in the laboratory experiments [2]. |
| MgO-C (1) | CRC2 | Very small driving force for direct dissolution. | No dissolution in the laboratory experiments [2]. |
| **MgO-C (1)** | **CRC3** | Small driving force for direct dissolution. | Minor direct dissolution in the laboratory experiments [2]. |
| $Al_2O_3$-$SiO_2$ | CRC1 | Large driving force for either direct (high refractory/slag -ratio) or indirect (low refractory/slag -ratio) dissolution. Indirect dissolution via spinel phase. Not enough thermal stability (melting). | Major direct dissolution in the laboratory experiments [2]. |
| **$Al_2O_3$-$SiO_2$** | **CRC2** | Large driving force for either direct (high refractory/slag -ratio) or indirect (low refractory/slag -ratio) dissolution. Indirect dissolution via spinel phase. Not enough thermal stability. | Major direct and indirect dissolution in the laboratory experiments [2]. |
| $Al_2O_3$-$SiO_2$ | CRC3 | Large driving force for either direct (high refractory/slag -ratio) or indirect (low refractory/slag -ratio) dissolution. Indirect dissolution via spinel phase. Not enough thermal stability. | Major indirect dissolution in the laboratory experiments [2]. |
| **MgO-$Cr_2O_3$** | **FSF1** | Clear driving force for the formation of olivine phase. Can form a protective layer (or cause mechanical stresses). No driving force for dissolution. | Calculation results in line with industrial experience. |
| $Al_2O_3$-$Cr_2O_3$ | FSF1 | Large driving force for the formation of spinel phase. Can cause mechanical stresses (or form a protective layer). Small driving force for indirect dissolution via spinel. | Calculation results consistent with laboratory experiments. |
| **SiC-$Al_2O_3$** | **FSF1** | Large driving force for the reduction of iron from slag (and formation of solid $SiO_2$ as slag composition changes). Potential gas formation. Highly reactive system. | Extensive reactions observed in laboratory experiments. |
| MgO-$Cr_2O_3$ | FSF2 | Large driving force for the formation of olivine phase. Can form a protective layer (or cause mechanical stresses). No driving force for dissolution. | Calculation results in line with industrial experience. |
| **$Al_2O_3$-$Cr_2O_3$** | **FSF2** | Clear driving force for the formation of spinel phase. Can cause mechanical stresses (or form a protective layer). Very small driving force for indirect dissolution via spinel. | Calculation results consistent with laboratory experiments. |
| SiC-$Al_2O_3$ | FSF2 | Very large driving force for the reduction of iron from slag (and formation of solid $SiO_2$ as slag composition changes). Potential gas formation. Highly reactive system. | Extensive reactions observed in laboratory experiments. |
| MgO-C (2) | VTD1 | No driving force for chemical wear in atmospheric pressure, but driving force for MgO+C-reaction in lowered pressure (not likely to occur in practice due to kinetic constraints) [1]. | No significant wear by dissolution based on the characterisation of industrial samples [1]. |
| MgO-C (2) | VTD2 | Driving force for several reactions: reduction of FeO (and MnO) from slag with carbon as a reductant; dissolution of carbon; precipitation of solid CaO (and MgO) from slag; formation of gaseous reaction products. Driving forces larger in the lowered pressure. Very reactive system (especially in lowered pressure). [1] | Increased wear of refractories when producing steel grades in which unreduced ladle slag is required [1]. |
| MgO-$Al_2O_3$ | VTD1 | Strong driving force for indirect dissolution via several new phases (CA2, CA6, C2M2A14). May cause layered structure close to the interface. Highly reactive system (not affected by pressure). [1] | Refractory material considered non-suitable for industrial slag-line applications due to high wear rate. Use of magnesia-carbon-bricks instead. [1] |
| MgO-$Al_2O_3$ | VTD2 | Very strong driving force for indirect dissolution via several new phases (CA2, C2M2A14). May cause layered structure close to the interface. Highly reactive system (not affected by pressure). [1] | Refractory material considered non-suitable for industrial slag-line applications due to high wear rate. Use of magnesia-carbon-bricks instead. [1] |

## CONCLUSIONS

Thermodynamic simulations provide a tool to predict to potential wear mechanisms of refractory materials caused by a contact with different kind of molten slags. Based on the simulation results it is possible to estimate the possibility for direct and indirect dissolution as well as formation of new phases on the refractory/slag-interface. The main results of the simulations made in this study for different pyrometallurgical refractory/slag-systems are as follows:

1.  MgO-C refractories used in the CRC process have a very good resistance against slags used in this process, but the driving force for direct dissolution increases as the slag basicity decreases.

2.  Al₂O₃-SiO₂-based refractories considered as a potential alternative for MgO-C-refractories proved to have neither sufficient thermal nor sufficient chemical resistance to be used in the CRC process.

3.  MgO-Cr₂O₃-based refractories used in the flash smelting furnaces in copper matte and nickel matte production have no driving force for dissolution, but nevertheless have a clear tendency to react with both copper and nickel production slags to form an olivine layer, which is likely to grow outwards from the refractory/slag-interface. This tendency is slightly larger for nickel production slags and smaller for copper production slags.

4.  Al₂O₃-Cr₂O₃-based refractories used in the flash smelting furnaces in copper matte and nickel matte production also have a tendency to react with slags and to form spinel phase, which in this case is likely to grow inwards inside the refractory material. There is also a small driving force for indirect dissolution (via formed spinel phase), which is slightly larger for copper matte production slags and slightly smaller for nickel slags.

5.  SiC-Al₂O₃-refractories considered as as an alternative for flash smelting furnaces proved to create a highly reactive system when in contact with flash smelting slags (both copper and nickel production). Refractory can act as a reductant and reduce oxidic iron

from the slag thus causing a new metallic phase (either solid or liquid) to form.

6.  MgO-C-refractories used in the steel ladle slag line have a very good resistance against reduced ladle slag, but can react aggressively with unreduced slags with higher FeO and MnO contents. Lowering the pressure creates a driving force for the reaction between MgO and C although this reaction is not likely to have a major role in the real process.

7.  Spinel-forming MgO-Al₂O₃-refractories used in steel ladles do not have a good chemical resistance against ladle slags.

The use of simulation tools may help to reduce the amount of required experiments and analyses, but it can never completely remove the need for validation. One should for example keep in mind, that the results of this study are based on thermodynamic simulations, which are not taking rate phenomena (*i.e.* reaction kinetics, transport phenomena) into account and are only indicative of the driving force for chemical wear.

**ABSTRACT**

Most of the industrial applications are subjected to severe work conditions in terms of heat, chemistry, and mechanical constraints. Nowadays, the existence of a numerical tool accounting for all the physics that take place is a major challenge for many industrial processes like steel and glass production, welding, nuclear fusion, etc. Some fully coupled theories exist in the literature [Hu and Shen 2013]. Rambert et al. [Rambert et al. 2006] developed a numerical tool accounting for thermal, transport, and mechanics but without the chemical reactions.

The goal of this study is to implement a coupled numerical tool within the framework of an irreversible thermodynamic process for reactive porous multiphase materials using a User-defined Element (UEL) subroutine. To validate the tool, an oxidation of a cylindrical shape SiC-based refractory castable under high temperature gradient is simulated in order to predict the swelling effects [Merzouki et al. 2014]. Note that some parameters are estimated due to the lack of reliable experimental data under high temperatures.

**INTRODUCTION**

In industrial applications, reactive porous multiphase materials are often encountered in processes where chemical reactions occur, such as combustion, catalysis, and chemical synthesis. The porous structure of these materials facilitates the exchange of reactants, products, and heat, making them suitable for various applications.

The behavior of reactive porous multiphase materials is governed by a mixture of physical and chemical factors. This comprises heat transfer, mass transfer, flow, chemical reactions, phase changes, and mechanical deformation. Modeling and simulating the various interactions and changes that occur within these materials necessitate the study of coupled thermo-chemo-mechanical processes. As a result, the requirement for a more improved knowledge of coupled multi-field phenomena has become increasingly critical, resulting in increased research interest in this area. Hence, fully coupled theories addressing thermo-chemo-mechanical interactions have been developed in the literature [Blond 2017; Hu and Shen 2013; Lemaitre et al. 2020]. Blond [Blond 2017] introduces the fully coupled problem using the irreversible thermodynamic process. Hu and Shen [Hu and Shen 2013] developed variational principles for coupled thermal-chemical-mechanical problems by applying the principles of non-equilibrium thermodynamics.

It is noted that numerous studies have been conducted on numerical simulation methods for solving coupled thermo-chemo-mechanical models. Rambert *et al* ([Rambert et al. 2006] examine the behavior of materials in which there is interaction between chemical species (chemical processes and diffusion), temperature, and elastic mechanical characteristics. Gigliotti and Grandidier [Gigliotti and Grandidier 2010] study the coupling of oxidation and mechanics in polymer matrix materials at high temperatures. Ulff *et al.* [Ulff et al. 2019] examine the impact of hydrogen diffusion on the thermomechanical behavior of nickel-titanium-based shape memory alloy structures. Loeffel *et al.* [Loeffel et al. 2013] investigate the oxidation of metal at high temperature. However, none of these models account for the effects caused by the chemical reaction, i.e., the link between mechanical deformation and reaction rate. On the other hand, many studies have exhibited the complicated relationship between chemical reactions and mechanical behavior [Craig 2012], i.e., it has been shown that the swelling is induced by oxidation of SiC-RC materials and leads to failure [Prigent et al. 2012; Rodrigues et al. 2011]. Thus, the full coupling between chemical processes and mechanical behavior must be considered.

In this paper, we derived the governing equations for fully coupled Thermo-chemo-mechanical system based on the irreversible thermodynamic process. Then, using a user-defined element (UEL) subroutine, we implement this model in a Abaqus finite element code. At last, we describe the application used to validate our tool. It consists of simulating the oxidation of SiC-based refractory material at high temperature [Merzouki et al. 2014].

**Coupled thermo-chemo-mechanical theory**

In order to define the thermo-chemo-mechanical model based on the irreversible thermodynamic process, it is necessary to determine the state variable, the balance equations, the behavior and evolution laws. A similar approach has been described in references [Blond 2017; Lemaitre et al. 2020].

The values of the state variables that maximize entropy S or decrease internal energy U while adhering to the system's mathematical restrictions related to equilibrium, laws of behavior, and laws of evolution describe the equilibrium state. Thus, it's crucial to select state variables carefully so that there are just enough independent variables to properly describe the model.

In this system, the state variables are as follows:
- The strain $\epsilon$
- The temperature T
- The mass title $x_i$
- The extent of the reaction $\xi_r$

According to the first principle of thermodynamics, the equilibrium equation is written as:

$$\rho\dot{u} - \dot{r} + div\,\vec{q} - \underline{\underline{\sigma}}{:}\underline{\dot{\epsilon}} - \sum_\alpha \frac{\rho\mu_\alpha}{M_\alpha}\dot{x}_\alpha + \sum_r \left(\sum_\alpha v_{\alpha r}\mu_\alpha\right)\frac{\dot{\xi}_r}{\Omega} + j^\alpha\,\vec{\nabla}\left(\frac{\mu_\alpha}{M_\alpha}\right) = 0 \qquad (1)$$

Where $\dot{u}$ is the internal energy, $\dot{r}$ is the external energy, q is the heat flux, $\sigma$ is the stress, $\mu_\alpha$ is the chemical potential, $v_{\alpha r}$ is the stoichiometric coefficient, $\Omega$ is the volume, $j^\alpha$ is the mass flux, $M_\alpha$ is the molar mass, $\alpha$ denotes the number of species and r denotes the number of reactions.

Furthermore, according to the 2nd law of thermodynamic, the inequality corresponds to:

$$\rho T\dot{s} \geq \dot{r} - Tdiv\left(\frac{\vec{q}}{T}\right) \qquad (2)$$

Next, the Helmoltz free energy depending on the four state variables is expressed as follows:

$$\psi = u - Ts \qquad (3)$$

Hence, substituting the first law of thermodynamics and the total derivative of the Helmoltz free energy in the 2nd law of thermodynamic, the Clausius-Duhem inequality becomes:

$$\left(\rho\frac{\partial\psi}{\partial\underline{\epsilon}^r} - \underline{\underline{\sigma}}\right)\underline{\dot{\epsilon}}^r + \rho\left(\frac{\partial\psi}{\partial T} + s\right)\dot{T} + \rho\sum_\alpha\left(\frac{\partial\psi}{\partial x_\alpha} - \frac{\mu_\alpha}{M_\alpha}\right)\dot{x}_\alpha + \sum_r\left(\rho\frac{\partial\psi}{\partial\xi_r} + \frac{\mathcal{A}_r}{\Omega}\right)\dot{\xi}_r - \underline{\underline{\sigma}}{:}\underline{\dot{\epsilon}} - T\vec{q}\overrightarrow{grad}\left(\frac{1}{T}\right)$$
$$+ \vec{j}^\alpha\vec{\nabla}\left(\frac{\mu_\alpha}{M_\alpha}\right) \leq 0 \qquad (4)$$

Where $\mathcal{A}_r = \sum_\alpha v_{\alpha r}\mu_\alpha$ is the affinity of the reaction.

Therefore, from the intrinsic dissipation, we can deduce the behavior laws of the reversible part $\left(\left(\rho\frac{\partial\psi}{\partial\underline{\epsilon}^r} - \sigma\right)\underline{\dot{\epsilon}}^r + \rho\left(\frac{\partial\psi}{\partial T} + s\right)\dot{T} + \rho\sum_\alpha\left(\frac{\partial\psi}{\partial x_\alpha} - \frac{\mu_\alpha}{M_\alpha}\right)\dot{x}_\alpha\right)$ and the evolution laws of the irreversible part $\left(\sum_r\left(\rho\frac{\partial\psi}{\partial\xi_r} + \frac{\mathcal{A}_r}{\Omega}\right)\dot{\xi}_r - \underline{\underline{\sigma}}{:}\underline{\dot{\epsilon}}\right)$. The remaining terms $\left(-T\vec{q}\overrightarrow{grad}\left(\frac{1}{T}\right) + \vec{j}^\alpha\vec{\nabla}\left(\frac{\mu_\alpha}{M_\alpha}\right)\right)$ are the exchange dissipation (thermal and mass dissipation).

Taking advantage of the Clausius-Duhem inequality and the separable form of the free energy $\psi(\underline{\epsilon}, T, x_\alpha, \xi_r)$, the stress, temperature, mass title, and rate of extent of the reaction [Merzouki et al. 2014] are written as:

$$\underline{\underline{\sigma}} = \rho\frac{\partial\psi}{\partial\underline{\epsilon}^r} = \rho(\lambda\,tr\underline{\epsilon}\,I + 2\mu\underline{\epsilon} - 3k\alpha'(T - T_{ref})I - 3k\beta\xi_r\,I)$$

$$\rho c\dot{T} = \dot{r} - div\,\vec{q} + T\frac{\partial\sigma}{\partial T}\underline{\dot{\epsilon}}^r + \frac{\rho T}{M_\alpha}\sum_\alpha\frac{\rho\mu_\alpha}{M_\alpha}\dot{x}_\alpha - \frac{T}{\Omega}\sum_r\frac{\partial\mathcal{A}_r}{\partial T}\dot{\xi}_r - \vec{j}^\alpha\vec{\nabla}\left(\frac{\mu_\alpha}{M_\alpha}\right)$$

$$(5)$$

$$\rho\dot{x}_\iota = -div\,\vec{J}_1 + \sum_{n=1}^r v_{in}M_i\dot{\xi}_n$$

$$\dot{\xi} = \frac{1}{2\xi}\,K_p\left(\frac{\rho x_i}{M_i}\right)^2\left(1 - \frac{Q}{K^{eq}}\right)^2$$

Where $\lambda$ and $\mu$ are Lamé parameters, $k$ is the bulk modulus, $\alpha'$ is the thermal expansion coefficient, $\beta$ is the chemical expansion coefficient, $\rho$ is the density, $K_p$ is the kinetic factor, $Q$ is the reaction product, and $K^{eq}$ is the reaction constant.

### Implementation of the numerical tool

Our model consists of three physics. Thus, we have three mechanical degrees of freedom, one thermal degree of freedom and n chemical degrees of freedom. The number of chemical degrees of freedom depends on the number of species and the number of reactions in the system. The standard elements in Abaqus cannot account for such number of degrees of freedom. However, it is possible to define our own element [Abaqus 2023] using the UEL subroutine (User-Defined Element). It enables the modeling of complex and non-linear material responses by allowing users to create their own constitutive models.

Chester *et al.* [Chester et al. 2015] use the UEL subroutine to implement a coupled diffusion-deformation problem for elastomeric gels. They define a new element to study their model. In contrary, inspired by the code of [Chester et al. 2015], we maintain the standard element of Abaqus C3D8T and add the chemical degrees of freedom (Fig. 1). Similar approach has been used in [Vasikaran et al. 2020; Charles et al. 2022]. Additionally, we include the coupled terms between the chemical and mechanical and thermal components. Hence, the stiffness matrix and the secondhand side of the equation (Fig. 1) are enlarged to account for the degrees of freedom associated with chemistry. Furthermore, Galerkin's method must be used to obtain the appropriate weak formulation from the governing equations in order to incorporate the additional terms in the UEL subroutine.
*Fig. 1 :The creation of the new element using UEL subroutine and the standard element of Abaqus and its corresponding matrix.*

### Validation of the model

Merzouki *et al*. [Merzouki et al. 2014] perform an experimental and numerical study to investigate the swelling induced by oxidation ( 6 ) of a cylindrical shape of SiC-based refractory castables. They show the expansion of the cylinder due to oxidation near the face exposed to high temperatures.
The reaction equation is defined by:

$$SiC_{(s)} + \frac{3}{2}O_{2_{(g)}} \rightarrow SiO_{2_{(s)}} + CO_{(g)} \qquad (6)$$

To solve their numerical model, the simulation is performed in three steps. First, the heat transfer equation is solved. Second, the mass balance equation is solved using the UMATHT subroutine. Finally, the mechanical behavior is addressed by employing the UEXPAN subroutines to incorporate thermal and chemical strains. This approach allows for the separation of the heat equation resolution from other physical phenomena, such as chemical and mechanical processes, thereby simplifying the energy balance equation. In other words, the coupling effect between chemical reaction and temperature is not included.

Therefore, the same model is simulated using our numerical tool in order to validate our implementation. In our model, must of the coupling effects are taken into consideration.

### CONCLUSIONS

In this work, completely coupled theories for three branches of physics — thermal, chemical, and mechanical — have been developed. A numerical tool is implemented thanks to the User-ELement subroutine. The chemical degree of freedom is activated in parallel with the mechanical and thermal degrees of freedom. Furthermore, all the coupling terms between chemical and other physics have been added to the extended matrix.

In the following, it is crucial to investigate the impact of each coupling term depending on the simulated model. Additionally, the time convergence of the numerical model must be evaluated. Also, due to the high number of degrees of freedom, the stability of the approach must be assessed.

Finally, this approach enables the consideration of all chemical reactions that can occur in a specific system. More chemical degrees of freedom can be added to the numerical tool, allowing for a comprehensive study of the model's behavior. Hence, understanding and accurately predicting the behavior of reactive porous multiphase materials is crucial for optimizing industrial processes and designing efficient systems.

## ABSTRACT

It is well known that the performance of industrial processes operating under hostile mechanical, chemical or, especially, harsh thermal conditions depends majorly on refractory ceramics. Thus, studies on the optimization of these materials are of great relevance for the industry, as changing their composition, microstructure, or project design can increase the equipment lifetime and/or decrease its maintenance halts. So far, several studies have used computational simulations to model the thermomechanical behaviour of ceramic refractory linings with joints, usually for steel ladles. However, few of them have focused on design optimization such as the correct dimensioning of expansion joints, optimised size of monolithic panels and spatial distribution and quantity of anchors. The present study aims to fill this gap by modelling the castable lining of alumina calciners, which is a less complex system in terms of refractory requirements compared to the steel-making processes. The work was based on the Finite Element Method (FEM) to predict the expansion behaviour of refractory panels under different features, specifically focusing on the design of expansion joints. The results pointed out the significant impact of considering temperature-dependent properties and frictional effects on the expansion behaviour of refractory linings. The findings indicated that these factors can increase the required size of expansion joints by up to 33.3% for the specific materials and geometry studied. Thus, the insights gained from this research can assist in optimising the design and sizing of expansion joints, ultimately adding to the efficiency and longevity of industrial processes operating in challenging thermal environments.

## INTRODUCTION

Calcination is the final stage of the Bayer process in the production of aluminium oxide. It involves the heat treatment of gibbsite ($\gamma$-Al(OH)$_3$) to remove its structural hydroxyl groups, leading to the formation of alumina (Al$_2$O$_3$) [1]. The prevailing equipment used by most alumina refineries for this process is the fluidized bed calciner. This technology operates by fluidizing the aluminium hydroxide particles in an upward airflow, creating a fluidized bed that eases heat transfer. During this process, the maximum temperatures typically range from 900 to 1100°C for the production of smelting grade alumina (SGA) [2].

Given the harsh conditions within the calciner, the refractory lining material plays a critical role in ensuring the feasibility and efficiency of the process. Apart from providing thermal insulation to the structure and reducing energy consumption, the lining acts as a protection against the severe thermomechanical and erosive stresses imposed by the process. Consequently, any failure in the performance of the lining can lead to production halts and significant financial losses.

Over the past few decades, significant developments have been made in refractory technology to improve the performance and lifespan of calciner linings. Innovative materials have been developed to enhance thermomechanical properties and minimise downtime for maintenance and repairing [3-9]. However, there remains a relative lack of attention focused on optimising the geometric design of refractory linings, despite being as important as the intrinsic material properties in determining the lining's performance and lifespan.

One critical parameter in refractory lining design is the expansion joint between panels. This gap plays a crucial role as it directly affects the generation of stresses resulting from thermal expansion, which can lead to detrimental effects on the lining integrity. If the expansion joint between panels is narrow, the contact-induced stresses can reach high levels, thereby increasing the risk of damage. Conversely, a wide spacing between panels can ease the penetration of high-temperature erosive particles into the lining, thereby spoiling the integrity of the equipment's metallic vessel and requiring unscheduled maintenance shutdowns. Additionally, unplanned failures in refractory linings have a higher impact on production losses [7]. Past experiences with calciners have shown that substantial refractory failures lead to a downtime of at least 14 days [7, 10]. For a calciner such as Metso Outotec's 5th generation CFB, which has a capacity of 3,500 tons of alumina per day [11], the associated production loss during this period could reach 49,000 tons of alumina. This loss amounts to approximately $17 million in revenue, assuming a price of $350 per ton of alumina. Additionally, the installation costs for new refractories can range between $1.5 and $3 million [7]. Hence, selecting the right balance for the panel expansion joint is of utmost importance to ensure optimal performance and longer refractory lining's life in industrial applications.

One likely method to forecast them in panels exposed to temperature variations is using analytical mathematical equations. The linear thermal expansion equation represents the most basic approach for estimating the required spacing between panels to accommodate their thermal expansion [5, 12, 13]. However, this model exhibits limited accuracy due to its unrealistic assumptions, particularly when applied to processes carried out at elevated temperatures. The complexity of such processes, including temperature gradients across the lining thickness and variations in material properties with temperature, requires the development of more robust models.

Numerical analysis using tools as the Finite Element Method (FEM) enables the modelling of complex systems, such as the thermal analysis of steel ladles in the steel industry [14]. Several studies have employed these methodologies to model the thermomechanical behaviour of refractory linings containing expansion joints. Gasser et al. [15-17] analysed specific sections of the lining and successfully predicted the thermomechanical behaviour using homogenization techniques. These studies helped to improve the prediction of stress and deformation in linings by considering the presence of expansion joints. However, there is currently no literature available regarding applying these methodologies for selecting their appropriate size in refractory linings.

Within this context, the present study aims to address this gap by employing numerical modelling to better predict the expansion behaviour of a refractory panel, accounting for conditions not considered by the simplistic analytical model, such as non-uniform temperature variations, temperature-dependent properties and the friction between the lining components.

## MATERIALS AND METHODS

The structure of the calciner furnace consists of three layers of materials: an outer metallic shell, an insulating layer followed by a dense one known as the working layer. The working lining comprises castable panels that are apart by expansion joints and held in place by metallic anchors. In this study, the panel geometry considered was parallelepiped with a square faced cross-section 1000 mm wide and 150 mm thick. The insulating layer and the metallic shell were 200 mm and 10 mm thick, respectively. The presence of anchors was not considered.

The material behaviour was assumed to be isotropic and linearly elastic. Table 1 shows the property data obtained from the literature. It was considered a calcium aluminate cement (CAC) bonded refractory castable (pre-fired at 1400 °C for 5 h) for the working layer [18, 19], a generic 55% $Al_2O_3$ for the insulating layer [20], and carbon steel for the metallic shell [21].

The investigation of the lining thermomechanical behaviour was carried out in two steps, considering a one-way weakly coupling between the thermal and thermomechanical analyses. First, a steady-state heat transfer model estimated the thermal response of the lining. Following, mechanical analyses were performed to investigate the thermal expansion, displacements and stresses within the lining system considering a quasi-static loading. The numerical models were developed using a Finite Element Method (FEM) approach and implemented using Abaqus/CAE software. The geometry was assumed as a quarter of the panel, considering the symmetry of the problem, and discretized using 90,000 linear hexahedral finite elements with full integration. Figure 1 presents the geometry and surfaces considered to define the problems' boundary conditions.

**Figure 1**. Geometry and surfaces of the numerical model. HF = Hot Face; CF = Cold Face. Dimensions in mm.

For the thermal analysis, a temperature of 1030 °C was imposed on the hot face of the castable. The transfer of thermal energy among the different layers was considered perfect. On the cold face of the metallic shell, both convection with a film coefficient of 4 W/m²K and radiation were taken into account considering an emissivity of 0.7. The surrounding air temperature outside the metallic shell was assumed to be 30°C, as well as the initial temperature throughout the lining volume.

For the mechanical analysis, the thermal profile obtained from the heat transfer was imposed as an initial condition. The cold face of the shell was constrained against displacement in the thickness direction (z-direction). The normal contact between the different layers was considered "hard" (following Abaqus/CAE manual), meaning that no penetration occurs between the parts and there is no transfer of tensile stresses across the interfaces. Two extreme scenarios were considered for the tangential contact between the parts (mechanical boundary conditions scenarios): (i) frictionless contact, where there is no resistance to sliding, and (ii) rough contact, where all relative sliding motion between two contacting

surfaces is prevented. Gravity was considered in the negative z-direction. The thermo-mechanical behaviour of the lining was evaluated by examining the impact of two parameters: (i) temperature-dependent properties (property scenarios), and (ii) mechanical constraints arising from friction between the lining components (mechanical boundary conditions scenarios).

The influence of temperature-dependent properties was evaluated by comparing the results of the analyses considering such scenarios with those that assumed constant constitutive laws. For the latter case, the material properties were considered to be equivalent to those at room temperature (30°C).

Finally, the displacement results for the numerical models were compared with those obtained with the classical linear thermal expansion model, commonly used to estimate the expansion joint between refractory panels, expressed as:

$$\Delta L(z) = L_0 \, \alpha \, (T(z) - T_0) \tag{1}$$

where $\Delta L$ represents the change in length of the material, $L_0$ is the original length, $\alpha$ is the coefficient of linear thermal expansion, T the temperature, and z represents the position along the thickness of the panel. For the temperature-dependent material properties case, $\alpha(T)$ was considered for each position at the lining thickness.

## RESULTS AND DISCUSSION

Table 2 presents the thermal profile obtained across the lining thickness for the two property scenarios considered. It was evident that when temperature-dependent properties were taken into account, the temperature at each interface, as well as that at the cold face of the metallic shell, decreased. This behaviour can be attributed to the decrease in thermal conductivity of the CAC castable with the temperature, which was the only property considered in the steady-state heat transfer analysis. Consequently, the thermal gradient within the castable, considering temperature-dependent properties, was higher (56.3°C) compared to the case with constant properties (23.7°C). Conversely, the thermal gradient in the insulating layer was lower when temperature-dependent properties were considered. This was because the thermal conductivity of the insulation was assumed to be constant in both scenarios.

**Table 2.** Temperature profile obtained from finite element analysis for the two property scenarios. Thermal gradient is presented for constant properties | temperature-dependent properties.

| Position | Temperature (°C) | | Thermal gradient (°C) |
|---|---|---|---|
| | Constant properties | Temperature-dependent properties | |
| HF – Castable | 1030 | 1030 | – |
| CF – Castable | 1006.3 | 973.7 | 23.7 \| 56.3 |
| CF – Insulator | 166.3 | 162.9 | 840 \| 810.8 |
| CF – Shell | 165.8 | 162.4 | 0.5 \| 0.5 |

Table 3 shows the in-plane displacement (x and y directions) results for the two property scenarios according to the linear thermal expansion model (equation 1), and along with the results obtained from finite element analyses for the two mechanical boundary conditions. Firstly, it is evident that, across all cases, the expansion at the hot face of each refractory layer is consistently greater than at the cold face. This indicates a wedge-shaped trend in the lining after experiencing temperature variation. Furthermore, when examining the case of constant properties, the impact of friction between the different layers of the lining becomes apparent. Assuming zero friction led to a behaviour that closely resembles that predicted by the analytical model of linear thermal expansion. However, when maximum friction between the layers was considered, the expansion of the system undergoes a significant change. In this case, the interface between the castable and insulating layer (i.e., the cold face of the castable and the hot face of the insulator) experienced smaller displacements compared to both surfaces in the frictionless contact case. Conversely, the extremes of the refractory lining (i.e., the cold face of the insulator

**Table 3.** In-plane displacement (mm) results for the two property condition cases according to the linear thermal expansion model and the two mechanical boundary condition scenarios.

| | Position | Linear thermal exp. model | FE Analysis | |
|---|---|---|---|---|
| | | | Friction-less contact | Rough contact |
| Constant properties | HF – Castable | 3.57 | 3.57 | 3.70 |
| | CF – Castable | 3.48 | 3.49 | 3.32 |
| | HF – Insulator | 3.60 | 3.59 | 3.31 |
| | CF – Insulator | 0.50 | 0.51 | 0.86 |
| | HF – Shell | 0.83 | 0.83 | 0.87 |
| | CF – Shell | 0.83 | 0.83 | 0.87 |
| Temperature - dependent properties | HF – Castable | 4.40 | 4.64 | 4.76 |
| | CF – Castable | 4.10 | 4.34 | 4.18 |
| | HF – Insulator | 3.48 | 3.46 | 4.18 |
| | CF – Insulator | 0.49 | 0.51 | 1.04 |
| | HF – Shell | 0.88 | 1.04 | 1.06 |
| | CF – Shell | 0.88 | 1.04 | 1.06 |

and the hot face of the castable) experienced larger displacements. This phenomenon occurred because the condition of rough contact between the surfaces prevented relative sliding and detachment between the parts, even when warping caused by the thermal gradient was presented, as depicted in Figure 2. The frictional forces acting between the surfaces effectively prevented the trend to slide the plates or separate them, resulting in a more constrained and interconnected system.

**Figure 2.** Deformed shape of the lining for the analysed cases.

The impact of temperature-dependent properties on the behaviour of the lining was even more contrasting. Firstly, there was an increase in the in-plane displacement of the castable due to its higher thermal expansion coefficient at elevated temperatures. The lower displacement of the insulator was not due to a decrease in its thermal expansion coefficient but was influenced by the lower temperature at the interfaces, resulting from temperature-dependent properties. When comparing the results of the analyses without friction versus rough contact, a similar behaviour was observed at the extremes of the refractory lining. These surfaces underwent an increased displacement in the case of maximum friction, whereas the interface castable–insulator showed an intermediate pattern between the behaviour of the two surfaces in the frictionless contact case.

It is also important to note that even in the case of frictionless contact, the results from finite element analysis considering

temperature-dependent properties significantly differed from those obtained using the linear thermal expansion equation. This highlights the complex and non-linear nature of the thermo-mechanical behaviour, which cannot be accurately captured by a simple linear expansion model.

The numerical model implemented using the finite element method not only enabled the estimation of displacements but also made the evaluation of the stresses generated within the refractory lining easier, providing valuable insights for project decision-making. The results of the analyses conducted for the cases considered highlighted that the maximum principal tensile stresses were higher when there was friction between the layers of the lining, as depicted in Table 4. Furthermore, in general, the stresses generated were lower when temperature-dependent properties were taken into account. This indicated that considering the variation of material properties with temperature can help to mitigate the magnitude of stresses induced within the lining system.

**Table 4.** Maximum principal stresses in each lining material for the property and mechanical boundary condition scenarios analysed.

| | Lining component | Max. principal stress (MPa) | |
|---|---|---|---|
| | | Frictionless contact | Rough contact |
| **Constant properties** | Castable | 0.91 | 83.97 |
| | Insulator | 25.08 | 62.07 |
| | Shell | 20.45 | 173.0 |
| **Temperature - dependent properties** | Castable | 2.51 | 72.90 |
| | Insulator | 14.44 | 48.60 |
| | Shell | 9.71 | 108.6 |

## CONCLUSIONS

The analyses presented in this study highlighted the necessity of revising the design approach for expansion joints in refractory linings. The conventional linear expansion model, commonly used for joint design, does not accurately predict the expansion behaviour of materials subjected to high-temperature process conditions.

The analyses conducted in this study highlighted that incorporating temperature-dependent properties along with friction between the layers can lead to a substantial increase in the required size of an expansion joint compared to calculations based on the linear thermal expansion model considering material properties at room temperature. The increase in joint size can reach up to 33.3% in certain cases, a value that can be further amplified by other factors such as the presence of anchors, increased panel size, different material properties, among others.

These findings emphasise the importance of considering the non-linear and complex nature of thermo-mechanical behaviour in refractory linings, and the necessity to develop more comprehensive design methods that account for temperature-dependent properties and mechanical constraints such as frictional effects. By doing so, the accuracy of joint design can be significantly improved, ensuring the structural integrity and longevity of refractory linings in high-temperature applications.

## ABSTRACT
The flow in the impact region of a tundish is known to be highly turbulent. High wear rates of the refractory lining can be associated with this phenomenon. Particularly, T- or delta-T-shaped tundishes are prone to this problem. Turbulence inhibitors are often incorporated to weaken turbulent flow and are therefore an effective measure to counteract the localised wear problem. In this study, an isothermal transient model of a tundish was established using CFD to simulate the flow performance of molten steel in a seven-stranded T-shaped tundish using the ANSYS Fluent software. Two types of flow stabilisers were designed and compared, focusing on the flow characteristics in the impact region. Additionally, a 1:3 water scale model was adopted. Dye injection tests with associated video recordings were completed to demonstrate the flow trajectories in the tundish. The residence time distribution curve and dead zone volume fraction were analysed using the CFD method and the water model. The results of the water model verified the accuracy of the CFD simulations; the newly designed turbulence inhibitor had a lower scouring velocity near the pouring area. Simultaneously, the dead zone volume decreased, the plug zone volume increased, and the flow in the tundish was optimised.
**Keywords:** Water model, CFD simulation, Tundish, flow stabilizer, RTD

## INTRODUCTION
With the increasing demand of steel users for steel quality, obtaining high-purity liquid steel effectively has become a core issue of great concern to enterprises. A tundish is the last metallurgical container before the solidification of liquid steel, and its metallurgical function is self-evident. Particularly in the production of clean steel, the role of the tundish is increasingly important, as it is no longer used as a simple shunt container, but it will also carry the function of further removal of inclusions, preventing the secondary refining of liquid steel from being contaminated during high-quality steel production [1–3].
Owing to the high turbulence in the middle region of the tundish, local wear may be caused, and flow-control devices such as retaining walls and turbulence inhibitors are generally employed to weaken the turbulence. Turbulence inhibitors, as important flow control devices in tundishes, can effectively prevent liquid-level fluctuations caused by high-speed injection flows and improve the quality of the billet [4,5].
Many scholars have studied different types of flow control devices and their combinations, such as flow control combination of upper and lower retaining walls, swirl turbulence inhibitors with square eaves, curved retaining walls, diversion holes or flow steel holes, among others [6–8]. This study was primarily based on an actual situation in a steel mill. In this study, a turbulence inhibitor with a baffle on the inner wall was designed, and a retaining wall with a 30° up-dip diversion hole was added to the outside so that the liquid steel would not cause more wear on the T-tundish. Good results were achieved, as described herein.

*Fig. 1: Local wear situation*

## OPTIMISATION MODEL DESCRIPTION
### Fundamental assumption
(a) Effects of the surface fluctuation of the molten steel, slag layer, and secondary oxidation of the stainless-steel liquid on the flow field of the tundish were ignored.
(b) The fluid was regarded as an incompressible Newtonian fluid with fixed physical properties.
(c) The flow of liquid steel in the entire tundish was turbulent with a low Reynolds number.
(d) The effect of temperature change on the flow of the tundish fluid was ignored.

### Governing equation
The basic, continuity, and momentum equations for the flow field simulation of the tundish are:

$$\frac{\partial \rho_m}{\partial t} + \nabla \cdot (\rho_m \overrightarrow{u_i}) = 0 \qquad (1)$$

$$\frac{\partial \rho_m}{\partial t} + \nabla \cdot (\rho_m \overrightarrow{u_i u_j}) = -\nabla p + \frac{\partial}{\partial x_i}\left[\mu_{eff}\left(\frac{\partial u_r}{\partial x_r} + \frac{\partial u_i}{\partial x_i}\right)\right] \qquad (2)$$

where $\rho_m$ is the fluid density, $u_i$ is the velocity of the fluid flowing in direction $i$, $u_j$ is the velocity of the fluid flowing in direction $j$, $p$ is the static flow pressure, and $\mu_{eff}$ is the effective viscosity.
In the process of tundish casting, the turbulence behaviour of molten steel is characterised by the standard low Reynolds number k-ε model.
The equation of turbulent kinetic energy ($k$) is:

$$\frac{\partial(\rho_m k)}{\partial t} + \frac{\partial(\rho_m k u_i)}{\partial x_i} + \rho_m \varepsilon = \frac{\partial}{\partial x_i}\left[\left(\mu_{eff} + \frac{\mu_t}{\sigma_k}\right)\frac{\partial k}{\partial x_i}\right] + G_k \qquad (3)$$

The turbulent kinetic energy dissipation ($\varepsilon$) is expressed as:

$$\frac{\partial(\rho_m \varepsilon)}{\partial t} + \frac{\partial(\rho_m u_i \varepsilon)}{\partial x} = \frac{\partial}{\partial x_i}\left[\left(\mu_{eff} + \frac{\mu_t}{\sigma_j}\right)\frac{\partial \varepsilon}{\partial x_i}\right] + \frac{1}{k}(\varepsilon C_{1\varepsilon} G_k - \varepsilon^2 C_{2\varepsilon}\rho_m) \qquad (4)$$

$$\mu_{eff} = \mu_m + \mu_t \qquad (5)$$

$$\mu_t = \rho_m C_\mu \frac{k^2}{\varepsilon} \qquad (6)$$

Here, $\mu_m$ is the viscosity of mobile molecules; $\mu_t$ is turbulence viscosity; $C_{1\varepsilon}$, $C_2$, $C_\mu$, $\sigma_k$, $\sigma_\varepsilon$ are constants corresponding to 1.44, 1.92, 0.09, 1.3, and 1.0.

To calculate the residence time of the liquid steel in the tundish, a certain amount of tracer is added into the inlet, and the following user-defined scalar (UDS) function is solved.

$$\frac{\partial(\rho\varphi)}{\partial t} + \nabla \cdot (\rho\varphi\vec{u_j}) = \nabla \cdot \left(\left(\rho D_0 + \frac{\mu_t}{Sc_t}\right)\nabla\varphi\right) + S_\varphi \qquad (7)$$

where $\varphi$ is the tracer concentration, $Sc_t$ is the turbulent Schmidt number, $S_\varphi$ is a source term for the concentration, $\mu_t$ is the eddy viscosity, and $D_0$ is the kinematic diffusivity of the tracer.

After the flow field was calculated, a residence time distribution (RTD) analysis was conducted to characterise the flow according to the definitions of the plug volume, dead volume, and mix volume[9].

The formula for the average residence time $T_a$ of each first-class liquid steel in the tundish is:

$$T_a = \frac{\sum t_i c_i \Delta t_i}{\sum c_i \Delta t_i} \qquad (8)$$

where $\Delta t_i$ indicates the time interval of the monitoring value, $t_i$ is the sampling time, and $c_i$ is the tracer concentration at the outlet corresponding to $t_i$ time.

In this study, the analytical model proposed by Pan et al. [10] was adopted to describe the deviation between the actual flow and ideal piston flow with variance as follows:

$$\sigma_j^2 = \int_0^\infty (t_j - \bar{t_j})^2 c_j(t_j)\,dt = \int_0^\infty (\theta_j - 1)^2 c_j(\theta_j)\,d\theta = \int_0^\infty \theta_j^2 c_j(\theta_j)\,d\theta - 1 \qquad (9)$$

$$\sigma^2 = \sum_{i=1}^n \sigma_i^2 \qquad (10)$$

The dead zone volume fraction is given by:

$$\frac{V_d}{V} = \int_{2t_a}^\infty c_j\,dt \qquad (11)$$

The total mixed flow volume fraction is expressed as:

$$\frac{V_{mj}}{V} = \sigma^2 - \frac{V_d}{V} \qquad (12)$$

The plug flow volume fraction is written as:

$$\frac{V_{pj}}{V} = \frac{1}{N} - \frac{V_{dj}}{V} - \frac{V_{mj}}{V} \qquad (13)$$

where $V_{dj}$ is the dead zone volume, $V_{mj}$ is the full mixing zone volume, $V_{pj}$ is the volume of the piston region, and $V$ is the volume of the liquid steel in the intermediate envelope.

**Boundary condition**

The following boundary conditions of the mathematical model for the seven-stranded tundish were determined based on the actual flow of the tundish:

(a) Liquid steel flows into the tundish from the ladle through the ladle nozzle. The velocity of the liquid steel in the ladle nozzle was vertically downward and the velocity distribution at the entrance section was the same. The entrance boundary was set as the velocity boundary, and the size was determined by the steel throughput and section size, according to the law of conservation of mass. $v_{in}=Q/S$, where $Q$ is the volume flow rate of the ladle nozzle, $S$ is the cross-sectional area of the ladle nozzle, and the turbulent kinetic energy and turbulent energy dissipation rate at the entrance are $k=0.01v_{in}^2$, $\varepsilon=2k^{1.5}/D_{in}$; $D_{in}$ is the inner diameter of the ladle nozzle.

(b) The liquid level of the tundish was set as the free surface, and the shear force was set to 0.

(c) The outlet type was set as the pressure outlet.

(d) The solid wall surface of the tundish was set as the nonslip wall surface.

The calculated grids used in this study were all hexahedral grids, and the main technological parameters of the continuously cast tundish are listed in Table 1. To reduce the calculation time, half of the model was processed in this study, and only the left part was calculated. Figure 2 shows the turbulence inhibitor design and mesh division used in this study.

Tab. 1: Main technological parameters of continuous casting tundish.

| Process parameter | Value |
|---|---|
| Tundish working capacity (t) | 37.2 |
| Tundish throughput (t/min) | 3.5 |
| Tundish bath level (mm) | 900 |
| Inside diameter of ladle nozzle (mm) | 80 |
| Immersion depth of ladle nozzle (mm) | 265 |

*Fig. 2: Design of (a) mesh, and (b) original and (c) proposed turbulence inhibitors.*

In the calculation, the liquid flow inside the tundish is considered to be an isothermal incompressible fluid, and the density and viscosity of the steel are constant. The specific values are listed in Tab. 2.

Tab. 2: Physical parameters of liquid steel.

| Density (kg·m$^{-3}$) | Viscosity (Pa·s) | Molar mass (g·mol$^{-1}$) |
|---|---|---|
| 7000 | 0.0061 | 55.85 |

**RESULTS AND DISCUSSION**

**Flow field of tundish under different turbulence inhibitors**

Fig.3 presents flow diagrams of the $y=0$ sections and the free surface of the two turbulence-inhibitor schemes. As can be seen in the case of the original turbulence inhibitors, because there is no flow control device, a higher speed will be generated from the two nearest outlets, which will reduce the residence time of the liquid steel in the tundish to a certain extent, resulting in short-circuit flow. The velocity of the liquid steel near the turbulence inhibitors will reach more than 0.1 m/s, which causes slag rolling. When the newly designed turbulence inhibitors and retaining wall are used for flow control, under the action of a turbulence controller, the liquid steel only has a large velocity in the small part above the turbulence inhibitors, while the velocity in other areas of the tundish is small. In addition, the liquid steel diffused around the impact zone and generated a flow to the liquid surface of the tundish. When the liquid steel flowing along the liquid surface hits the sidewall of the tundish, it generates a downward circumferential flow, which is conducive to inclusions floating up. Compared with the original turbulence inhibitors, the velocity of the newly designed turbulence inhibitors at the free liquid surface is relatively small, with the maximum of only 0.05 m/s, and slag rolling probability decreases.
*Fig. 3: Flow diagrams of the free surface and y=0 sections of free liquid surface under (a) (c) original and (b) (d) new turbulence inhibitor design schemes.*

Fig. 4 displays velocity contour plot of the original and the newly designed turbulence inhibitors at the free surface. Compared with the original turbulence inhibitors, when the new turbulence inhibitors were applied to the retaining wall, the liquid steel flowing from the ladle nozzle to the bottom of the inhibitors was blocked by the baffle on the turbulence inhibitors. Therefore, the velocity in the impact zone of the tundish is relatively low, which helps reduce the local wear in the impact zone, as shown in subfigures (a) and (b). The velocity reduction at the wear position can be as much as 50% (0.2–0.1 m/s).
*Fig. 4: Velocity contour plot at the free liquid surface under (a) original and (b) new turbulence inhibitor design schemes.*

Fig. 5 presents the velocity cloud diagrams of the different sections in the impact zone under the two turbulence inhibitor schemes. It is clear that the newly designed turbulence inhibitors combined with the retaining wall with a diversion hole effectively reduced the turbulence velocity in the impact zone and helped reduce the original local wear phenomenon.

*Fig. 5: Velocity clouds for different sections at the impact zone of the (a) original and (b) new turbulence inhibitors designs.*

Fig. 6 displays the cloud diagrams of the turbulent kinetic energy at the free surface and $x=0$ section for the two schemes. Compared with the original turbulence inhibitor, the turbulent kinetic energy of the molten steel in the impact zone of new turbulence inhibitor was mainly concentrated in the interior. When the original turbulence inhibitors were used, the turbulent kinetic energy of the molten steel in the impact zone of the entire tundish was generally large, and the turbulent kinetic energy of the free liquid surface near the impact zone of the tundish reached 0.0015 $m^2/s^2$, which easily caused slag and molten steel exposure. Simultaneously, the turbulent kinetic energy in the impact zone with the new turbulence inhibitors was lower than that with ordinary turbulence inhibitors.

*Fig. 6: Turbulent kinetic energy distributions at the free surface and x=0 section of the (a) (c) original and (b) (d) new turbulence inhibitors designs.*

**RTD curve analysis**

Fig.7 presents the RTD curves of the tundish for the different schemes, and Tab.3 provides the analysis results corresponding to the RTD curves for the different schemes. According to Figure 8 and Tab.3, the response time of the newly designed turbulence inhibitors and the flow control device of the retaining wall increased by 35.7 s, the average residence time increased by 200 s, the dead zone volume decreased by 22%, and the plug zone volume increased by 17%. As shown in the figure and table, the RTD curves of the newly designed turbulence inhibitors significantly differ from those of the original turbulence inhibitors. The newly designed turbulence inhibitors can not only reduce local wear, but also promote the floating of inclusions. Thus, the new turbulence inhibitors can improve the flow state of molten steel in the tundish impact zone as well as reduce the local wear.

Fig. 7: RTD curves for tundish under different designs.

Tab. 3: Results of RTD curves under different designs

| Design | $t_r$/s | $t_p$/s | $t_a$/s | $v_p$/% | $v_d$/% | $v_m$/% |
|---|---|---|---|---|---|---|
| Original | 37.3 | 159.3 | 531.8 | 15.4 | 24.2 | 60.3 |
| New | 77 | 333.6 | 716.8 | 32.5 | 14.1 | 53.4 |

where $t_r$ is the tundish response time; $t_p$ is the tundish peak time; $t_a$ is the average residence time; $v_p$ is the plug zone volume ratio; $v_d$ is the dead zone volume ratio; and $v_m$ is the mixing zone volume ratio. In summary, the flow state of the liquid steel in a tundish impact zone can be improved with a new design of turbulence device.

**Water model and model validation**
Based on the original design scheme, a water model experiment was conducted considering the ratio of 1:3 using a similarity criterion. During the experiment, Kcl solution was selected as the tracer. After the flow field was stabilised for 3 min, the tracer was injected through the ladle water outlet for 1 s. The obtained distribution trend of the red tracer in the tundish at different times was similar to the mathematical simulation results. In addition, the "stimulus response" technique was adopted to measure the RTD of the liquid steel in the tundish, and the electrical conductivity corresponding to the Kcl concentration at each outlet was monitored by the conductance electrode inserted at the outlet. Finally, the RTD curve was drawn. Through comparison and analyses, the RTD curves for the tundish measured via numerical simulation calculations under various flow control devices and water model experiments had good consistency in variation. The error in the overall average residence time in the tundish was maintained at approximately 5%. This shows that the model can accurately calculate the RTD curve for a tundish. However, the turbulence model, tracer diffusion model, and RTD analysis method adopted in this study are consistent with the above research. Therefore, the simulation results of the influence of different turbulence inhibitors on the flow of molten steel in the tundish, as well as the RTD curve using this model are credible. Figure 9 shows camera snapshots of original design water model from 0 to 180 s.

Fig. 9: Images of original design for tundish at 0–180 s.

**CONCLUSION**
(a)Compared with the original turbulence inhibitors, use of the newly designed turbulence inhibitors to reinforce the retaining wall significantly improved the local wear problem. The velocity reduction at the wear position can be as much as 50% (0.2–0.1 m/s).

(b)Using the new design turbulence inhibitors compared with the original turbulence inhibitors, the response time of the newly designed turbulence inhibitors and the flow control device of the retaining wall increased by 39.7 s, the average residence time increased by 185 s, the dead zone volume decreased by over 40% and the plug volume was more than doubled. Thus, the flow field in the tundish was effectively improved.

## ABSTRACT

The steel industry is a key driver of new developments in the refractory industry due to its high market share (>70%) and the harsh conditions involved in the steelmaking processes. In addition, the annual refractory consumption in a special steel plant that produces more than 750.000 ton of steel per year, can reach around 10.000 ton. The RFCS European E-CO-LadleBrick project aims to develop an ecological and economic waste management of the ladle refractory bricks by implementing circular economy criteria (Reduce, Reuse, Re-manufacture and Recycle). Due to the higher impact, it is very important to promote the reduction in the waste generation by optimizing the use of the refractories. Could AI help, in this sense, to the first of these R's and reduce the refractory consumption in the ladles?

To answer this question, this work proposes a methodology by using two sources of information: First, refractory remaining thickness measurements obtained through a 3D laser equipment, and second, the information of the operation variables with the greatest influence on refractory degradation, collected heat-by-heat by a steelmaker. By means of using this information, this paper presents a Machine Learning tool with the main purpose of optimizing the refractory consumption: 1) by estimating the Remaining Useful Life with the information of the operation variables and 2) by estimating the wear of the MgO-C refractory lining that a specific heat can suppose. The work has been validated in a real application with data from a relevant steel company of the Basque Country (Spain).

## INTRODUCTION

Around 35 to 40 million tons per year of refractory are produced worldwide [1], of which the steel industry is responsible for up to 70% of the total demand [2]. In this context, Artificial Intelligence (AI) techniques have been applied to Industry 4.0 and more specifically to different fields of application in Steel Making [3-5]. For instance, authors in [3] give a general but basic overview of the possibilities of AI in different fields of application in Steel Making. [4] presents a "playbook" in an early stage to guide/design effective advances in AI have the potential to impact innovation. Finally, [5] examines the relevance of Industry 4.0 related opportunities and challenges as drivers for Industry 4.0 implementation in the context of sustainability, taking a differentiated perspective on varying company sizes, industry sectors, and the company's role as an Industry 4.0 provider or user.

Regarding specific Machine Learning (ML) approaches, in [6] a temperature prediction model to be used as an advisory system for the casting process is presented. The used methodology transforms empirical expertise on the casting process into a model of qualitative nature. Moreover, in [7] a literature review related to heat transfer in steel-making ladle refractories is shown. The reviewed works are classified into experimentally and theoretically focused researches and besides some strategies for improving temperature control have been considered. In [8] the factors which affect temperature

variations between furnace tapping and teeming are analysed, and a procedure to determine the probable temperature change is posed. Similarly, authors in [9] propose the use of an Artificial Neural Network (ANN) to obtain an estimation of the slag Corrosion of MgO-C in ladle refractories, with several input features such as: %CO(g) in test atmosphere, Brick-slag exposure time, Test temperature (ºC) and CaO/SiO2 ratio of the slag. Finally, [10] obtains decisive factors that have great relevance in the determination of the wear, namely: basicity excursions versus MgO-C Refractory Lining Life, impacts of temperature fluctuations on lining life, residual thicknesses and non-uniform wear of bricks and micrographs of last working surfaces of residual bricks, among others.

Motivated by the growing interest and awareness of both the scientific community and society in applying more sustainable models in the Steel Industry, this paper focuses on a key aspect that will lead us unequivocally to Best Available Technology (BAT) methodology to follow: *Optimization of the use of steel ladles by AI*. This optimization is approached in two different ways: 1) Estimating the Remaining Useful Life (RUL) in order to maximize it, i.e., by providing information of the possible remaining heats that a specific ladle can support. 2) Estimating the wear of the most limiting areas of the ladle, i.e., the areas of maximum affection of the ladle.

Finally, the work is structured as follows: Section 2, focuses on detailing how the optimization problem, named *Optimization of the use of steel ladles by AI*, is approached. Section 3 analyses the results obtained and finally, Section 4 presents the conclusions of the work.

## OPTIMIZATION OF THE USE OF THE STEEL LADLES BY ARTIFICIAL INTELLIGENCE TECHNIQUES

### Data collection and pre-processing

*RUL estimation model*

Currently, in our real case study the remaining brick thicknesses are manually registered by the steel maker and are performed twice throughout the ladle life: at reparation and at demolition phases (in cold conditions).

On the other hand, the operation variables that are used heat by heat, i.e., *Sulphur in vacuum, KWh, Lime, Alumina Sulphur to overturn, time of vacuum, spar, argon, nitrogen, Oxygen overturn, slag, Desulphurisation speed, steel liquid*, are automatically collected. Both sources of information are used in this work to estimate the RUL of the ladle.

Firstly, an integration of both sources of information is done by splitting the information of the operation variables before reparation and between reparation and demolition phases. With all the variables collected in those two groups, new statistical variables have been built to be the input for the ML models. Specifically, the statistical variables that have been considered, are *mean*, *standard deviation* and *accumulated sum* of the variables for both groups which are considered as inputs, "x", of the RUL estimation model. Moreover,

the number of useful lives reached in the two phases of the campaigns (at reparation and demolition) is also obtained and used as "y" for the RUL estimation model.

*Ladle wear estimation model*

Regarding the data for the Ladle wear estimation model, a total amount of 12 campaigns is analysed, 10 of which will serve to train the model, and 2 to validate it. These campaigns integrate a total of 368 thickness measurements (311 for training and 57 for validation) performed with a commercial laser equipment, the LaCam Mobile unit by Ferrotron-Minteq. Four zones are selected as areas of maximum affection (Figure 1): Plug Transition Zone, Plug Wall Zone, Nozzle Transition Zone and Nozzle Wall Zone for which the Ladle wear estimation model is executed.

*Figure 1: Areas of maximum affection of the ladle, i.e., Plug Transition Zone, Plug Wall Zone, Nozzle Transition Zone and Nozzle Wall Zone (in red colour).*

In order to obtain a quality dataset by using the 3D points cloud the following methodology has been accomplished:

– Data cleaning: Transformation and Alignment of measurements: To achieve spatial coherence to obtain a time series in which the degradation is reflected, a grid is built with specific dimensions. Then, the 3D point clouds are placed on the corresponding grid element. Besides this, to analyse and compare the degradation of the thickness at specific locations, the position of the elements of the grid should be consistent throughout all the measurements. Therefore, a procedure for aligning the measurement files that contain the point clouds is done chronologically (from heat zero to 80, for example) according to the number of heats performed between corresponding measurements.

– Treatments of NaNs and Slag: In both cases it is quantified and located the areas of maximum affection of each phenomenon. In both cases the zones are very well defined, and two specific methodologies were designed to maximize the amount of the elements of the grid.

– Selection of areas of maximum affection: In order to select these areas, each and every one of the pre-processed ladles are analysed. The result of this comparison pointed out systematic similarities located in four areas: Plug Transition Zone, Plug Wall Zone, Nozzle Transition Zone and Nozzle Wall Zone (Figure 1).

– Obtaining the time series: In order to achieve the training process the information that comes from the 3D laser measurements in the grids included in the selected areas; instead of using the "Minimum

thickness of the area" in each of the measurements carried out per campaign, the "Percentile Q5 of the thicknesses of the area" is used, because the minimum one is reached in a very abrupt way on many occasions, which does not help the aforementioned learning process (Figure 2).

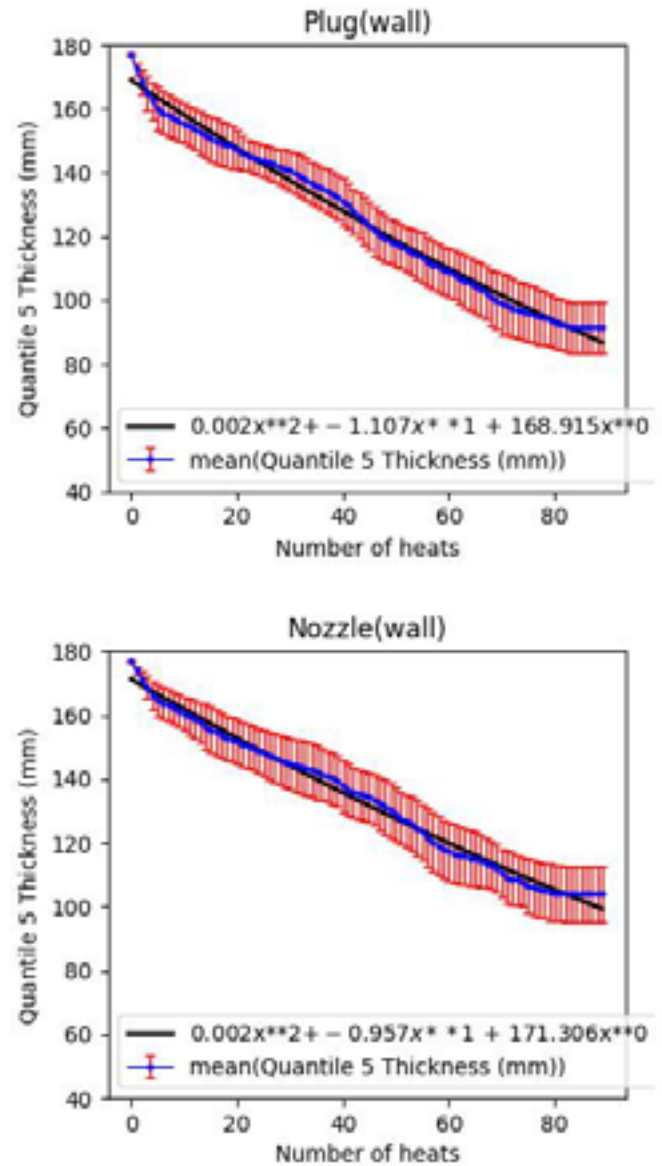

*Figure 2: Graphical representation of the regression curves (black), and mean values of the Q5(blue) of the thickness ± std(red) in the Plug Wall Zone.*

– Integration with the operation variables: For each instance in which there is a measurement, the remaining thickness is transformed to be integrated with the operation variables This process has been done for those four areas of maximum affection, the Wear Rate (Equation 1) "y" is computed as:

$$WR_i = \frac{(t_{(i-1)} - t_i)}{f_i}, \qquad (1)$$

being
$\begin{cases} t_i: \text{Remaining Percentile } Q_5 \text{ thickness at time } i. \\ f_i: \text{Number of heats integrated between measurements } i \text{ and } (i-1). \\ WR_i: \text{Wear Rate at time } i. \end{cases}$

Regarding the operation variables: Each instance must bring together the information of the heats performed up to that moment. In this use case, this transformed information has been obtained through the average and the accumulated value of all the operation variables of the performed heats. Moreover, the average and the accumulated value of all the operating variables "x" are considered as input for the models.

**Artificial Intelligence Techniques**

For both models, different AI algorithms have been used: 1) Random Forest (RF), XGBoost (XGB) and K-Nearest Neighbours (KNN).

– "Ensembling" is the technique to build a "model of models", that is, a few models are trained, and the final model does not depend on the prediction of a single scheme, but on several assemblies. The assembly concept is a good way to reduce the variance in the prediction, which is, extracting the most stable statistical component (least variance). There are two kind of ensemble methodology:

–*Bagging* is a way to decrease the variance in the prediction by generating additional data for training from dataset using combinations with repetitions to produce multi-sets of the original data. For example, **Random Forest**.

–*Boosting* is an iterative technique which adjusts the weight of an observation based on the last classification. If an observation was classified incorrectly, it tries to increase the weight of this observation. For example, **XGBoost** (Figure 3).

*Figure 3:XGBoost Boosting example.*

– **KNN**: KNN algorithm uses 'feature similarity' to predict the values of any new data points. This means that the new point is assigned a value based on how closely it resembles the points in the training set. And K, is the number of nearby points that the model will look at when evaluating a new point. The reason of comparing the IA models by using KNN, is because the number of instances is not very high so techniques such as KNN can be favoured by this fact.

**RESULTS**

In this section the results obtained for both estimation ML models (RUL and Ladle wear) are shown.

In order to evaluate the precision of both models, different test datasets reserved for this purpose are used. In the case of the RUL estimation model, the campaigns carried out during 2021 from January to December are reserved for this purpose. In the case of the Ladle wear estimation model 2 campaigns from a total of 12 are reserved to be used as test.

The metrics used to validate the performance of both models are the following: RMSE, MAE, Maximum committed error, Minimum committed error, and finally R-squared, $R^2$, which is a statistical measure that represents the proportion of the variance for a dependent variable that is explained by an independent variable(s) in a regression model.

Figure 4 presents the results of the RUL estimation model obtained by the XGBoost (in number of heats). Note that the x-axis represents several test campaigns, and the y-axis represents the number of heats supported by the ladles. The real RUL is shown in blue colour while the prediction is in cyan colour. The error metrics obtained are: RMSE of 2.295, MAE of 1.579, maximum error of 4.639, minimum error of 0.005 and $R^2$ of 0.067. The error distribution of the RUL estimation model is presented in Figure 5.

*Figure 4: Results of the RUL estimation model. The real value is represented in blue and the predicted in cyan.*

*Figure 5: Error distribution of the RUL estimation model.*

Similarly, Figure 6 presents the wear estimation results (in mm) obtained by different algorithms per validation campaigns: Random Forest (Rf) in red line, XGBoost (XGB) in cyan dashed line, 4-Nearest Neighbours (4NN) in black dotted line. The real wear rate is shown in solid blue line. Note that the y-axis is the error rate (mm), and the x-axis shows a detail of the campaigns used for the validation. On the other hand, given that the best results have been obtained by the XGB algorithm, Figure 7 shows the punctual error obtained in each prediction, and the histogram of the distribution of the error is presented. The metrics obtained are RMSE of 1.119, MAE of 0.710, maximum error of 5.1874 and minimum error of 0.055.

*Figure 6: Results of the wear estimation model per validation campaign in the PLUG wall Zone.*

*Figure 7: Error distribution for the XGB algorithm in the PLUG wall Zone.*

## CONCLUSIONS

This paper presents a ML tool with the aim at optimizing the refractory consumption. Specifically, RUL and ladle wear rate estimation models are proposed for optimizing the use of steel ladles by AI techniques. It shows promising results, with a MAE of 1.5 heats for the RUL estimation model and 0.7 mm for the wear rate estimation model.

Future work will be delved in improving the results by including other relevant features as the composition of the steel. In this sense and continuing with the line of research, a hybridization of different methodologies to increase accuracy maintaining the speed of computation is proposed. Also, the implementation and testing of several multi-layer (deep) random vector functional link neural networks variants as straight-forward implementations is part of future work.

# ARTIFICIAL INTELLIGENCE APPLIED TO ENHANCE THE THERMAL MANAGEMENT OF TORPEDO LADLE CARS

MGG Campos, B. Luchini, P. van Beurden, T. van der Velde, S. Sinnema
Tata Steel Netherlands, Velsen-Noord, Netherlands

H. Kuiken
Quantillion Technologies, Amsterdam, Netherlands

## ABSTRACT

The steel industry is highly complex. Steel manufacturers have to monitor all kinds of processes, maintain the operation and reduce the emission of $CO_2$. Advanced digitalization tools are vital to evolve toward a more sustainable, optimized, integrated, and agile operating model. Representing processes and systems as a digital twin with artificial intelligence-based optimization and scheduling models greatly enhances the decision-making on logistics, refractory maintenance, and energy efficiency. In this context, the thermal management of the torpedo ladle cars (used to transfer hot metal from the blast furnace to the steelmaking plant) has an important role. In this paper, the development of an artificial intelligence system to support decision-making on selecting the most energetically favorable torpedo car is presented. The application uses a simulation-based digital twin consisting of reduced order models of validated FEM models to forecast the torpedoes' refractory lining and pig iron temperatures. In addition, the system includes the refractory wear, location, and number of the torpedoes to indicate the most suitable to be selected for hot metal transportation. This increases the life of the equipment and avoids unnecessary heat losses, thereby reducing production costs and energy consumption. Thus, these new technologies lead us to solve existing logistics management challenges, improve process control, and prepare steel companies for the future.

## INTRODUCTION

The digital transformation in the steel industry provides the potential to reduce costs, improve profit margins and create more sustainable processes. Advanced analytics, machine learning, artificial intelligence, cloud solutions and digital twins are some of the technologies present in the ongoing digital transformation. In particular, applying the related technologies to the production processes allows the industry to become greener.

In this context, the hot metal route significantly impacts this challenge. The torpedo cars transport hot metal from the blast furnace to the steelmaking. The hot metal temperature affects the steel plant process as this can introduce a reheating step or reduce the amount of scrap in the converter if the temperature is too low. Therefore, the thermal management of torpedo cars is essential for green steel transformation [1].

This complex and ambiguous procedure involving several variables requires a multi-disciplinary solution [2]. An artificial intelligence system to support real-time decision-making on selecting the most energetically favourable torpedo car is being developed. The application uses a digital twin based on reduced-order models from complex finite element (FEM) thermal simulations. The refractory lining age, thermal conditions, and the torpedo's location define the most suitable torpedo to be filled and emptied.

The insights and capabilities of the AI solution provide a scenario planning for more dynamic and long-term decision-making clearness reducing the accumulative thermal losses during operation. We present the first results on the hot metal temperature losses by applying the artificial intelligence system.

## APPROACH

The torpedoes are responsible for transferring the hot metal from the blast furnace to the steel plant and its operation is described in Figure 1. The torpedoes are pre-heated and the cycle begins at the blast furnace, where the liquid metal is poured into the torpedo car. The hot metal resides in the car for transportation and treatment (BOS buffer). After it reaches the BOS plant, the vessel is emptied into a hot metal ladle. After that, the empty car returns and waits in the blast furnace buffer until the next cycle (aging).

*Fig. 1: Operation and cycle of the torpedo cars from the blast furnace to the basic oxygen steel plant (BOS).*

Nowadays, the decision of which torpedo from the blast furnace buffer should be filled is based on the first-in-first-out principle (FIFO) [3]. This methodology is rather simplistic and does not include energy efficiency, refractory lifetime and hot metal temperature and quality. Therefore, the development of an artificial intelligence model combined with the digital twins can enhance the multifactorial analysis, improving energy efficiency in the ironmaking procedures.

## METHODOLOGY

### Finite element model

Finite element model is a powerful tool for simulating and analyzing the behavior and the physical aspects of complex scenarios under various conditions. These models can be used to develop new equipment, verify the temperature distribution at certain heat conditions, and analyze failures and non-linear problems.

A three-dimensional 1/4th symmetric transient model of the torpedo was used to calculate the thermal condition, see Figure 2. Natural convection on the external shell and radiation and convection on the internal surfaces were included as boundary conditions. In addition, temperature dependent for the materials properties and the age of the torpedoes were considered.
*Fig. 2: Finite element model of the torpedo car.*

A thermocouple measurement campaign was conducted to monitor the torpedo ladle car's refractory lining temperatures and validate the finite element model [1]. The agreement between the FEM model and the thermo-couples was very good, see Figure 3.

*Fig. 3: Thermocouple measurements. The diamonds are the measured temperatures, the solid lines are the calculated temperatures by FEM.*

One of the main disadvantages of FEM models is that they require a lot of computational resources and time. Therefore, using these models in real-time applications and daily operation is difficult. The reduced order model can be used in this context, described in the next section.

**Reduced order model**

A reduced order model (ROM) is a simplified representation of a complex system that captures its essential dynamics while reducing computational complexity [4]. Creating a reduced order model involves the following general steps (Figure 4):

*Fig. 4: General steps to create a reduced order model [5].*

The first step is to define the problem to solve, identifying the system's essential variables, parameters, and governing equations. In this case, the problem's output parameters are the refractory and hot metal temperatures.

To create a reduced order model, you need either experimental data or a high-fidelity numerical model of the system. However, a design of experiments is essential to define the training dataset and optimize the model's accuracy. The finite element model of the torpedo described in the previous section was used to generate the data. The singular value decomposition theory is used to develop the reduced order model itself and the dataset is split into training and validation [5,6]. Creating accurate reduced order models can be a complex task. It might be necessary to iterate through the steps above, considering different parameters, model forms, or refining the data used for training.

The digital twin was generated, and it can be deployed. It was also necessary to assess the accuracy of the digital twin by comparing its predictions with independent simulations, Figures 5 and 6.

*Fig.5: Comparison between the predicted refractory temperatures using the DT and the FEM model.*

*Fig. 6: Comparison between the predicted hot metal temperatures using the DT and the FEM model.*

The digital twin showed high agreement with the FEM modeling. The accuracy of the digital twin was 99% for both refractory and hot metal temperatures when compared with FEM results. Therefore, using the digital twin during production and having a thermal state for each torpedo car in operation is possible.

By associating the digital twin with artificial intelligence algorithms it is possible to optimize the decision making on the torpedo management and selection.

**Artificial Intelligence**

Artificial intelligence (AI) systems can be highly effective in solving multi-factorial problems due to their ability to process large amounts of data, analyze complex patterns, and make optimized decisions.

AI algorithms can analyze various factors, constraints, and objectives related to scheduling, such as how many torpedoes are in the fleet, productivity, refractory temperature, empty time and full time. By formulating scheduling as an optimization problem, the AI system can reduce the hot metal temperature losses and $CO_2$ emission.

There are several types of AI and optimized algorithms. Customized heuristic algorithms (CH) and reinforcement learning (RL) are two approaches to solving problems, including scheduling issues.

Heuristic algorithms are designed based on domain-specific knowledge and problem understanding. They rely on predefined rules, heuristics, or algorithms crafted by human experts. These algorithms often exploit specific problem characteristics to find good solutions quickly. On the other hand, RL approaches do not rely on predefined rules or problem-specific knowledge. Instead, they learn optimal policies through interactions with the environment. RL algorithms can adapt to various problem domains without requiring explicit human expertise.

CH generally requires manual design and tuning by experts. They may adapt well to changing environments or new problem instances with additional modifications. Therefore, they may only explore within established heuristics, limiting their ability to discover novel and potentially better solutions.

RL algorithms learn through trial and error, continuously improving their performance over time. They can adapt to new situations and handle changing environments. RL models are trained using reward signals to guide the learning process and optimize long-term performance, see Figure 7.
Figure 7. Reinforcement Learning agent-environment interaction

RL algorithms inherently balance exploration and exploitation. They explore different actions and strategies to discover optimal policies while gradually shifting towards exploiting the learned knowledge to maximize rewards. RL can potentially find new, improved solutions beyond what human-designed heuristics may have considered. However, the convergence to optimal policies may take time and unexpected action can happen depending on the problem's complexity and the training process.

Both algorithms were used to compare the hot metal temperature losses by optimizing the thermal management of the torpedo cars.

## RESULTS

The estimated algorithms' performance was defined by computing hot metal temperature loss based on average values (means). The hot metal temperature loss is calculated by subtracting the average temperature of the hot metal that arrives at the BOS plant from the temperature of the hot metal that comes from the blast furnace to a torpedo.

First, the customized heuristic algorithm was compared with the FIFO methodology over one week, see Figure 8 and Table 1.

Fig. 8: Hot metal temperature for CH and FIFO over one week.

Tab. 1: Comparison of the mean hot metal temperature loss after one week.

| Algorithm | Hot metal temperature loss (°C) |
|-----------|--------------------------------|
| FIFO | 0 |
| CH | -7 |

The CH performed better than the actual methodology used in current operations, reducing 7°C in the mean hot metal temperature loss.

The RL was modelled only over two days due to its complexity, it requires a long computation time. The hot metal temperature results of RL, FIFO, and CH are shown in Figure 9 and Table 2. In addition, a random agent was included as a baseline for comparison with the other algorithms. The random agent facilitates seeing if the RL is simply with unexpected or optimal behavior.

Fig. 9: Hot metal temperature for RL, CH and FIFO over two days.

Tab. 2: Comparison of the mean hot metal temperature loss after two days.

| Algorithm | Hot metal temperature loss (°C) |
|-----------|--------------------------------|
| FIFO | 0 |
| CH | -9 |
| RANDOM AGENT | -3 |
| RL | -12 |

The results show the potential of using the RL algorithm to optimize the thermal management of the torpedoes, minimizing the hot metal temperature losses and maximizing the production control.

## CONCLUSIONS

Digitalization is essential for the steel industry as it allows for real-time monitoring and control of manufacturing processes, leading to improved operational efficiency and more sustainable operation. Additionally, by leveraging AI capabilities, scheduling problems can be solved more efficiently, accurately, and adaptively. AI systems can help optimize resource utilization, reduce costs, improve process control, and make the steel industry greener.

In this context, an artificial intelligence system based on a digital twin was developed to select the most energetically favourable torpedo car. The digital twin is created from reduced order models (ROM) of complex finite element models.

Two optimization algorithms were used to compare the results. The customized heuristic algorithms are based on human expertise and problem understanding, while reinforcement learning learns optimal policies through environmental interactions. Customized heuristics can be efficient and effective for specific problem instances or classes, whereas reinforcement learning offers adaptability, scalability, and potential for generalization across different domains.

In summary, both algorithms showed the significant potential of the solution in reducing the accumulative thermal losses during torpedo cars operation and reducing $CO_2$ emissions. CH reduced 7 °C of the hot metal temperature loss over one week. On the other hand, the reinforcement learning reduced 12 °C over two days. However, optimizing the reinforcement learning algorithm to model long periods is necessary.

In addition, this methodology can be expanded to other installations, for instance, hot metal and steel ladles. It will drive to solve existing and future logistics management challenges, improving process control and refractories life, and reducing $CO_2$ emissions.

# THE USE OF NUMERICAL MODELLING FOR REFRACTORIES OPTIMISATION IN THE REHEATING FURNACES AT TATA STEEL NEDERLAND

Bruno Luchini, Frank van Sikkelerus, Florus Beukema, Ed Wortel, Sido Sinnema.
Tata Steel Nederland, IJmuiden, The Netherlands

**ABSTRACT**

Tata Steel in IJmuiden (NL) produces approx. 7 million tons of steel per year. In order to cope with such volume, the IJmuiden site makes use of 4 slab reheating furnaces. Refractories are crucial components for a stable operation and a high quality end product. With energy prices in historical peak, reducing heat-losses in the furnaces became an even stronger objective. In this study, we discuss how numerical simulation based on finite element method (FEM) assists Tata Steel in the decision-making process, from materials selection up to geometry optimisation of refractory components like support walls and anchor bricks. The study also sheds light on the trade-off between using an 1D simplified model and a more detailed 3D FEM model.

**INTRODUCTION**

Slab reheating furnaces are crucial components in the steel manufacturing process. They are used to reheat slabs to the desired temperatures before the hot rolling stage. The reheating furnaces operate in temperatures up to 1350°C. Tata Steel produces approx. 7 million tons of steel per year. In order to cope with such volume, the IJmuiden site makes use of 4 slab reheating furnaces (Fig. 1). Last year furnace 21 was replaced by the walking beam furnace 25 at Tata Steel in IJmuiden, reducing energy consumption by 1.0 PJ/year. Refractory materials play a vital role in this installation due to the extreme temperatures involved. They are designed to withstand the intense heat and minimise the heat losses to the surroundings. The refractories act as a protective barrier, resisting thermal shock, corrosion and thermo-mechanical stresses, thus maintaining the structural integrity of the furnace and optimising its performance.

Numerical modelling has emerged as a valuable tool for optimising refractory performance in various industrial applications, including reheating furnaces [1,2]. The models are used in the materials' selection, heat losses estimations and geometry optimisation during the design phase of furnace 25. Through computational simulations, one can simulate the behaviour of distinct refractory materials under specific operating conditions, enabling for informed decision making. These models can be rather simple, like 1D thermal analysis, or very complex, taking into account multiple factors such as thermal conductivity, heat capacity and corrosion, allowing for a comprehensive evaluation of the refractory's performance. Additionally, numerical simulations can identify design issues and easily evaluate different mitigation strategies. By leveraging numerical modelling techniques, industries can optimise the refractories performance, reduce the energy consumption and extend the lifespan of the refractory linings, ultimately leading to improved operational efficiency and cost savings.
*Fig. 1: Downstream route – Tata Steel in IJmuiden*

## THE USE OF NUMERICAL MODELLING AT TATA STEEL'S REHEATING FURNACES

Furnace 25 is the newest walking beam furnace at Tata Steel in IJmuiden. During its design phase, several models were created to select the most suitable materials and design strategies. One good example where numerical modelling was useful is the simulation of the thermo-mechanical behaviour of the roof. As it can be seen on Fig. 2a, part of the roof of furnace 25 has an inclined slope. This design feature was not present in any of the other furnaces in IJmuiden. A numerical model was used in order to understand the behaviour of this design before installation. The model represents only a section of the roof and makes use of symmetry planes to reduce computational costs while maintaining physics fidelity. The model was used to evaluate the temperature (Fig, 2b), deformation (Fig. 2c) and stress over strength ratio <SSR> (Fig. 2d and 2e) in the roof components. The stress over strength ratio <SSR> is a temperature dependant failure criterion which takes into account the measured max principal strengths at different temperatures. The equation for this criterion is given by equation 1. One of the main concerns in such structure is related to the level of stress the anchors would be subject during operation. The models have shown medium levels of SSR in the anchors. To be even safer, the expansion allowances were revised based on the outcome of the model, reducing the SSR level of the anchors.

$$SSR(T) = \frac{\sigma_1(T)}{\sigma_{measured}(T)} \qquad \text{Equation 1}$$

**NECESSITY OF 3D MODELS**

1D simulation is typically appropriate when the thermal behaviour is predominantly one-dimensional, such as in structures with uniform thickness and when heat flow occurs primarily in one direction. On the other hand, 3D simulation is necessary when the thermal behaviour of the structure is inherently three-dimensional or if it involves complex geometries, complex heat flow paths and varying material properties. 3D simulations provide a more detailed representation of the system capturing localized variations.

Therefore, in a reheating furnace project, if one is interested in the temperature distribution along a flat wall, where the refractory and insulating lines present constant thicknesses, and when the heat flow is predominantly unidirectional, a 1D calculation can result in a good approximation.

An interesting example where 3D simulation had to be employed in the design evaluation of reheating furnace is the materials' specification behind the anchor bricks. The anchor has a rather complex geometry and the bolt act as a heat sink. Therefore, a 1D approximation in this location is imprecise. With the 3D model it was possible to verify that the insulation material initially selected would be subject to temperatures higher than its working specification. The 1D model of the wall (not considering the bolt's heat sink effect) predicted that all materials were within working specifications.

Based on the results a redesign of the refractory construction was made (Fig. 4). The two main target were to keep temperatures below the working temperature for each material and to reduce the heat loss. The results showed that all materials have met this criteria and heat loss was reduced by 19%. Thus, 3D simulation is recommended for a finer and optimized design in those situations.
Fig. 3: Temperature distribution in the different structures behind the anchor brick

Fig. 4: Re-design of the the anchor brick construction of the furnace wall

As previously mentioned, 1D simulation is appropriate when the thermal behaviour is predominantly one-dimensional. In this case, using a 3D simulation would result in increased expensed resources without much added value. In Fig. 5a, one can see that the results attained by the 3D model far from the anchor bolt (line AB), where the heat flux is mainly unidirectional. The 1D (Fig, 5b - green line) and 3D (Fig, 5b - black line) results are very much comparable.

## CONCLUSIONS

The article underscores the significant role of numerical simulation, particularly finite element method (FEM), in optimizing refractory performance in Tata Steel Nederland's slabs' reheating furnaces. Through simulations, materials selection, geometry optimization, and informed decision-making processes are facilitated, ultimately leading to stable operation, high-quality steel production, and minimized heat losses. The study showcases the application of numerical modelling in evaluating the thermo-mechanical behaviour of the furnace roof and anchor bricks, highlighting the necessity of 3D models for complex geometries and three-dimensional thermal behaviour. Additionally, the article emphasizes the value of comparing 1D and 3D models, noting that while 1D simulations provide a good approximation for predominantly one-dimensional thermal behaviour, 3D simulations offer a more detailed representation of the system, capturing localized variations and enabling a finer and optimized design. Furthermore, the article highlights the example of anchor bricks where the use of a 3D model was essential to accurately assess temperature specifications and facilitate a redesign of the refractory construction, resulting in reduced heat loss. Overall, numerical modelling proves to be a valuable tool in achieving optimal design and operational outcomes, reducing energy consumption, and prolonging the lifespan of refractory linings.

# A NEW STANDARD FROM WRA FOR DIGITAL EXCHANGE OF REFRACTORIES DATA

Alexander Platzer, Bernardo Gosaric de Barros,
RHIMagnesita, Vienna, Austria and Contagem/Brasil
and
WRA, Bruxelles, Belgium

## ABSTRACT

Bringing product information for customers to describe refractory products is done daily thousands of times, but in many different ways and forms, some being safer than others and many of them not digital. The data transfer process in B2B transactions defines quality, speed and mostly trust. As the world is more and more digital and many other industries further up in the value chain are using digital standards to exchange product information the World Refractory Association (WRA) has supported the development of a digital refractory exchange data standards (REDS) to also facilitate this development, which can become a requirement soon down the value chain. The paper presents the approach, the structure and also a way to generally exchange refractory product information.

## INTRODUCTION

Imagine you want order food online. You open one of the apps that allows you to select between a variety of different styles of cooking, Indian, Italian, Chinese, or Thai for example. You select the one you feel in the mood for, then you continue your select one of several different restaurants serving your favoured food style. Once you have selected your trusted food supplier you scroll through a list of different dishes, with nice pictures and descriptions that allow you to pick what you hunger for. Life can be so easy, right? But did you ever consider what allows you to do that? All the different restaurants are having a pre-specified way to enter their food information, in other words the food delivery service uses a specific data standard to provide the information the restaurant wants to supply over the food-app. So while the food names, descriptions and pictures my vary in stile and depth, the structure of the presentation remains the same, irrespectively if it is Thai or Italian. As a (hungry) user this allows us quick absorption of the information and focus on the details of product of interest. We want clear information on the product, not a different structure of presentation when we change from one restaurant to another one and we clearly have to always find out if the selected dish contains a compound that might cause an allergic reaction. After we've found our dinner of the day we're ready to press the order-button, but wait, there's also this restaurant, where you know the food is really good, because you already ate there before, unfortunately it is in a different part of the city so walking there is taking too long and it's not on the food-app. However, you're sure that you still have their folder lying around to order by phone, so you start searching your apartment for it. 20 minutes later you give up the search, because you couldn't find their folder and you go back to the food-app, order and online. This shows the second benefit, digitally available online data cannot be misplaced, you just go on the dedicated platform and retrieve it from there.

As users of a food- or any other kind of commercial app we like this type of comfort, more so, we take it for granted. The question is why we as refractory producers are not aiming to provide a comparable comfort when dealing with our product information to our customers. Consequently, the question arises: "how are we exchanging information on our products in the refractory industry?". While the author was not able to draw a statistically reliable sample to answer this question scientifically, his gut feeling makes him believe the refractory industry behaves in most cases like the normal, average person, dealing with data. The German newspaper "Die Zeit" has evaluated early this year the most common formats to exchange data in Germany in 2023. Surprisingly DIN A4 (the most common paper format in central Europe) is still ruling data exchange, followed by the well-known

*Fig. 1: Prevalent data formats in Germany in 2023.[1]*

office PC-file-formats. Now unsurprisingly this also matches the author's daily work experience. While it is not fair to extrapolate this pattern to an entire industry, conversations with representatives of refractory suppliers as well as customers revealed this was also their normal way of handling data. This is somewhat bewildering as there's a shared understanding that data has value, so handling it carefully and efficiently would be the logic thing to do. On the other side it is only human to use what is there (paper, word and pdf) and make the most out of it, but it is equally human to ask the fundamental question of any innovation, "Can we do this in a better way?". Improvement however comes with the effort to change something, and change can make people feel uncomfortable. "Why do I need this?" is the classic defence mechanism we always perceive at others but never at ourselves. So let's answer the question.

## WHY THE REFRACTORY INDUSTRY SHOULD HAVE A PRODUCT OR RFRACTORY DATA EXCHANGE STANDARD

Søren Kierkegaard is believed to have said "Comparison is the end of happiness and the beginning of dissatisfaction.". Still comparing is necessary to understand where you are in a process, into which direction you can improve or what could hit you unprepared if you don't understand how others dealt with a comparable challenge. So, once you start comparing you find out that there are thousands of different data standards in use today. These standards cater to various sectors, including finance, healthcare, manufacturing, telecommunications, transportation, energy, retail, and more. Each industry and domain may have multiple standards specific to their needs. Here are a few examples:

1. EDIFACT (Electronic Data Interchange for Administration, Commerce, and Transport): EDIFACT is a widely used international standard for electronic data interchange. For example, in the automotive industry, it is utilized for various business processes, including purchase orders, shipping notices, and invoicing, enabling seamless data exchange between automotive manufacturers and suppliers. Alternatively, the North American region would be the equivalently working ANSI ASC X12 standard.
2. SWIFT (Society for Worldwide Interbank Financial Telecommunication): SWIFT is a messaging network used by banks and financial institutions to securely send and receive financial transactions globally. It provides a standardized format for international payments, messages, and instructions.
3. XBRL (eXtensible Business Reporting Language): XBRL is a standard for electronic communication of business and financial data. It enables the exchange and analysis of financial statements, regulatory filings, and other business reports.

4. HL7 (Health Level Seven): HL7 is a set of international standards for the exchange, integration, sharing, and retrieval of electronic health information. It facilitates interoperability and data exchange between different healthcare systems.

5. XML (eXtensible Markup Language): XML is a widely used standard for structuring and organizing data. It is platform-independent and allows for the exchange of structured information between systems.

6. JSON (JavaScript Object Notation): JSON is a lightweight data interchange format. It is widely used for representing structured data and is particularly popular for web-based applications and APIs.

Data standards have become the norm in the B2B-world. They come in many types and sizes, and all have one goal, to provide the customer/receiver with the data set needed. Handling data efficiently, allows for simplification, transparency and can become a service through the right technology.

Fig. 2: with the customer in focus, data and technology can create value through more transparency, service delivered and simplification of handling [2]

The requirements of vertical data-integration and circular economy drive towards the availability and accessibility of product data as one element in the digital chain.

The refractory industry could benefit significantly from a product exchange data standard. Here are some ways the industry could profit from implementing such a standard:

1. Streamlined Procurement Process: A product exchange data standard would provide a common format and structure for exchanging information related to refractory products, such as specifications, material compositions, dimensions, and performance characteristics. This would simplify the procurement process by enabling seamless communication between buyers and suppliers, reducing errors, and speeding up the ordering and fulfilment cycle.

2. Enhanced Product Information: By adhering to a data standard, refractory manufacturers can provide detailed and standardized product information, including technical specifications, testing data, safety certifications, and usage guidelines. This would enable customers to make informed decisions and compare different products more easily, leading to improved purchasing decisions and higher customer satisfaction.

3. Improved Supply Chain Efficiency: With a product exchange data standard, the refractory industry can achieve better supply chain integration and efficiency. The standard would enable automated data exchange and integration between suppliers, manufacturers, distributors, and end-users, resulting in faster order processing, improved inventory management, and reduced lead times.

4. Facilitated Equipment Integration: Refractory products are often used in conjunction with other equipment and systems in industrial processes. A product exchange data standard could include information on compatibility, installation requirements, and maintenance procedures, enabling better integration of refractories with other equipment. This would simplify installation and maintenance processes, reduce downtime, and enhance overall system performance.

5. Compliance and Traceability: A product exchange data standard can incorporate regulatory requirements and traceability features. This would assist the refractory industry in complying with industry regulations, environmental standards, and safety guidelines. It would also enable tracking and documentation of product origins, materials used, and performance history, ensuring transparency and accountability in the supply chain.

## WHAT THE WRA REDS-TEAM HAS CREATED

In early 2021 (shortly before Covid started) the WRA formed a taskforce to work on Refractory Exchange Data Standards (REDS). The taskforce was formed by employees of RHIMagensita, Refratechnik, Vesuvius, Harbison Walker International and later joined by Almatis and Calderys. Two workstreams were defined. The first focuses on refractory product data which should be shared

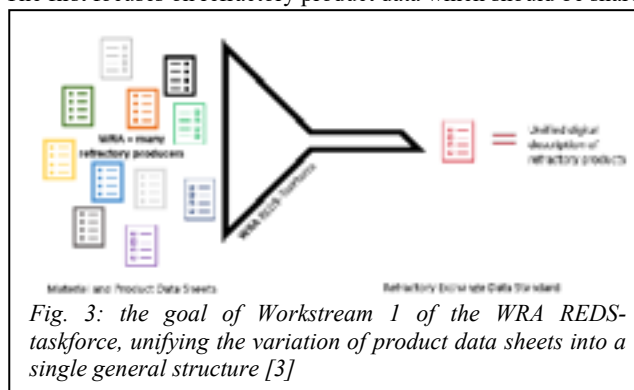

Fig. 3: the goal of Workstream 1 of the WRA REDS-taskforce, unifying the variation of product data sheets into a single general structure [3]

with the customer, the second should define how data around the usage of a refractory product at customer site can be shared with the refractory producer. The group decided to focus on the first workstream to start with. Covid restrained progress heavily in the beginning, later the different views on how structure of the standard should look like, what it should contain and how certain information should be shared took quite some time and effort. The result is (at least for the author) almost unbelievable: for the first time, a group of some of the largest refractory suppliers agreed on a unified, single way to generally describe refractory products. The developed standard allows equally to describe a brick, a castable or a functional product. While it is of course necessary to have a unified way of describing to form a standard, the fact that this level of agreement could be reached across all products classes and participating producers, is remarkable. The taskforce worked hard together to get to this point. When the result was then finally presented to a group of selected customers, the taskforce learned, that some customers where already thinking beyond the intended idea of how the product data could/should be provided, while others were not so easily convinced. Therefore, the WRA decided to create an MVP (Minimum Viable Product = pilot project) of an exchange platform, which uses the Product REDS inside. While this platform is only the conveying framework, allowing for the data exchange, it is extremely necessary and helpful to understand the process and benefits.

## HOW THE PRODUCT REDS IS STRUCTURED

The content of the REDS is not bearing any surprised for anyone making or using refractory products, and it shouldn't. The product data standard is like a universal translator, allowing to describe and understand the qualities of a product on a digital level, or, like back in school, it is the structure that grammar is providing to make meaning out of what one is saying. And of course, like every country has their own specific words and sentence structures, refractory products require special descriptions which are rooted in the material property descriptions, the way these products need to be packed and shipped, and where they can finally be used. All of this the REDS holds in the following structure presented in Tab 1.

Tab. 1: Structure of the Product REDS

| Section | Description | Number of categories | Number of sub-categories/ fields | „Must" fields |
|---|---|---|---|---|
| Application | Area, purpose, function of application | 3 | 10 | 1 |
| Logistic | Origin, storage, packing, quantity, brand name | 5 | 21 | 4 |
| Manufacturing | Fabrication, on-site processing for unshaped and shaped products | 4 | 79 | 9 |
| Product Family | Refractory categories | 1 | 3 | 1 |
| Classification & Certificates | Health and safety, environm., & production requirement | 5 | 23 | 2 |
| Chemistry & Mineralogy | Chemical composition & containing minerals | 22 | 74 | 0 |
| Chemical Resistance | CO-resistance, alkaline resistance, etc. | 5 | 12 | 0 |
| Physical Properties | Density, porosity, CCS, MoR, RuL, CiC, etc. | 28 | 130 | 4 |

The standard should allow to describe every refractory product. As visible in Tab 1. every section contains a lot of individual fields ("number of subcategories/fields"), some of them being mandatory to be filled ("must fields"). This is necessary to allow for a minimum description. It has also to be noted that not every product can contain information in all of the non-mandatory fields, as e.g. it does not make sense to specify a mixing liquid or additive, which is necessary for a castable, for a brick. In other cases, the specific data point may not be available for a specific product because it has never been generated up to this point in time.

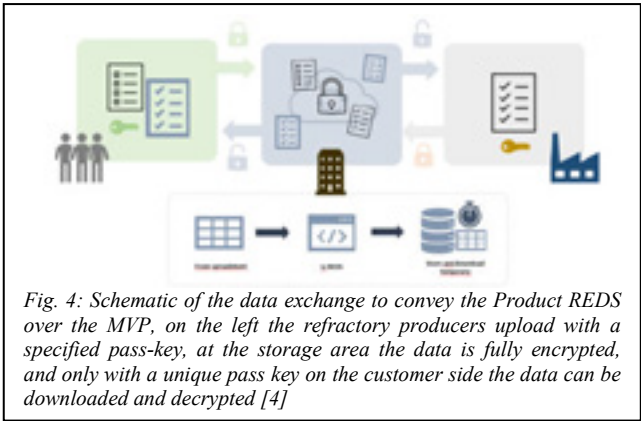
With a defined structure in place the pathway for a secure, efficient, and automatable data exchange is clear.

**An MVP to convey the Product REDS**

For most people data transfer process is not a very tangible subject, while the benefits as described in the Introduction are naturally more accessible. Like the benefits help to capture the "Why", it is equally important to understand the "How", how is the data standard put to use to allow for the benefits realization. The task force therefore decided to develop a simple data exchange platform as an MVP (minimum viable product). The MVP concept in a simple form defines the basic functional version of a solution, aiming to:

1. Validate a project viability.
2. Reduce costs for a solution release.

Both converging to validate if the proposed solution covers "the job to be done" which means the desirable problem to solve with the current proposal. It allows stakeholders to experience the product and collaborate for better versions through constant feedback. The MVP concept was created back in 2001 by Frank Robinson CEO of the American IT consulting company SyncDev Inc., but got its notoriety with the best-seller: "The Lean Startup" from Eric Ries only in 2011. For the REDS-Task force team it was equally important to create the desired exchangeability of the data standard but also to keep the character of the refractory business. This means that the exchange of product information via the Product REDS must remain between one customer and one refractory producer only. Further, to make the standard be used by all potential refractory producers, the entrance barrier needs to be low. Therefore, different file formats and structures needs to be accepted for upload a product description/specification, reducing this way complexity and simplifying user journey and experience. While the original product description is uploaded, inside the platform it is converted into the REDS model, and encrypted before being stored into the database, which makes it not possible for someone hosting the exchange platform to read the data. To access, download and decrypt the product information in the WRA-RDX (Refractory Data eXchange) platform the customer uses the unique access key only valid for this individual data transaction. The exchange platform must provide a "4 eyes only" data exchange working with data and environment security to avoid data leaks. Security measures must be considered not only in the back-end but also in the front-end to guarantee the deliver and access for data only to respective parts involved.

*Fig. 4: Schematic of the data exchange to convey the Product REDS over the MVP, on the left the refractory producers upload with a specified pass-key, at the storage area the data is fully encrypted, and only with a unique pass key on the customer side the data can be downloaded and decrypted [4]*


WRA-RDX platform will follow 3 pillars: Usability, Security and Reliability. Usability refers to the user experience, with focus on a easy-to-use interface and journey through each process. Security to guarantee the deliver and access only for those authorized and involved into exchange transactions which will be applied individually and environmentally. Reliability represents the transparency history within the environment allowing the trace of transactions between parts involved and total volume by WRA. To achieve this several features are required to work together within the MVP:

- Access will only be possible through authentication.
- Distinct functional areas designed based on entities roles and needs: Suppliers (S), Customers (C), WRA (W)
- Exchanges transactions directly between entities.
- Data stored encrypted, accessible and readable by entities related to transaction.
- Upload functions responsible to convert data to REDS.
- "Limited-time" availability control per transaction
- Exchanges history volume collected to support resources usage and possible re-dimensioning.
- WRA has no access to content delivered or stored.

- WRA will only manage access to platform and KPIs related to usage history.

**THE FEAR OF COMMODITIZATION**

Does this data standard make us more comparable and by that make refractories a commodity? There are two counter questions to raise, first "are our customers not already comparing our products today?" and second "what is a commodity product in the refractory world?" The first question can be answered with a clear yes, but of course we make it a little easier to compare products from different suppliers. That is customer service. But it will not change the quality of our products or their performance in the field, which is what our customers are buying. The second question is also easy to answer, as like in most other industries, some refractories are commodities fulfilling an "easy task", while others are tailormade to withstand a harsh chemical attack or optimized to enhance the transfer of liquid metals. You can also compare this to coffee for example. You can buy it in an industrialized form but also from small independent local farms/producers. The quality and flavour of the local farm/producer can in many cases excel the industrialized product even if is organic but the consumer will choose the option which fit it´s taste and pocket.

So, nothing will change in the performance or quality of our products because we can convey product details to single customer in a unified digital way, we only help our customer to make that decision, which products he prefers to buy. Also, sending a product description does not take away the personal exchange which is central in an industry where building trust into the quality and performance of a product is so crucial.

**CONCLUSIONS**

Most changes are often perceived as critical or even unnecessary, but change is the only constant in our lives and digitalization has brought us a lot of beneficial changes over the last decades. Our customer industries are faced by their customers to use digital data standards, and this will trickle down to our industry, so why not being ahead of the curve and setting a Product Refractory Exchange Standard out of our industry to serve our customers today? Therefore, we must embrace the change as an opportunity to improve our processes, products and mainly new ways of serving our customers with them at the center of our process which will add value to the chain through a simplified operation through digital communication that adds value as well to their daily routines with fast integration and also as a result of our industry improvement in its customer-centricity maturity levels. Soon everyone will understand that data standards will help to make the refractory industry more efficient and consistent.

# CONVERTER ON LIFE–SUPPORT: A STRUCTURED APPROACH TO DETERMINE THE GOVERNING PARAMETERS OF REFRACTORY WEAR TO STABILISE AND PROLONG THE LINING LIFETIME

F. Vermeulen, W. Tesselaar,  E. Gisolf

Tata Steel Nederland, Velsen-Noord, Netherlands

**ABSTRACT**

The average wear and the spread in total lifetime of the refractory linings of the converters at Tata Steel IJmuiden has been increasing under the influence of alterations in both the BOS process and the refractory maintenance strategy. To minimise the risk of premature failure and loss of production, a stable and predictable lifetime of the converter refractory lining is required. Laser scanning is of vital importance for the prediction of refractory wear and the influence of refractory maintenance on it, but is difficult to interpret. This study provides a case study in which through data processing, data analysis and Mood's median testing, slag washing (SW) and slag splashing (SS) are found to significantly reduce converter vessel lining refractory wear.

**INTRODUCTION**

Converter availability is an important parameter for many BOS plants to minimise costs and maximise production. Converter availability is strongly influenced by refractory life. The life of a converter is depending on three main parameters: refractory material and construction, process parameters and maintenance strategy (Siebring et. al, 2008). Multiple process parameters influence the refractory wear and can potentially be optimised to reduce wear: thermal cycling, slag composition, temperature etc. Next to influencing process parameters, performing refractory maintenance potentially reduces the wear rate as well. However, maintenance of refractory takes time, which means it can have a negative effect on the production level of steel.

Tata Steel IJmuiden has three converter vessels. Under favourable market conditions all three converters are used simultaneously (except when one undergoes a reline). Generally, when three converters are available, sufficient time is available for maintenance. However when a converter is in reline, performing maintenance can have a direct effect on the production rate. The planning for a reline depends on the expected life of the converter vessel. The life can be significantly influenced by refractory maintenance.  At Tata Steel IJmuiden there are currently four main refractory maintenance techniques in use for the converter: 1) slag washing (SW), 2) slag splashing (SS), 3) brick patching and 4) gunning. Brick patching is a technique where a small portion of slag is left in the converter and recycled refractory is added. The converter is tilted so that the material is positioned at the desired spot. The slag mixture is left there for several hours to cool and is believed to form a protective layer. Slag splashing and slag washing are both based on the idea that if the slag has the right composition and temperature (and therefore the right viscosity), it will stick to the lining forming a protective layer. SW is a technique where the remaining slag after tapping is moved along the refractory lining by rocking the converter back and forth. With slag washing it is not possible to cover the trunnion areas with a protective slag layer. SS requires the use of the oxygen lance. After tapping, the oxygen lance is lowered into the converter in the upright position and starts blowing nitrogen. The flow of nitrogen causes the slag to splash up against the lining. The nitrogen is believed to have an additional cooling effect and SS is assumed to cover a larger area of the vessel than SW.

Between two production heats different refractory maintenance techniques can be used to prolong the life of the refractory lining Depending on production pressure (=time available), slag composition, temperature, wear rate, planning, number of converters in use,  availability of equipment in the case of gunning, reblows, remaining thickness of the lining and/or reline planning, no maintenance is done or  one or multiple maintenance techniques can be used, e.g. SS followed by SW.  This may be used in several subsequent heats or as a single event. In IJmuiden, the frequency of refractory maintenance increases with the age of the lining.  In IJmuiden SW is done in ~18% of the heats and SS in ~10%. To follow the wear of the linings, IJmuiden uses one mobile laser scanner for all three converters. The use of a mobile scanner (instead of a fixed scanner per converter) means extra time for positioning the scanner and position finding (knowing the exact location and angle of the converter relative to the scanner), resulting in time loss that can't be used for production and/or maintenance and as well as the risk of a deviation in the measurement or measuring error. As a result,  laser scans, to follow the wear of the converter are roughly made in ~15% of the heats.  The frequency of the scanning slightly increases with the age of the refractory lining to approximately 18-20% in the last 10% of its life, but never to 100% of the heats. Performing refractory maintenance and making laser scans are not synchronised, which means that different combinations of maintenance techniques could precede a single laser scan. The same applies for the process conditions. The laser scanner scans the lining surface including slag, skull and possible remnants of refractory maintenance. To assess the effectiveness of refractory maintenance on the refractory wear rate, multiple consecutive laser scans are required to minimise the effects of other process conditions and reduce the influence of the measuring error on the scans. Multiple laser scans can cover dozens, even hundreds of heats and this means that the resulting refractory wear rate assessment corresponds to a plethora of different combinations of refractory maintenance.

In the past, the effectiveness of different refractory maintenance techniques was analysed by looking at a long period of a certain maintenance technique and to find a correlation with the average wear rate in that period. However, the results of this approach were not very conclusive and were often even contradictory. Even though we are convinced that SW and SS are effective techniques to lower the refractory wear, this simple linear approach sometimes led to the conclusion that they have a neutral to negative effect. Therefore more complex data analysis methods were explored.

This research proposes to use a segmentation-method based on moving averages in combination with Mood's median test to analyse the effectiveness (Mood, 1950). It will focus on SW and SS, and will not include brick patching or gunning.

**METHODS**

Data analysis was performed within the Data Science & Engineering environment in Azure Databricks from Microsoft. The data consisted of minimum residual thicknesses from laser scans, converter, campaign and heat identifications and refractory maintenance techniques derived from logged process phase data. Minimum residual lining thickness is obtained by determining the lowest point of a predefined area in a laser scan (see fig. 1). These predefined areas include among others: the charge pad and sections of the knuckle and tapping breast. The lowest point is preferred instead of average, modus or median because it represents the distance to a potential breakout. Minimum residual thickness versus heat number leads to a wear line as seen in figure 2.
*Fig. 1: Laser scan of converter vessel 23Q after 3181 heats. Colours represent minimum residual thickness. Red grit shows the predefined areas.*

*Fig. 2: Wear lines based on minimum residual thickness measurements for two knuckle areas during converter campaign 23Q.*

## Segmentation-method

The segmentation-method is a method in which time periods are defined from a large data set in which specific conditions are met. These periods or segments are analysed and subsequently collected in a new dataset that forms a uniform hypothetical subset. Generally, more datapoints within a dataset will lead to less variance in predictions. By using the segmentation-method it is possible to use short segments/ periods that are normally rejected because of sample size by combining them with longer segments. It should be noted that in the case of the laser scans of the converter lining, shorter segments have a lower probability to unveil a true trend in wear rate. The segmentation-method handles this problem by normalising. Longer segments carry more datapoints, and trends found in these segments therefore weigh proportionally more. Moreover, it is assumed that deviations caused by short segments are normally distributed. Nonetheless, to prevent outliers from contaminating the dataset, segments must consist of at least ten consecutive scans in order to be approved. In this research the segmentation-method was applied to a dataset comprising all converter campaigns from three converter vessels over the period 2018 – 2023. This results in a dataset covering 67,126 heats, 30 campaigns and 9506 laser scans.

Table 1: The four types of segments defined by the fraction of SW and SS over the previous 100 heats.

|  | Void | SS only | SW only | SW or SS* |
|---|---|---|---|---|
| SW | $\leq 0.2$ | $\leq 0.2$ | $\geq 0.5$ | $\geq 0.5$ |
| SS | $\leq 0.2$ | $\geq 0.5$ | $\leq 0.2$ | $\geq 0.5$ |
| *In the case of the SW or SS segments, either the MA SW or the MA SS must be equal or greater than 0.5 (can be both as well). | | | | |

## Segmentation definition

Segment conditions were chosen to define periods in which the refractory maintenance consisted of only SS, only SW, SW or SS (or both) or nothing (Void). For each converter campaign moving averages were calculated. This resulted in fractions of heats over the preceding 100 heats that had a specific type of refractory maintenance. Generally, there is no refractory maintenance performed during the first 100-200 heats of a campaign. Segment

definitions consist of minimum and maximum value for the fraction of both SS and SW. The segment definitions can be found in table 1. Because the fractions of SS and SW are based on a rolling average of 100 heats prior, the start and end of each segment was shifted 50 heats into the past.

## Linear regression and Mood's median test

After the segments have been determined, the corresponding wear lines are used to determine the average change in minimum residual thickness per heat per segment (slope). These slopes are obtained performing linear regression on the segments with the Scikit-learn module in Python (Pedregosa et al., 2011). A new dataset is formed in which each laser scan in each segment corresponds with a slope. Consequently, each laser scan within a segment will yield the same slope. From the new dataset boxplots are made per segment type per area and Mood's median tests are applied on these sample populations to establish whether the difference is significant. Mood's median tests were performed using the SciPy module in Python, settings were set to default.

## RESULTS

Visualisations of data processing can be seen in figures 2 through 5. Keep in mind that these visualisations are subsets of the complete data set. Figure 2 shows the rolling averages of SS and SW of converter campaign 23Q. It can be seen that periods of SS and SW alternate and near the end of the converter lifetime they were performed both. Figure 3 shows how the data from figure 2 was translated into segment types. It should be noted that undefined data remains between these segments. This data was deemed ambiguous because of lack of strong preference for a specific maintenance strategy and was not used for further analysis.

Table 2 contains the number of segments per segment type and the combined number of datapoints (laser scans) withing these segments per type. It can be seen that the SS only type yields far less segments (9) than for example the SS or SW type (53). It should also be noted that even though the Void type has fewer segments than the SS or SW type (37 and 53 resp.), the total number of datapoints within these segments is more than tripled (4166 and 1162 resp.). Thus, void segments contain more datapoints per segment.

*Fig. 2: Rolling averages for Super Slag Splashing (SS) and Slag Washing (SW) over 100 heats during converter campaign 23Q.*

*Fig. 3: Segment periods based on the rolling averages from fig. 2 for converter campaign 23Q. Note that SS and IS segments types are per definition an IS or SS type segment as well.*

Table 2: Number of segments per segment type and total number of datapoints (laser scans) within these segments.

|          | Void     | SW only  | SS only  | SW or SS  |
|----------|----------|----------|----------|-----------|
| segments | n = 37   | n = 9    | n = 30   | n = 53    |
| datapoints | n = 4166 | n = 170 | n = 732 | n = 1162  |

A visualisation of the minimum residual thickness of a section of the knuckle area for SS segments is shown in figure 4. Although a trend can be seen, it is also apparent that the variability in change between two scans is large. After performing linear regression (fig. 5), only the calculated trend (slope) is left. Note that longer segments tend to have intermediate slopes. Slopes are given in mm change per heat. The more negative the slope, the higher the refractory wear.

*Fig. 4: Super slag splashing streak segments from the Knuckle_SW area. Segments are from multiple campaigns and are presented as change in minimum residual thickness compared to the first scan in the segment.*

*Fig. 5: Super slag splashing streak segments from the Knuckle_SW area. Segments are from multiple campaigns and are presented as calculated minimum residual thickness. Slopes are shown.*

*Fig. 6: Boxplot visualising the distribution of the average calculated wear per segment (slope) per segment type for the Knuckle_SW area.*

Boxplots of the slopes per segment type for the Knuckle_SW area are shown in figure 6. Void segments yield the steepest negative slopes for all areas. In almost all cases either SW only or SS only type segments have the least negative slopes. This can be seen in table 3 as well. Table 3 shows that any type of refractory maintenance results in lower median wear rates compared to no refractory maintenance.

The outcomes of the Mood's median tests for each segment type against the Void segment type for the knuckle areas are presented in Table 4. The results are presented in P-values. The lower the P-value, the higher the chance that the median of the two sample groups differs significantly. It is generally accepted that P-values should be lower than 0.05 to detect a significant difference (this translates to a 95% certainty that the sample groups are different).

Table 3: Medians per segment type per test per area. Results for knuckle areas are shown.

|              | Void  | SS only | SW only | SW or SS |
|--------------|-------|---------|---------|----------|
| Knuckle char | -0.15 | -0.08   | -0.05   | -0.08    |
| Knuckle NE   | -0.14 | -0.12   | -0.09   | -0.10    |
| Knuckle NW   | -0.13 | -0.07   | -0.09   | -0.08    |
| Knuckle tap  | -0.10 | -0.06   | -0.09   | -0.09    |
| Knuckle SE   | -0.14 | -0.10   | -0.11   | -0.11    |
| Knuckle SW   | -0.12 | -0.10   | -0.10   | -0.10    |

Table 4: Results from Mood's median test per area. P-values are given for void segments against maintenance segments. Results for knuckle areas are shown.

|              | SS only  | SW only  | SW or SS  |
|--------------|----------|----------|-----------|
| Knuckle char | 6.25E-20 | 1.00E-43 | 2.58E-50  |
| Knuckle NE   | 4.47E-17 | 1.78E-41 | 3.18E-65  |
| Knuckle NW   | 1.82E-02 | 1.27E-25 | 9.72E-48  |
| Knuckle tap  | 2.88E-04 | 4.73E-03 | 2.23E-14  |

| Knuckle SW   | 4.87E-13 | 1.61E-09 | 6.10E-11  |

**DISCUSSION**

Based on the medians it can be concluded that performing refractory maintenance (either SS or SW) results in lower wear rates (gentler or even positive slopes for the segments). These results can be statistically justified trough Mood's median tests. This is a great improvement compared to previous trials and is the first time that the influence of refractory maintenance on refractory wear is isolated from all other process parameters. Moreover, this approach has a generic set-up and can be applied to future trials consisting of other variables. However, there are some points of attention:

1. The quality of all hypotheses, calculations, models and conclusions are ultimately based on the quality of the data. In the case of refractory wear rates of a converter vessel, it is dependent on the quality of the laser scans. Even if the accuracy of the scan itself is suffucient, the question often remains: 'What is it that we scanned?'. This research aimed to bypass that question by compiling data, using moving averages and looking at larger trends. On the other hand, it cannot be disregarded that these techniques have their own shortcomings and that relations may stay hidden by reducing the variability. Using moving averages poses a challenge in particular. They carry information of multiple datapoints but are presented as a single one. In this research a large window of 100 datapoints was chosen. This enabled segments to yield relatively stable averages during an increased amount of heats. More heats within a segment increases the probability that a segment contains enough laser scans to be approved. But moving averages covering a large window lead to a diminished influence of a single datapoint

660

and its direct neighbours. Consequently, the chances of creating false positives/ negatives increase. Risk of creating false positives/ negatives is highest at the beginning and end of segments. To reduce this risk, the duration of the segments was shifted 50 heats towards the past. In this new definition the moving averages are better aligned with the observed wear. In future studies this could be optimised further.

2. The data is heavily modified to mute the influence of process, outliers and the limitations of laser scanning in general. The dataset on which Mood's median tests were applied consisted of slopes. A single slope was obtained per segment and to keep the original sample size and to account for the length of each segment, this single value was duplicated for each of the datapoints withing the segment. Although this helps transforming seemingly incoherent data into a more robust dataset, it does so by creating many duplicates. Performing any form of statistics on such a dataset poses its own unique challenges. For example: The Mood's median test calculates a grand median between two sample groups. All data is then divided into groups larger and smaller than the grand median. Values that correspond to the grand median are either grouped below or above the grand median. They could also be ignored and discarded. This research used default settings for the Mood's median test from the Python SciPy module which classifies them as below the grand median. However, with the introduction of many duplicates in the dataset this setting has a much greater effect. Simply ignoring this data is not an option either because this implies discarding a large portion of you data which is in agreement with the grand median (up to hundreds of datapoints for Void type segments). Using the right statistics is key for understanding the outcomes of refractory trials, optimising process conditions or performing maintenance. Therefore, optimising and applying the right type of statistics should be a priority for BOS plants.

3. It is assumed that the influence of the process can be disregarded due to the large dataset (assuming occurrence of process conditions and refractory maintenance are independent variables and that the doseffect of process conditions consequently evens out in a large dataset). In reality the relation might be more complicated. Process conditions ultimately all lead to refractory wear. And refractory maintenance, although intended to be done preventively, is often carried out reactively. This cause-and-effect relationship between harsh process conditions and subsequently increased frequency of refractory maintenance in combination with moving averages will influence the outcomes. On top of that, it could also be argued that more refractory maintenance is performed when production pressure is low. Low production pressure could be accompanied by larger temperature fluctuations or specific steel grades. Which in return influence refractory wear as well. When carrying out data analysis, it is important to identify these relations and correct the analysis accordingly.

4. It is assumed that the settings for refractory maintenance were constant throughout the dataset (or were at least randomly distributed). In reality there is a large variety in amount and composition of slag, nitrogen flow, nitrogen flow duration, lance height etc., and they are prone to trends in time. Further research will investigate the influence and significance of these settings.

Despite these opportunities for optimisation and improvement this research demonstrates that structured and statistical assessment of refractory wear of converter linings is possible. Current and future analysis of trials at Tata Steel IJmuiden BOS2 will be performed similarly. It helps to optimise the choices for refractory maintenance. This will help to make the optimum choice between production (yes or no time for maintenance) and life (availability of converters due to relines). A further improvement will be fixed scanners that will be installed at each converter. It will result in more scans and a higher scan accuracy which will be used in the above data analysis for further improvement of the availability of the converters.

## CONCLUSIONS

Through statistics, data processing and analysis on a large dataset it is possible to confirm effectiveness of refractory maintenance in reducing refractory wear of a converter.

Super Slag Splashing (SS) and Slag Washing (SW) are statistically proven effective refractory maintenance techniques that reduce refractory wear and can prolong converter lifetime. Overall SS is effective in reducing median refractory wear. With the more detailed knowledge it is possible to improve the maintenance strategy for the converters in IJmuiden

# INTO THE UNKNOWN: EXPLAINING AND PREDICTING SLAG LINE WEAR BASED ON PROCESS PARAMETERS

Ana Gil, Warbout Tesselaar, Elizabeth Gisolf, Tata Steel, IJmuiden, The Netherlands

**ABSTRACT**
Steel ladles are an essential tool for steel production and are "exposed" to a wide variety of chemical and physical reactions which lead to the wearing of the refractory lining. Thus, being able to predict the effect of operating conditions on wear is critical to ensure high and stable life and, consequently, high ladle availability and minimum refractory cost. Over the past year, wear rate at slag line, as well as transition area between slag line and wall, has become the bottleneck for ladle life. Therefore, understanding, predicting and controlling wear at the slag line has become critical for the ladle life stability and performance. The aim of this project is to create a descriptive model capable to identify the key process variables which affect the wear at slag line level. An advanced analytics approach was followed due to the complexity and sizeable number of process parameters. Prior to diving in, both the target areas and target function (wear rate based on minimum remaining thickness) were defined. Hypotheses generation and prioritization were carried out by a team of experts, followed by identification, transformation, visualization and cleaning of corresponding process variables. The modelling was carried out using a histogram-based gradient boosting regression tree estimator. The results indicate an overfitted model, describing well the training set ($R^2$=0.82) and poorly the test set ($R^2$=-0.1). The accuracy of the inputs for the target function was of concern since a MSA revealed lack of reliability and repeatability on the laser scanning measurement. A descriptive model based on a per-heat-basis is therefore not possible using the currently available data. The inaccuracy of the measurement can, however, be minimized by performing analysis on a per-campaign-basis. An example is the study on increased wear at the transition area between wall and slag line wear linings. The outcome of the study has led to a change in slag line wear lining design which enabled a wear reduction of around 25%, a decrease in frequency of ladles out-of-service at this location and an increase in ladle life of about 2.5 heats.

**INTRODUCTION**
Steel ladles are an essential tool for steel production. Therefore, the security, the availability and the reliability of steel ladles are critical to ensure a safe and smooth operation. During a complete campaign, A-campaign and B-campaign, the ladle is "exposed" to a wide variety of chemical and physical reactions under harsh conditions. In order to withstand the treatments and guarantee a safe working environment, refractory materials are carefully selected for each part of the ladle. Selecting the right refractory, i.e. with adequate chemical and thermo-mechanical properties, for all areas enables a balanced wear and, consequently, the full use of the wear linings.
The steel plant of Tata Steel Ijmuiden has a fleet of 23 steel ladles of which, under normal operating conditions, 12 are in production and 2 in stand-by. When in service, the refractory lining is monitored by performing visual inspections on a heat-basis as well as measuring the remaining thickness by laser scanning in roughly 50% of the heats.

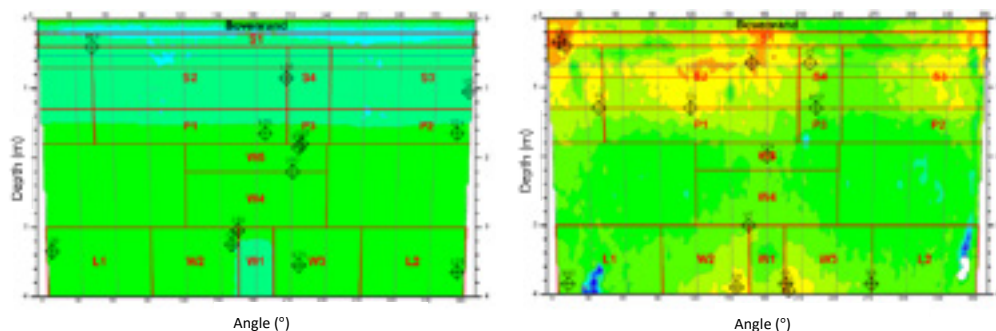

*Fig. 1: Remaining thickness of the refractory lining in mm at beginning and end of campaign, measured by laser scanner. S1 to S4 are slag line subareas.*

The monitoring of the remaining thickness of the wear lining provides insight to the operators so that informed decisions can be made and safe operation can be ensured. Furthermore, the collected data is the basis for a life prediction dashboard used for daily planning. The effect of process conditions is not yet incorporated in the ladle life prediction and, therefore, process variability is not accounted for.
Furthermore, an increase in ladle life requires understanding of wear [1].

**PROBLEM STATEMENT**
The performance of the steel ladle is mainly defined by the worst performing wear lining refractory area. In ideal conditions, the wear lining at all areas wears uniformly and, consequently, end of life can be predicted and planning can be made. However, in the majority of the cases, increased wear at a single location culminates in the relining of the ladle without fully utilizing the complete wear lining.
Over the past years, wear rate at slag line level has become a bottleneck for ladle life as 32% of the ladles are removed from service due to low residual thickness at this location. Moreover, an additional 8% of the ladles show increased wear at the transition area between slag line and wall (barrel).
In addition to the non-optimal ladle life, the variability and unpredictability of wear has led to logistical maintenance challenges and lower ladle availability. Thus, understanding, predicting and controlling wear at the slag line has become critical for the ladle performance, e.g. life and availability.
The first steps of developing a logistic ladle model, able to understand, predict and control wear, have been taken [1]. The end findings and outcomes of part of the project described in this paper will be incorporated into the logistic ladle model as a descriptive model for slag line wear.

**APPROACH**

Over the past decade, the increasing amount of data collected and available in industrial plants has facilitated the transition from an empirical to a data driven problem solving approach. Furthermore, tools such as practical problem solving (PPS), 6-sigma and advanced analytics (AA) have been fomented as the desired approach to find suitable and sustainable solutions promptly.

Even though wear at slag line and wear at the transition area slag line-wall are similar in concept, the complexity of the problems has required different approaches. The high number of process variables potentially affecting the wear at slag line qualifies the investigation for an AA approach, using Microsoft Databricks as a Python programming platform. On the other hand, a simpler and faster methodology could be used for investigating the root cause for increased/variable wear at the transition area, i.e. 6-sigma with support of Minitab software.

**Defining target area**

The first step in the project was to identify the target area(s) within the slag line, i.e. determining the set of coordinates (angle and depth) containing the points with lowest remaining thickness at the end of the campaign. As shown in Fig 2, the location of the thinnest point at end of the campaign is spread over all the slag line subareas (S1, S2, S3 and S4) with occasional overlapping of multiple campaign points. The definition of a single well defined area is not possible based on this information alone. Instead the frequency of campaigns with the thinnest points at a specific set of coordinates (depth and angle) is required and described using a heat map (Fig 3).

*Fig. 2: Location of the minimum remaining thickness at slag line level at the end of campaign (depth is measured from the top of the ladle). One dot represents one or more campaigns.*

*Fig. 3: Number of steel ladles with lowest remaining thickness at end of campaign per set of coordinates. Identification of target areas A1, A2 and A-ring.*

Two critical areas, A1 and A2, and a reference area (A-ring) have been defined. A1 and A2 are small areas containing 27% and 32% of the data set, respectively. A-ring is a reference area containing both A1 and A2 and representing 81% of all campaigns.

**Target Function**

Defining the correct target function is crucial to ensure a successful outcome. Even though the objective of this project has been clearly identified as slag line wear rate, it was still to define if the determination of wear would be based on the minimum or average remaining thickness, and if all laser scans or only data acquired between consecutive heats would be considered. Aiming to select the best option, the distribution of the data was visualized with histograms and boxplots (Fig 4).

Wear rate calculated based on the minimum remaining thickness presents higher intensity distributions as extreme values are more often observed. Furthermore, the box plots suggest a narrower distribution, in particular, to the wear at A2 area. Opting for a determination based on the minimum remaining thickness also prevents averaging of combined effects of build up (skull formation) and wear.

At Tata Steel IJmuiden, steel ladles are used to produce all steel grades at any given time. Thus, a steel ladle undergoes all secondary steel treatments, e.g. stirring station, ladle furnace and RHOB, in a random sequence during its life. As scanning of the remaining refractory thickness is not performed every heat, the target function includes points based on multiple heats that underwent different secondary treatments. In order to include these data points, aggregation of the process data of these heats is needed. Hence, effect of process parameters (treatment dependent) on wear are averaged and relationships can be missed. However, averaging over several heats does enable the reduction of the noise-to-signal ratio.

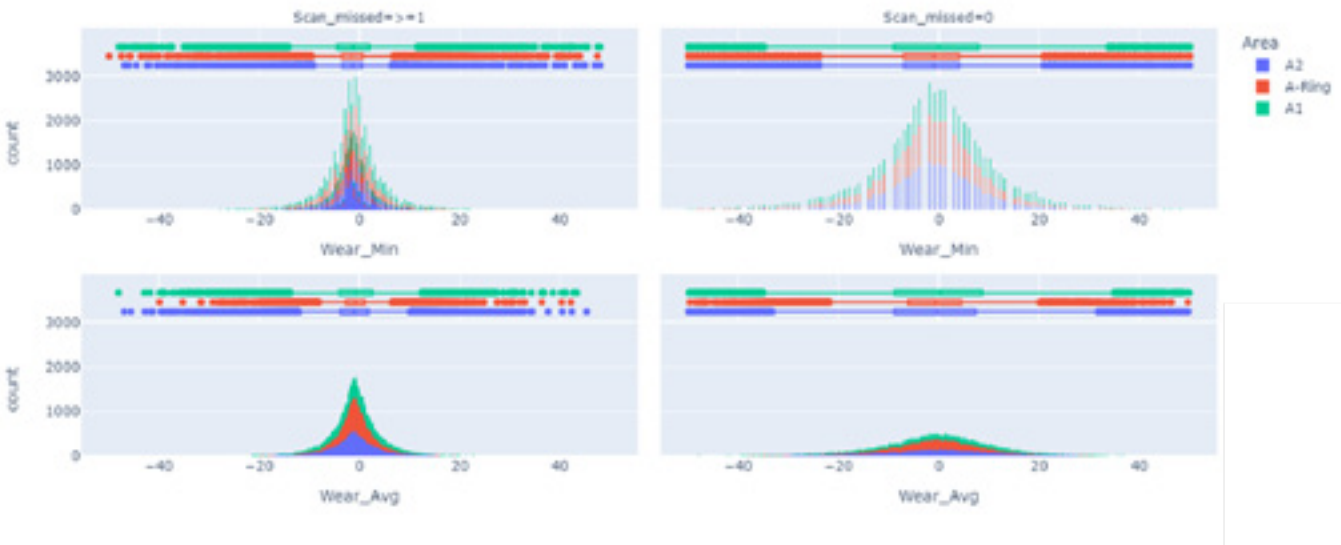
Upon weighing pros and cons, the target function is to be determined based on minimum thickness and only data from consecutive heats is to be included.


*Fig. 4: Distribution of minimum and average wear for consecutive and non-consecutive heats.*

**Selection of process variables**

Identification, collection, determination and cleaning of variables are a fundamental and cyclical process to achieve a suitable descriptive model. In the attempt to identify all potential causes of wear variation at slag line level, the hypotheses, a brain storming session was held with a team of experts from the different departments (i.e. production, maintenance and technical). After listing and prioritizing the hypotheses, the corresponding process variables were identified, collected and visualized. Unfortunately, not all hypotheses could be tested as some process data was not available or could not be extracted.

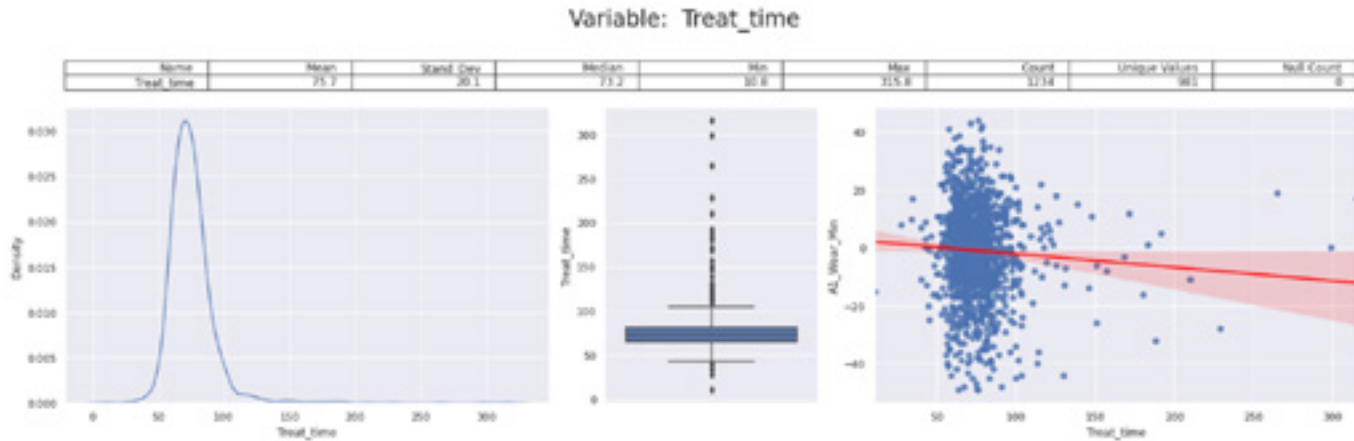
Depending on the type of data, a different set of descriptive statistics (e.g. median, mean, standard deviation, count of nulls, etc.) and graphical representations (e.g. boxplots, time series) were done. The aim was to facilitate the data cleaning by identifying time dependent changes, boundaries and outliers. An example for a numerical variable can be seen in Fig. 5.


*Fig. 5: Example of the descriptive statistics and graphical representations for a numerical variable.*

For some of the proposed hypotheses, none of the process variables were on their own representative of the parameter to test. As a result, synthetic variables were created based on the already cleaned process variables and a similar set of descriptive statistics and graphical representations was made. Furthermore, categorical variables of interest were converted to numerical using OneHotEncoder.

Despite the overlap in general process variables, such as tapping or casting conditions, each secondary treatment installation (ladle furnace, stirring station and RHOB) has a distinctive set of variables reflecting its own operations and parameters. In order to minimize the amount of data lost as well as to ease potential correlations, the data was split per route.

The last step prior to modelling is to eliminate highly correlated variables, which was carried out for each data set using a correlation matrix. Fig. 6 provides an example for the ladle furnace data set.
*Fig. 6: Correlation matrix for a reduced set of variables for ladle furnace route.*

**Modeling**

After the failure of the linear regression and random forest estimator in generating a meaningful model, the histogram-based gradient boosting regression tree estimator was attempted. As shown in Fig 7, the model is overfitted as it describes well the training set ($R^2$=0.82) but poorly the test set ($R^2$=-0.1). Potential causes are: the number variables is high for the data set size, a critical process variable(s) has not been included or wear at slag line is not accurately represented by the target function. As the target function is determined based on the minimum residual thickness measured by laser scanner, the capability of the measuring system must be assessed. A Measurement System Analysis (MSA) was performed, revealing a lack of reliability and repeatability across the different steel ladle areas. As the measurement error can be within the same range as the wear between two consecutive heats, a descriptive model based on a per-heat-basis is not possible.

*Fig. 7: Outcome of the* histogram-based gradient boosting model

The inaccuracy of the measurement can, however, be minimized by performing analysis on a per-campaign-basis. An example is the investigation on increased wear at the transition area between wall and slag line wear linings. Following a similar methodology but a 6-Sigma approach, frequency of ladle furnace heats, stirring efficiency, treatment time and amount of MgO added were identified as root causes for the increase in wear. Based on these findings and aiming to mitigate the effects, the design of the slag line wear lining was adjusted by increasing the height by 10cm. In addition to a reduction in wear of around 25%, the new design reduced significantly the frequency of ladles out-of-service at this location and enabled an increase in ladle life of about 2.5 heats comparing with standard design ladles.

**CONCLUSIONS**

In spite of a suitable working model for slag line wear not being achieved, this study has revealed the challenges of establishing relationships between wear rate and process parameters on a per-heat-basis using the data acquired by a low accuracy laser scanner. That was further supported by the successful outcome, i.e. decrease in wear and increase in life, of the per-campaign-basis analysis performed on the increase wear at the transition area study.

To enable further steps in the development of the logistic ladle model at Tata Steel IJmuiden, a capable laser scanner with high accuracy is required as well as an increase of scanning frequency to a per-heat-basis.

## ABSTRACT

Refractory linings perform an essential role in most of the metallurgical processes, acting as thermal energy barriers and ensuring structural integrity. The refractory selection and lining design must consider the main wear mechanisms, the interaction between the refractory and liquid metals or slags, the costs, and the environmental impacts associated with its production and application. Maintaining the best performance of the materials in use requires good operational practices, the quality of the refractory products during installation, the quality and control of the application practices, and the continuous tracking of each step. In the case of refractory castables, the evaluation of the production and application aspects of the products were carried out by collecting samples during the maintenance/repairing of the linings along the overhaul of an alumina calciner and comparing the fundamental properties of the castables with the standard values previously obtained during the selecting/development steps. The analysis pointed out which were the expected properties of the refractories, and the differences with reference indicators, pointing out potential regions of the calciner that could undergo earlier repair or anticipated failure. The variability of the properties with application features, such as the quantity of water during mixing, time of mixing, temperature, etc, were detected. In conclusion, the study validated and showed the importance of tracking the performance of refractories, fostering the systematization of the methodology for higher productivity and lower costs.

## INTRODUCTION

Refractories play a crucial role in high-temperature processes such as alumina calciners and furnaces. The performance of refractory materials directly affects the efficiency and productivity

*Fig . 1: Main steps for tracking the performance and quality of refractory linings in industrial applications.*

of these processes. Any downtime required for repairing and maintenance of refractories can have a significant financial impact on the overall accounting and management of such operations. Therefore, it is essential to have a reliable method to track the condition of refractories before and during their use and to predict their performance over time.

The difficulty in predicting the actual condition of refractories during operation arises from the harsh environment they are exposed, including extreme temperatures, thermal cycling, chemical reactions, and mechanical stresses. These factors contribute to the gradual degradation of refractory materials, leading to their eventual failure. Traditional approaches to monitoring and tracking refractory condition often rely on visual inspection and empirical decisions, which is subjective and lacks quantitative data.

Usually, the process of guaranteeing the performance of refractory lining in industrial process is based on three steps: those activities that occur prior, during and after the installation [1], specially for the case of castable refractories. The process cycle is summarized in Fig. 1.

### Pre-installation

Pre-installation activities for refractory applications in industrial sites involve analysis of previous failures and meticulous planning. These activities assess the existing condition, determine the causes of failure (i.e., predominantly abrasion or thermal shock for alumina calciners), and select the appropriate refractory materials and installation techniques.

The overhaul team need to prepare a detailed specification, which shall include the several materials and project features of the products to be used, the thicknesses of each region, the methods of application, the use of anchor materials, geometry and welding details, etc. The contractor, companies that deal with the installation of refractories, should provide a comprehensive execution plan in accordance with the industry requirements. It must account for the suitable material storage, possible substitutions and challenges, the procedure for sampling the refractories for material qualification, the time required to finish the work, etc. The refractory manufacturer should delivery the materials properly, on-time, and provide sufficient technical information for analysis of the overhaul team.

### Installation

The process is shutdown during installation and the overhaul execution plan starts. After demolition, the surfaces are prepared for good adhesion and bonding between the substrate and the new refractory material. The substrate surface is typically cleaned by removing any loose debris, dust, or contaminants. It may also involve roughening the surface to enhance the mechanical interlocking between the substrate and the refractory castable. Pre-wetting the substrate with water is often carried out to prevent rapid water absorption from the castable (when this is the case), which can cause

drying shrinkage and result in cracks. It is important to highlight that the water quality plays a fundamental role during the installation of refractory castables. Additionally, formwork or molds may be used to shape the refractory material during installation, especially for complex lining geometries.

Following the surface preparation, the refractory castable or monolithic material is mixed and then applied using various methods such as gunning, casting, or shotcrete. The specific application method depends on factors like the size and shape of the area to be lined, access restrictions, and the desired thickness of the refractory lining. During installation, it is important to achieve proper packing of the material to minimize the presence of voids or air pockets, which can lead to reduced performance and susceptibility to damage. Vibrators or manual tamping may be used to ensure adequate compaction.

The temperature of the water, the environment, the substrate, and the mix are fundamental to guarantee the time and efficiency of the material properties, specially when the lining is curing, during dry out (in case of castables) and heating. Those heat treatment steps shall meet the requirements of the manufacturer and the ones stablished prior to installation. If not carried out adequately, the structural properties can be affected, and the safety and cost efficiency ruined.

**Post-installation**

Monitoring the performance of refractories after installation in industrial processes involves tracking various parameters, including wear of the lining, shell temperatures, spalling occurrence, and process data. These monitoring activities are essential for assessing the condition of the refractory lining, identifying potential issues, and implementing timely maintenance or repair measures.

The wear of the refractory lining is a critical aspect to monitor as it indicates the material's degradation over time. Wear can result from factors such as abrasion, erosion, chemical attack, or thermal cycling. Regular inspections, visual assessments, and measurements of lining thickness are conducted to evaluate the extent of wear and determine if it is within acceptable limits. Monitoring wear allows for proactive planning of maintenance schedules, including repairing or replacing worn sections of the refractory lining before it affects the performance or integrity of the industrial process [1, 2]. Alves et al [3] showed that using ultrasound techniques for evaluation, selection and classification of ceramic anchors applied in reheat furnaces roof and walls allowed the identification of main defects and the thermal shock resistance of the anchors. The decay on the elastic modulus and thermal shock resistance of the anchors enabled the prediction of the lining lifespan, showing the actual performance of the refractory.

Monitoring shell temperatures can be another crucial aspect of refractory performance tracking, for industrial processes that inspection and lining thickness measurement take place only prior to installation or repairing, during an overhaul. Excessive shell temperatures indicate potential failure of refractory material and temperature sensors, or thermal imaging techniques, could be employed to measure and monitor the temperature distribution across the metallic shell. By closely monitoring these temperatures, any anomalies or hotspots can be detected, indicating areas of potential concern. Actions can then be taken to mitigate the effects, such as adjusting operating conditions, optimizing insulation, or implementing localized repairs to prevent further damage.

In the case of alumina calciners each of these steps is adjusted to fit the specific requirements and the downtime for installation takes approximately 14 days or even more. According to Teider et al [4], depending on the calciner's capacity and the economic conditions, this downtime can represent a potential loss of between USD 5–15 million in revenue. The pre-installation step is critical to avoid delays, which would increase the revenue losses. Usually, it can last more than one year of planning, qualification of materials and analyzing historical data, for the overhaul success. The authors also stated the lack of studies relating the in-situ observations, post-mortem analyses and selection based on quantitative requirements, pointing out that the refractory performance could be significantly improved. That would depend on carrying out these main steps in a systematic methodology to produce meaningful information, fostering the performance of refractories and helping high temperature industries optimize the lifespan of their refractory linings, leading to improved thermal efficiency, reduced downtime, and increased overall productivity.

Therefore, this study aims to present a practical method for tracking the refractory performance, showing its use on a real case scenario of an alumina calciner. The method points out the activities from the main three steps that were tracked, the data that was collected and the analyses that were carried out. The comparison of the refractory properties evaluated in two occasions, on the qualification step (pre-installation) and on samples collected during the overhaul (installation), showed a significant discrepancy. This was associated with the selection key indicators, used to identify the differences found, and to the region of the calciner in which the material was applied. Enabling the overhaul team to anticipate actions for preventing further downtime.

**METHODOLOGY**

The main goal of this study was to establish a simple and effective refractory tracking performance methodology specifically tailored for alumina calciners. The methodology encompasses various steps that ease on comprehensive monitoring and evaluation of refractory materials throughout their lifecycle. The key steps involved in the methodology are as follows:

*Material selection (pre-installation)*

The method of material selection involves several steps to ensure the appropriate choice of materials for a specific project or application. The steps involved were:

1. Identification of the main failure mechanism: understanding and evaluating the historical refractory damage/wear and crack's behavior of previous visual inspection reports. These activities drive the material selection to high thermal shock, corrosion, or abrasion resistance materials, to meet the specific requirements that guarantee the process integrity.

2. Evaluation of performance improvements: exploring new refractory technologies for optimizing the refractory lining, as low cost, fast-drying, low energy consumption, or fast-application products.

3. Prospection of suppliers: searching for the available manufacturers and materials that could fulfil the defined refractory requirements.

4. Qualification of material samples: characterization of the product properties to compare the different available refractories, aiming the selection of the most suitable and the acquisition of quality data for further tracking analysis (standard value). In this study, two tests were carried out: one to evaluate the abrasion/erosion resistance (ASTM C704-15 [5]) and other to check the refractoriness under load (DIN 51053 Standard [6]).

5. Overhaul planning definition: purchasing the refractory materials and scheduling the downtime with the contractor, according to regions to be repaired during the overhaul. Herein, three regions of the calciner were analyzed: pre-heater (PF), furnace (FR) and holding vessel (HV).

*Material application (installation)*

During the refractory application a series of steps need to be carefully handled to provide appropriate data for the tracking analysis:

1. Compeling of mixing parameters: acquiring several data from the castable mixing step as the water content, pH and temperature, powder temperature, mix temperature, dry

667

mixing time, wet mixing time, and the room temperature during the installation day.

2. Overhaul sampling during installation: two distinct moments for sampling the material: firstly, as received by the manufacturer (CPR) and, secondly, as prepared for each region of the calciner (CPA). The procedure consisted of gunning or casting the castable in brick-shaped molds to ship it for testing in the laboratory.

3. Overhaul sample qualification: characterization of the overhaul samples properties according to testing during the material selection step.

4. Tracking analysis: comparison of the standard and overhaul samples results to identify material nonconformities and the regions of the calciner that would require careful attention.

*Material inspection (post-installation)*

After starting of the calciner, the steps that follow consist in monitoring the key indicators of the refractory performance, specially for the regions where the overhaul samples showed nonconforming results.

1. Verification of hot spots: periodically monitoring the shell temperatures to identify the regions where the refractory failure might have happened, which would increase the heat transfer from the interior of the calciner to the vessel shell (as the refractory act as an insulator of the process).

2. Visual inspection: analyzing the lining condition during any downtime to check whether the condition of the refractory has changed unexpectedly.

*Tab. 1: Sample labeling for the overhaul, for qualification step and for the technical datasheet to the high-alumina castable in different preparation conditions.*

| Samples | Calciner | Region |
|---------|----------|--------|
| CPA 12 | #2 | Preheater - PF |
| CPA 14 | #2 | Furnace - FR |
| CPA 17 | #2 | Holding Vessel - HV |
| CPR 03 | Prepared by the contractor as received | |
| LAB | Prepared by 4Cast/UFSCar | |
| TDS | Prepared by the supplier | |

In this study, one refractory material was analyzed. It consisted of an alumina low cement castable, which main components were tabular alumina and mullite. The installation method was gunning and the amount of water suggested by the supplier was in the range of 5.8 to 6.6 liters/100kg of dry powder. All the sample labelling is presented in Tab. 1. Four samples were prepared by the contractor on site (CPA 12, 14 and 17, CPR 03), one was prepared by 4Cast (LAB) and one consisted of the properties from the material technical datasheet (TDS).

**RESULTS AND DISCUSSION**

The results of tracking the refractory performance presented in this study yielded the following discussions. First, the increase of the predictability of the material lifespan, optimizing the repair planning and driving special attention to specific regions of the calciner, and second, the identification of the mostly likely cause of deteriorated properties of the refractory.

Based on the previous results, the calciner's regions preheater, furnace and holding vessel had specific areas that required a refractory with a high erosion resistance. Fluidized bed calciners are driven by an air flow of alumina particles that leads to high abrasion on the surface of the refractories. The material selection considered the process conditions of the calciner and the previous inspection data, that had unveiled the scratched surface of the refractory panels. The material selection step considered a gunning application

*Fig . 2: Abrasion/erosion resistance for the different samples.*

method, for shortening the installation time and reducing the overhaul downtime. The requirements of main wear mechanism and installation method were used to search the available materials and suppliers. After lab testing several of them, the best one was selected and it was set as the standard value for tracking analysis. In Fig. 2, the values of the abrasion/erosion resistance of standard sample are shown by the red bars in two firing temperatures 1000 ºC and 1250 ºC.

Also in Fig. 2, the eroded volume of other samples is also presented. The black bars (TDS) are the technical datasheet values and the colored ones are the values for the samples prepared on site. The overhaul samples were taken for each of the repaired regions, defined during planning. They were prepared by the contractor and shipped for lab analysis. One can note that all the samples diverged from the standard one. In special, sample CPA 17 that showed a high eroded volume, almost ten times higher than the standard value. The CPA 17 was sampled during installation of the material in the holding vessel. Due to the low erosion resistance, it could be expected that that region would certainly require a repair and a special monitoring during operation. Knowing in advance which region would demand a specific action, save time and material waste during the overhaul.

Although CPA 17 showed the lowest erosion resistance, CPA 12 and 14 had similar analysis and probably would have its lining lifespan reduced. The sample prepared as received by the refractory manufacturer, CPR 03, showed similar erosion resistance as the technical datasheet, but still higher eroded volume than the standard one.

*Fig . 3: Refractoriness under load for the different samples.*

In Fig. 3, the refractoriness under load of the samples were investigated. Note that the softening temperature, $T_{soft}$, for the overhaul samples were approximately 150 ºC lower than the standard one. In the case of some uncontrolled operational time that increases the average operational temperature of the firing zones (usually around 950 ºC), the refractory could already undergo critical deformation, as it is usually recommended to operate at temperatures below $T_{soft}$ and maximum at $T_{0.5}$ (also presented in Fig. 3). If that is the case, the material could melt, decreasing its thickness and lifespan. Again, acknowledging this information right after the installation drove attention to monitor this regions and better planning of the overhaul. Note that both erosion resistance and refractoriness of the CPA samples were downgraded compared to the standard properties.
*Fig . 4: a) Water content of the overhaul samples compared to the recommended in the technical datasheet (TDS). b) Overhaul sample as received for properties characterization highlighting a macro crack in the refractory block.*

The amount of water of the samples were compared with the amount suggested by the manufacturer to find one explanation for the results. Fig. 4 a) showed that all the samples were out of the range specified. The one prepared as received required or used less water than the specification and the ones prepared during installation required higher amount. The increase of water content from 1 to 2 % higher than the specified can significantly affect the properties of the refractories after firing. Higher porosity leads to lower elastic modulus and, consequently, decrease the erosion resistance and refractoriness under load of the material. That could explain why the qualification of the overhaul samples was downgraded as shown. The quality of the bricks when received for analysis in the laboratory already contained some macro cracks due to the shaping process, as can be observed in Fig. 4 b). However, note that sample CPR 03 that used less water than the suggested by the supplier had a similar erosion resistance as the technical datasheet. It was clear that during application of the high alumina castable some irregularities appeared and that revealed that the material in use had completely different properties than the one made in the laboratory. The qualification of the material diverged from its desired performance due to application issues.

Tracking the performance of the refractories by analyzing key parameters helped to predict the lining lifespan after the overhaul. The post-installation step consisted of monitoring and doing visual inspections when available. During the analysis of the shell temperatures, it was identified a hotspot at the holding vessel region that needed repairing. Due to other problem with the calciner that resulted in shutdown, the contractors were able to repair the region while the problem was being fixed. This shows the potential of the methodology to provide data for better decision making concerning the lifecycle of the refractory lining.

Running the same methodology to all calciner regions and materials for an overhaul requires effortful work and produces a lot of data. It is important to have well-qualified people collaborating in all steps, to ensure the best tracking analysis, and to have a system and method to process all the information rapidly. Nowadays, there is a lot of opportunity for digital solutions for helping the refractory end-users and manufacturers along the tracking of the refractory performance, by using cameras, lasers and sensors, software and modules, machine learning and modeling, etc. It a step to meet on-going desires of modern refractory industrial practices.

**CONCLUSIONS**

The establishment of a simple refractory performance tracking methodology for alumina calciners, furnaces, and other high temperature processes is essential for effective maintenance and improved operational efficiency. The proposed methodology encompasses various stages, including planning, sample collection, material analysis, and data analysis. Implementing this methodology enables better monitoring of the refractory condition and decision-making regarding repairing.

The results obtained through the methodology highlighted the importance of considering factors such as water content, the erosion resistance and refractoriness, in selecting and evaluating the refractory performance. The information gathered through the methodology facilitates the repair planning and optimization of maintenance strategies, reducing the time and mostly the cost involved in an overhaul.

Ultimately, this study showed that tracking the refractory performance development to application can improve reliability, reduce downtime, and enhance financial indicators. Further research and implementation of this methodology across various regions and installation can contribute to advancements in refractory performance and maintenance practices, including better digitalization throughout the steps.

**ABSTRACT**

MgO-C refractories are zonally installed in the heating units of steel and iron production. In these conditions, refractory materials are exposed to multiple corrosive factors. The interaction with aggressive liquid slags of variable basicity is one of the main factors which determine the wear rate of MgO-C refractories. In this work, we show the unusual attempt for selecting the MgO-C refractories of various properties, but comparable corrosion resistance to specific conditions. The designed and industrially produced MgO-C products were characterized by different ratios of the sintered to fused magnesia raw materials and variable forming pressure. 20 laboratory corrosion tests were conducted in an induction furnace. Then, corrosion resistance of MgO-C refractories was assessed using Self Organizing Maps (SOM). The input variables in the used algorithm were: apparent porosity of materials before and after coking, decarburization rate of MgO-C materials after tests at 900°C and 1100°C, chemical composition of designed materials, temperature of the corrosion test and slag basicity. Physicochemical properties of MgO-C materials and their wear rates were used to classify the materials of different starting composition into groups of comparable corrosion resistance.

## 1. INTRODUCTION

MgO-C refractories are used as linings of heating devices in steel and iron metallurgy processes. Manufacturers and end-users of refractories must provide safe and the longest possible operation of refractories in exploitation conditions. The operation time of heating devices is determined by the intensity of the corrosive wear rate of refractories and ranges in steel convertors approximately from to ….. The most critical corrosive factors for MgO-C refractories are the decarburization of the material's hot face, associated with the oxidation of carbon contained in MgO-C materials and slag corrosion [1]. The decarburized hot face of MgO-C material is loose, and porous, thus, exposed to liquid flow and erosion. For this reason, slag may infiltrate easily into the matrix, thus, promoting corrosion.

Several studies describe the corrosion mechanism of MgO-C refractories by a liquid slag [2]-[8]. In the context of corrosion resistance, the authors mainly underline the importance of raw materials' chemical purity ($CaO/SiO_2$ ratio, concentration of selected impurities $Fe_2O_3$, $Al_2O_3$, $B_2O_3$), size of MgO crystals and quality of graphite used for MgO-C bricks production.

Scarce information can be found in literature concerning the impact of fused/sintered MgO (primary raw material in MgO-C production) on the corrosion resistance of MgO-C bricks. Lao *et al.* [9] conducted a comparative study of the wetting and corrosion behaviour of fused magnesia and microporous magnesia aggregates by molten slags of different $CaO/SiO_2$. Benavidez *et al.* [10] compared the corrosion resistance of three commercial bricks composed of fused magnesia, fused and sintered magnesia, and only sintered magnesia in the composition, describing its wear mechanism.

Currently, statistical tools and machine learning (ML) techniques becomes more widely applied in the field of refractory materials. The application of selected ML-supervised techniques was reported to effectively predict the wear rate of refractories installed in heating devices [11]-[14]. ML-unsupervised techniques are also applied, e.g., for extraction the comparable groups of data in large data sets [15].

ML algorithms are expected to allow engineers to select materials with an optimized cost-to-quality ratio by substituting fused raw materials with sintered ones. Therefore, the aim of this work was the application of ML-unsupervised algorithm to identify the groups of refractory materials of comparable corrosion resistance among 10 variants of MgO-C refractories composed of different ratios of fused/sintered magnesia raw materials.

## 2. MATERIALS AND METHODS

### 2.1. Materials

MgO-C materials were industrially produced based on ten different formulations (designated as 1-10) and using different ratios of fused-to-sintered magnesia raw materials, as presented in Tab. 1. The grain composition of mixtures was designed with the use of the Dinger–Funk model using a distribution coefficient $q$=0.37. Bricks were shaped with the use of hydraulic pressing machines to obtain the rectangular shapes (400x150x100 mm), and applying two different final shaping pressures of 120 MPa and 180 MPa. Finally, twenty variants of MgO-C materials were obtained (ten formulations and two values of final shaping pressure applied), with 8 bricks for each variant which gives 160 bricks produced in total. After shaping, bricks were tempered for 36 h at 180°C. The following magnesia raw materials were used in starting composition: fused magnesia FMI (MgO min. 97.5 wt. %, $Al_2O_3$ 0.1 %, $Fe_2O_3$ 0.1%, $CaO/SiO_2$ min. 3.5), fused magnesia FMII (MgO 97.0 wt. %, $Al_2O_3$ 0.3 %, $Fe_2O_3$ 0.8 %, $CaO/SiO_2$ min. 2.0), sintered magnesia SMI (MgO 94.0 %, $Al_2O_3$ 0.6 %, $Fe_2O_3$ 2.9 %, $CaO/SiO_2$ min. 0.4), sintered magnesia SMII (MgO 98.0 %, $Al_2O_3$ 0.12 %, $Fe_2O_3$ 0.5 %, $CaO/SiO_2$ min. 3.0) and sintered magnesia SMIII (MgO 97.0 wt. %, $Al_2O_3$ 0.2 %, $Fe_2O_3$ 0.85 %, $CaO/SiO_2$ min. 1.8). FMI, FMII, SMI and SMII were used in different proportions in compositions while SMIII was fixed at constant amount of 12 wt. %. Flake graphite constituted 10 wt. % for all compositions. Phenol-formaldehyde resin was used as a binder in each formulation (liquid - 2 wt. %, powder - 1 wt.%).

Table 1. Composition of designed MgO-C refractory materials, wt. %.

| Formulation | FMI | FMII | SMI | SMII |
|---|---|---|---|---|
| 1 | 77.00 | - | - | - |
| 2 | - | 77.00 | - | - |

### 2.2. Methods

#### 2.2.1 Physicochemical properties

Apparent porosity (*AP*) and bulk density (*BD*) of specimens were measured acc. to standard PN-EN 993:1, apparent porosity ($AP_k$) and bulk density ($BD_k$) after coking acc. to PN-ISO10059/PN-EN 993:3. Decarburization tests at 900°C ($u_1$) and 1100°C ($u_2$) were conducted separately. The heating rate was 50°C/h to achieve the assumed temperature in both decarburization tests. The dwell time in maximum temperature in both tests was 3 h. The average $O_2$ concentration in a chamber during a decarburization test at 900°C was 15.37 % (standard deviation of 0.75 %) and 16.12 % (standard deviation of 0.93 %) at 1100°C. Decarburization rate (*u*) was

estimated with the use of Eq. 1, where $D$ is the initial diameter of the cylindrical specimen (before heat treatment), while $d$ is an average of four diameters of the unreacted core (after heat treatment).

$$u = \left[1 - \left(\frac{d}{D}\right)^2\right] \cdot 100\% \qquad (1)$$

### 2.2.1. Corrosion tests

Corrosion tests of produced MgO-C refractory materials were conducted in a medium-frequency induction furnace. The furnace chamber was covered with a steel lid at the top. The non-alloy structural steel S235JR (PN-EN 10025-2:2007) was used as a source of liquid melt during the test. After achieving the assumed temperature of the liquid melt (1650°C/1720°C, depending on test number), the synthetic slag was added at the top of the liquid melt. The temperature of a liquid was measured during the test with the use of thermocouples immersed directly in the melt. The crucible made of prepared refractory shapes was shown in Fig. 1a, and the induction furnace during operation in Fig. 1b.

*Fig. 1 a. Refractory crucible after installation in an induction furnace, b. corrosion test with slag at the top.*

Overall, 160 shapes were selected for corrosion tests out of all 20 variants of produced MgO-C refractory materials (8 shapes for every variant). Corrosion tests were conducted in 4 Blocks, namely, Block I: slag with CaO/SiO₂ of 0.8 and temperature 1650°C; Block II: slag with CaO/SiO₂ of 0.8 and temperature 1720°C; Block III: slag with CaO/SiO₂ of 1.6 and temperature 1650°C; Block IV: slag with CaO/SiO₂ of 1.6 and temperature 1720°C. In each test block, 9 shapes were installed in a furnace: 8 shapes for measuring the wear rate, and 1 shape at the casting side, which was not taken into consideration. The wear rate ($w$) of tested materials was determined acc. to Eq. 2:

$$w = \frac{S_c}{S_i} \cdot 100\% \qquad (2)$$

where $S_i$ is the initial cross-section surface of the test material, and $S_c$ is the corroded surface of the test material, as demonstrated in Fig. 2.

*Fig. 2. Cross section of MgO-C refractory shape after a corrosion test in an induction furnace.*

The results of the wear rate measurements were normalized to obtain values in the range of 0 to 1, where 0 means the lowest wear rate and 1 is the highest wear rate.

### 2.2.2. Analysis after corrosion tests

After corrosion in the induction furnace, statistical analysis and machine learning evaluation were conducted for tested materials. The analysis was developed with the use of the "R" programming language. Assessment of differences in obtained values of properties between tested materials was performed by the Kruskal-Wallis test and 'kruskal.test()' function. For determining the normality of data distribution 'shapiro.test()' function was used. All mentioned functions are assigned to the library *stats*. Self Organizing Maps (SOM) algorithm was applied, with the use of 'som()' function assigned to the *kohonen* library, to find the groups of materials of comparable corrosion resistance. The quality of clustering was assessed with the use of 'somQuality()' function from the *awSOM* library.

## 3. RESULTS AND DISCUSSION

### 3.1. Chemical composition of produced MgO-C refractories

Chemical analysis of produced refractories was presented in Tab. 2. The main differences between formulations refer to the CaO/SiO₂ ratio of the magnesia part. The highest CaO/SiO₂ was registered for formulation 1 of 2.28, while the lowest for formulation 10 of 0.40. Significant differences were also detected in the amounts of impurities in produced materials, including Fe₂O₃ and Mn₃O₄ which affects the high-temperature performance.

Table 2. Chemical characteristics of MgO-C refractory materials wt. %.

| Formulation | MgO | Al₂O₃ | SiO₂ | CaO | Mn₃O₄ | Fe₂O₃ | CaO/SiO₂ * |
|---|---|---|---|---|---|---|---|
| 1 | 96.73 | 0.40 | 0.74 | 1.69 | 0.09 | 0.29 | 2.28 |
| 2 | 96.46 | 0.41 | 0.81 | 1.45 | 0.04 | 0.71 | 1.79 |
| 3 | 97.07 | 0.30 | 0.68 | 1.40 | 0.09 | 0.39 | 2.06 |
| 4 | 96.81 | 0.35 | 0.74 | 1.19 | 0.10 | 0.74 | 1.61 |
| 5 | 97.34 | 0.30 | 0.57 | 1.11 | 0.08 | 0.54 | 1.95 |
| 6 | 96.64 | 0.43 | 0.72 | 0.98 | 0.24 | 0.93 | 1.36 |

| 9 | 94.84 | 0.49 | 1.43 | 0.75 | 0.70 | 1.71 | 0.52 |
| 10 | 94.15 | 0.74 | 1.60 | 0.64 | 0.77 | 2.00 | 0.40 |

*in the magnesia part of the starting composition (refers to raw materials in Tab. 1).

### 3.2. Physical properties

Alternations in the physical properties of MgO-C refractory materials were presented in Fig. 3 – Fig. 6. For shaping pressure of 120 MPa, apparent porosity ($AP$) of produced MgO-C refractories varied from 4.20 % to 13.80 %, while for 180 MPa it ranged from 2.30 % to 12.40 % (Fig. 3). Comparable trend in apparent porosity was registered after coking ($AP_k$) where results varied from 8.50 % to 17.90 % (120 MPa) and 7.40 % to 15.70 % (180 MPa) (Fig. 4). Decarburization rate at 900ºC ($u_1$) ranged from 54.95 % to 87.02 % (120 MPa) and 49.79 % to 85.73 % (180 MPa) (Fig. 5). Decarburization rate at 1100ºC ($u_2$) was higher for 120 MPa shaping pressure of 64.08 % to 91.88 %, and lower for 180 MPa of 59.90 % to 87.5% (Fig. 6).

*Fig. 3 Apparent porosity of MgO-C materials.*

*Fig. 4 Apparent porosity after coking of MgO-C materials.*

*Fig. 5 Decarburization rate at 900℃ of MgO-C materials.*

*Fig. 6 Decarburization rate at 1100℃ of MgO-C materials.*

### 3.3. Wear rate

Results of the wear rate of MgO-C materials were presented in Fig. 7. Wear rate was found to depend on the temperature of the corrosion test and CaO/SiO$_2$ ratio in slag. 7-10 formulations-based materials containing sintered magnesia SMI (MgO 94.0 %, CaO/SiO$_2$ min. 0.4) exhibited the lowest corrosion resistance. 3-6 formulations-based refractories were reported to possess comparable corrosion resistance.

*Fig. 7 Wear rate of MgO-C materials.*

Application of Shapiro-Wilk statistics showed that measured temperatures during the corrosion test as well as the wear rates are not normally distributed. For this reason, Kruskal-Wallis test was applied to reveal if the wear rate is significantly influenced by temperature. Moreover, it was checked if the CaO/SiO$_2$ in the used slag influences the measured wear rates. For the measured temperatures during corrosion, Kruskal-Wallis statistics showed *chi-squared* of 50.41 and *p-value* of $6.534 \cdot 10^{-5}$, while for the CaO/SiO$_2$ ratio in slag *chi-squared* equalled 103.6 with *p-value* of $1.487 \cdot 10^{-13}$. These results clearly indicate that, wear rates are significantly differentiated by both temperature and CaO/SiO$_2$ ratio in slag.

### 3.4. Self-Organizing Maps

For the application of the SOM algorithm, the following properties of designed MgO-C bricks were used: apparent porosity (*AP*); apparent porosity after coking (*AP$_k$*); CaO/SiO$_2$ ratio (*CS*) and MgO content (*MgO*) of magnesia part in starting composition; decarburization rate at 900°C (*u$_1$*); decarburization rate at 1100°C (*u$_2$*) and wear rate after corrosion test (*w*). All initial data were normalized to obtain values in the range of 0 - 1. The analysis was divided into 4 groups, according to the corrosion tests blocks (1650°C and 1720°C, and 2 slags of different basicity, refer to *2.2.1*).

The analysis aimed to identify the groups of refractory materials of comparable corrosion resistance among 10 variants of produced MgO-C refractories composed of different ratios of fused/sintered raw materials.

SOM maps for the corrosion tests were presented in Fig. 8 (Block I), Fig. 9 (Block II), Fig. 10 (Block III) and Fig. 11 (Block IV). The codes plot on the left side of each figure corresponds to values of selected properties (the larger the quarter the greater the value of the property), and the wear rate map on the right side of each figure corresponds to the average wear rate assigned to each cluster, containing specific MgO-C variant of materials. For the map with the wear rate, the deepest-red colour refers to the clusters containing materials with the lowest wear rate, while the lightest-yellow clusters correspond to the materials with the highest values of the wear rate. Tab. 3 lists the materials assigned to the clusters in each of the maps. Materials located in the same cluster are considered materials of comparable corrosion resistance.

*Fig. 8 SOM maps for corrosion results in Block I.*

*Fig. 9 SOM maps for results of corrosion test in Block II.*

*Fig. 10. SOM Maps for results of corrosion test in Block III.*

*Fig. 11. SOM maps for results of corrosion test in Block IV.*

After the results in Tab. 3, we can conclude that it is possible to substitute fused magnesia with sintered one in MgO-C materials with no loss of corrosion resistance. For example in tests of Block I, cluster 3 contains formulation 2 and 4-based MgO-C materials, shaped at 180 MPa. According to the composition of starting mixture Tab. 2, formulation 2-based material contains 77 % of fused magnesia (FMII) while and formulation 4-based material contains 50 % of fused magnesia (FMII) and 27 % of sintered magnesia (SMII). Such interchangeability of raw materials would be economically beneficial for both manufacturers of refractory and end-user as well as would contribute to a more sustainable utilization of currently strategic raw materials.

Table 3. MgO-C materials assigned to clusters of comparable wear rates.

| Cluster | Block I | Block II | Block III | Block IV |
|---|---|---|---|---|

Block I-IV (refers to the corrosion test described in 2.2.1)

## 4. CONCLUSIONS

- 20 variants of MgO-C refractory materials were designed and industrially produced, based on different contributions of sintered and fused magnesia raw materials in a starting composition.
- After conducting 20 corrosion tests, high differentiation in the wear rate of materials was observed which was subsequently assessed with the aid of machine learning tools.
- The application of Self-Organizing Maps algorithm enabled classifying the materials (containing different amounts of fused and sintered magnesia) of comparable corrosion resistance
- It is recommended to always check the algorithm's results and compare them to the expert knowledge and experience.

## ABSTRACT

Masonry refractory linings are commonly employed in industrial vessels to protect against extreme working environments. Mortarless refractory masonry is frequently used in the working lining of steel ladles to contain the molten steel and limit heat losses. During operation, such masonry lining undergoes high thermo-mechanical loads, primarily due to the complex thermal and mechanical boundary conditions. Therefore, large-scale experiments are required to characterise the behaviour of such structures, leading up to their optimisation. This work presents a novel approach for the experimental characterisation of refractory linings using a laboratory-scaled pilot steel ladle. This 3D pilot model is a scaled representation of a ladle that includes all the linings as an industrial ladle. The pilot ladle was tested under transient thermal loads, and its behaviour was assessed through thermocouples, strain gauges and DIC (digital image correlation). The experimental observations describe a complex and nonlinear global behaviour of the pilot ladle due to thermal gradient, creep of the refractories and damage. Finally, the results obtained from these experiments were used to validate numerical models using a 3D meso-modelling approach. The numerical simulations revealed a good agreement with the experimental outcome that can further be employed to investigate and design an industrial steel ladle.

## 1. INTRODUCTION

Steel ladles play a crucial role in the steelmaking industry. They are employed as industrial vessels to transport and refine molten steel and are exposed to a harsh operating environment. Normal operating conditions of these vessels include high temperatures, high thermal stresses, slag attack, and degradation of layers in contact with molten steel [1]. Steel ladles are often built with multiple layers of refractory masonry linings enclosed within a thick steel shell to withstand extreme operating conditions. Each layer comprises refractory materials with different thermal, mechanical, and chemical properties. The selection of refractory materials for these layers depends on their designed purpose, such as thermomechanical behaviour, thermal insulation, and chemical stability. Therefore, knowledge of the thermal, mechanical, and chemical behaviour of the refractories becomes essential to optimise their consumption in extreme working environments.

The working lining of a steel ladle is usually constructed with mortarless masonry. The joints of such masonry provide a physical break in continuous media, which can reduce the stress build-up. These dry joints show a high nonlinear behaviour affected by material type, contact area distribution, and the spatial and size distributions of the asperities on the surfaces [2]. Therefore, large-scale experimental campaigns are required to evaluate the global behaviour of refractory masonry under varying thermal and mechanical boundary conditions. These campaigns also validate the material properties derived from experiments at material levels, noting that limited work is available in the literature regarding the large-scale experimental evaluation of such masonry.

Oliveira et al. [3] experimentally investigated the mechanical behaviour of mortarless refractory masonry under uniaxial compression with various loading conditions at ambient and high temperatures (900°C). Their work highlights the heterogeneity in mortarless refractory due to dry joints and its influence on thermomechanical behaviour, which is widely used in steel ladles. Further, Ali et al. [4] evaluated the mechanical behaviour of the mortarless refractory masonry in a biaxial press under various loading and boundary conditions at ambient and high temperatures (1500°C). They observed permanent deformation of bricks due to viscoplastic behaviour. This experimental campaign shows the presence of viscoplasticity in alumina spinel bricks at high temperatures and its impact on refractory masonry under different loading conditions. Gasser and Poirier [5] investigated the thermomechanical behaviour of mortarless refractory masonry in a laboratory pilot that resembles a steel ladle. The test was conducted with only one layer of refractory lining and was performed under transient thermal loading with a maximum temperature of 1000°C. They observed that the elastic strains observed from the steel shell reveal the thermomechanical behaviour of the refractory lining. The behaviour of the lining was influenced by the dry joints present and the contact between the bricks and steel shell.

Finite element models are often used to investigate or design industrial installations such as steel ladles with different linings of refractory masonry. The data obtained through experimental campaigns are used to calibrate models with varying degrees of complexity from linear thermo-elastic to more complex models, including viscoplasticity and damage [1,6,7]. However, the behaviour obtained through such models for a steel ladle is not validated due to a lack of experimental investigations. Therefore, experimental work must be carried out to validate numerical models on an assembly representing an industrial ladle subjected to a thermal loading similar to normal operating conditions (around 1500°C).

This work presents a novel experimental setup for large-scale refractory masonry to characterise a pilot steel ladle that undergoes similar thermomechanical loadings as an industrial ladle to gather data to validate numerical models.

## 2. DEVELOPMENT OF THE PILOT LADLE

The scale of the pilot ladle should be such that it is small enough to be handled at the laboratory level and big enough to represent the global behaviour of an industrial ladle. The other difficulties involved with the scale are the thickness of the steel shell and the size and shape of the refractory bricks. To tackle these challenges, preliminary numerical investigations were developed, assisting with the design and, ultimately, contributing to the choices made regarding the installation itself. From the design optimisation process, only the barrel part of the ladle with 1500 mm diameter and 500 mm in height was made, as shown in Fig. 1. This configuration contains all refractory linings with identical lining thickness as in industrial ladle enclosed within a 6 mm thick steel shell.

*Fig. 1: Graphical illustration of the pilot steel ladle showing pilot ladle, refractory linings, and top and bottom insulation.*

The working lining is made of mortarless masonry with alumina spinel bricks, providing good thermal, chemical and mechanical stability at high temperatures. The safety lining is constructed with bauxite brick, offering better thermal insulation than working linings with good mechanical behaviour. Insulation lining is used to reduce the heat losses in the ladle. The material used in this lining is aluminium silicate which has low thermal conductivity. The insulation board is an additional lining component to further reduce

heat losses. This microporous material offers excellent thermal properties while it is highly compressible.

For the measurement of thermal fields, thermocouples were used. An assembly of thermocouple placement was installed at three different locations and layers of the pilot ladle (spaced at about 120° in the plan view), as shown in Fig. 2 (total of 18 thermocouples). Six type K thermocouples were installed in different refractory linings at one location. One type S thermocouple was placed near the innermost part of the working lining. Additional thermocouples were placed inside the bottom insulation layers to monitor the heat losses.

*Fig. 2: Placement of thermocouples to measure thermal fields.*

DIC was employed to monitor displacement and strains in the working lining through a cut window in the top lid and on the exterior section of a steel shell. Additionally, three high-temperature spot welding foil strain gauges from Kyowa (self-temperature compensating) were placed on the structure's cold face, close to the thermocouples shown in Fig. 2.

## 3. EXPERIMENTAL RESULTS

Fig. 3 shows the final experimental setup of the pilot steel ladle with all components and measurement devices. Two tests were performed on a pilot with new working linings (NWL) by applying thermal load through 18 heating elements. Once the target temperature was achieved, an eight-hour dwell time was used for all the tests. The test specimen NWL-01 was tested till 1250°C to check the structural safety of the pilot ladle, while the other test reached 1400°C. This experimental device was constructed and tested at the Ceramics Research Centre (CRC) of Tata Steel in Ijmuiden, Netherlands.

*Fig. 3: Experimental setup of the pilot ladle.*

Fig. 4 shows the average temperature evolution observed in the installed thermocouples at various heights. At the beginning of the thermal loading through heating elements, the whole assembly of the pilot ladle was at room temperature of around 16°C. The thermal loading was applied at a rate of 4°C/minute. It is possible to notice that the applied rate of thermal loading was sustained till 500°C of the furnace temperature. Afterwards, the rate of loading decreased due to increased power requirement. However, at the 20th hour, the furnace temperature reached 1250°C for both tests. For the test specimen NWL-01, the applied temperature was kept constant for the next eight hours, and for the other test specimen, the applied

temperature was increased to 1400°C. Once the 1400°C desired temperature was achieved at the 36th hour, the same was kept constant for the next eight hours.

For both specimens, temperature evolution observed in the linings is very similar. Moreover, irregular temperature evolution can be observed at the different linings at 100°C, which can be attributed to the evaporation of free water. The temperature evolution and distribution in the ladle linings exhibit the expected thermal behaviour of a steel ladle. Temperature measurement data provides insight into the behaviour of different layers in the lining when applying thermal loads. Considering the selection of materials used in the linings and their different thermal properties, a complex temperature distribution from the hot face to the exterior of the steel shell can be observed.

*Fig. 4: Average temperature evolution observed during experiments.*

As mentioned, the working lining is built with dry joints. Therefore, measurements were taken before and after the experiments on both specimens to observe the change in the joint thickness. Tab. 1 presents the measurements taken for the head joint at the hot face. The influence of the dry joint on the global behaviour can be observed through the strain gauges installed on the outer steel shell.

*Tab. 1:Change in the thickness of head joints.*

|  | NWL-01 | | NWL-02 | |
|---|---|---|---|---|
|  | Before | After | Before | After |
| Mean joint thickness (mm) | 0.32 | 0.40 | 0.23 | 0.47 |
| Standard deviation (mm) | 0.30 | 0.26 | 0.27 | 0.31 |
| Largest joint (mm) | 1.68 | 1.46 | 1.77 | 1.25 |

The performance of the steel shell is a critical issue in the behaviour of the refractory linings subjected to thermal loads. Fig. 5 shows the average mechanical strain observed in the circumferential direction through strain gauges on the exterior surface of the steel shell. The strain evolution confirms a highly nonlinear behaviour during thermal loading. During the early stage of the test, a slight increase in the strain can be observed. This increase can be attributed to the closing of the head joints in the working lining as well as the closing of the gap between the linings. Once these joints are closed, a steady growth in the strain can be observed till about the 20th hour. The effect of the joint thickness can also be noticed from the maximum strain observed. NWL-02 exhibits stiffer behaviour compared to NWL-01. This difference was expected as the average head joint thickness in the working lining is smaller for NWL-02 (0.23 mm) compared to NWL-01 (0.32 mm). After the 20th hour, strain reduction can be observed till the end of the test. In NWL-01, the maximum applied temperature was lower (1250°C) than NWL-02 (1400°C). Therefore, during the dwelling period for NWL-01, no significant drop in strain was observed. However, for NWL-02, despite a rise in applied temperature after the 20th hour (consequently an increase in thermal expansion), a gradual reduction in the strain was observed (from 0.57 to 0.48 mm/m). This reduction is due to the viscoplastic behaviour of the alumina spinel bricks in the working lining that becomes prominent after 1200°C.
*Fig. 5: Average circumferential strain evolution.*

DIC analysis measures the total strain on an inspected surface. Under thermomechanical loading, the total strain comprises of elastic, thermal and inelastic strain. Fig. 6 shows the evolution of circumferential strain observed from DIC analysis on the steel shell. The figure also shows the expected thermal strain due to temperature rise in the steel shell and total strain (calculated thermal strain plus measured average strain from strain gauge). The total strain observed from the DIC shows similar behaviour as the calculated strain. The differences observed between the observed and calculated strain may be partly due to the hot air draft that affects the image captured by the camera, particularly when DIC values are lower.

*Fig. 6: Circumferential strain evaluation at 250mm height of the shell and strain distribution at the 44th hour.*

Fig. 7 shows the evolution of the strains in the circumferential direction, measured at 25 mm and 130 mm from the hot face of the working lining brick. The values presented are the average strains observed from virtual extensometers at both bricks. The strain evolution shows an increase in strain at both locations as the temperature increases due to thermal expansion. The strain level observed at 25mm from HF is low compared to the expected 12 mm/m thermal strain. The difference is due to the combination of thermal expansion, onset of viscoplasticity and joint closing. However, the strain observed at 130 mm from HF is comparable with the thermal strain due to expansion at that location, 8.8 mm/m expected vs 7 mm/mm measured. This lower difference suggests less relevance of joint closing and no viscoplasticity at that location.

*Fig. 7: Circumferential strain evaluation at 25mm and 130mm from the hot face and displacement distribution at the 44th hour.*

## 4. VALIDATION OF NUMERICAL MODEL

Finite element models are often used to design or analyse steel ladles. Meso and macro modelling approaches are often used for this purpose. This work employed the meso modelling approach, where units (bricks) and joints are modelled separately. The model was made by taking advantage of the periodic geometry of the pilot ladle to reduce computational costs. Fig. 8 presents the 3D view of the meso model used and a plan view of the geometry showing the thicknesses of linings (mm).

*Fig. 8: FE meso model of pilot ladle showing the 3D and top view.*

The analysis was performed using coupled thermal and mechanical analysis. The observed value of the furnace temperature was used as the thermal load at HF with a heat transfer coefficient of 600 W/m²K. The exterior face of the steel shell was exposed to room temperature with a heat transfer coefficient of 50 W/m²K. The thermal and mechanical properties of the materials were taken from [1,6]. For all the materials, temperature-dependent elasticity was used. Additionally, the viscoplastic behaviour of the working lining was used. The measured value of head and bed joints from test NWL-02 was used in the model for the working lining masonry. These joints follow an exponential closure behaviour as described in [2]. The model was supported in gravity by a rigid plate (allowing separation in tension) and a friction coefficient of 0.7. The temperature distribution obtained with the numerical model shows good agreement with the experimental result, as shown in Fig. 9. The result validates the thermal properties of the materials used in the model.

*Fig. 9: Temperature evolution in the FE model along with the experimental result of NWL-02.*

The evolution of circumferential strain in the steel shell of the FE model shows a good agreement with the experimental result, as shown in Fig. 10. The strain evolution can be expressed by the closing of the joints in working linings and gaps between the linings in the beginning. After joint closure, a steady rise in strain till the 20th hour, when the temperature at HF reaches 1200 °C. Afterwards, strain reduction can be observed. However, the drop in strain in the numerical model is not as prominent as in the experimental result.

This difference could be due to creep parameters used in the model, which requires further investigation.

Nevertheless, the obtained behaviour is well within the bounds of the experimental outcome. Fig. 10 presents the distribution of maximum principal creep strain in the working linings of the pilot. A strain concentration can be observed near the joints at HF, which is expected due to high-stress concentration. Higher creep strain can generally be noticed near the HF, and no creep at the CF of the working lining due to temperature distribution which influences the creep parameters.

*Fig. 10: Circumferential strain evolution in steel shell in FE model and experiment along with distribution of creep strain in working lining at the 44th hour.*

Fig. 11 shows the evolution of total strain observed at the 25 mm from HF in working linings and the results obtained from the DIC analysis at that location. A good agreement between the results can be noticed. The figure also presents the total strain's thermal, elastic and creep strain components. As the applied temperature increases, a rise in thermal strain can be observed due to thermal expansion. After the joint closure, a build-up of elastic strain can be observed. An increase in the creep strain and, consequently, a reduction in the elastic strain can be observed once the temperature at that location reaches 1200 °C.

*Fig. 11: Evolution of circumferential strain and DIC result.*

## 5. CONCLUSION

Mortarless refractory masonry exhibits complex behaviour when subjected to high thermal loading, particularly with complex and multi-material industrial applications. Thus, characterising refractory masonry behaviour is essential for designing or investigating industrial vessels using it. Moreover, limited experimental works focusing on the thermomechanical characterisation of refractory masonry are available in the literature. This experimental campaign describes a novel simplified approach for the thermomechanical characterisation of a steel ladle's cylindrical shell without the constraints of ladle bottom and molten steel.

The thermal behaviour observed through various thermocouples presents a similar distribution of temperatures between the refractory linings for all tests. Tests performed on specimens with new working linings show the influence of evaporation of free water around 100 °C. The effect of the dry joint thickness can be observed by measuring mechanical strain in the circumferential direction on the exterior side of the steel shell. The working lining with a larger mean thickness of joints demonstrates lower strain on the steel shell than the lining with a small joint thickness. The effect of viscoplasticity that becomes prominent around 1200°C in working lining bricks was also observed through strain gauges on the steel shell.

The result presented here shows that the meso modelling approach provides a reliable response of the structure. This result also validates the various thermal and mechanical properties of the materials found in the literature. Moreover, this approach can be used to perform parametric analysis to identify critical material and geometric properties. Furthermore, the experimental and numerical outcome of this work can be used to validate other modelling approaches, such as homogenised macro models.

# DIGITALIZATION TO REALIZE AN AUTOMATIC AND CONTINUOUS REFRACTORY MAINTENANCE SYSTEM SCANTROL™ 4.0 FOR THE EAF

Rolf Lamm, Minteq International GmbH, Duisburg Germany

## ABSTRACT

The new requirements and challenges brought about by the transformation to "Green Steel" call for intelligent concepts in the production of steel. The increasing number of electric arc furnaces, accompanied by high competitive pressure, require steel producers to introduce innovative measures to reduce costs, CO2 emissions and improve safety.

The paper presents the latest development in digitalization to realize an automatic and continuous refractory maintenance system for the electric arc furnace (EAF), which is tailored to the requirements of contemporary steel production in a modern steel mill. The automatic system has eliminated the disadvantages of intermittent, personnel-intensive refractory maintenance and follows the "no person on the floor" safety philosophy. The functionality of the SCANTROL™ 4.0 system (laser scanner-controlled measurement of refractory thickness, visual display of scan results and intelligent material application of repair compound) has significantly improved productivity, working conditions and the decision-making ability of steelworkers.
The overall effect at the EAF steelplant has included:

- Reduction in total refractory consumption
- Increased furnace availability by reducing "Power Off" delays
- Improved operational safety
- Integration of the determined data into an "Industry 4.0" environment

## THE CONCEPT

The use of refractory materials is one of the main causes of downtime in electric steel plants. This applies both to the relining of the furnace and to the maintenance of the refractory materials by spraying and fettling. Classic maintenance by spraying requires very hard manual work with a hand lance in front of the furnace, which requires two employees. Already in 2003, the first fully automated refractory maintenance system from Minteq® was installed in a German steel mill. From then until today, a lot has happened technologically in laser scanning technology, analysis of measurement data, digitalization of results and repair spraying robots.
Today, a modern maintenance system for refractory linings consists of four main components (Fig. 1).

Fig. 1 Components of the fully automatic maintenance system

- LaCam® Laserscanner measures the residual refractory thickness of the furnace.
- SCANTROL™ interface module, linking the above-mentioned components, to evaluate the measurement data, analyse the application strategy and control the robotic maintenance unit.
- MINSCAN™ robotic maintenance system to repair the refractory lining in different areas of the EAF.
- High temperature video cameras provide additional safety, improved performance, and visual inspection capability.

These four components are combined in a mechanical robotic system, the LaCam® - MINSCAN™ manipulator. The spray materials, which are stored in silos and transported into the MINSCAN™ by batch guns, are specifically designed for improved flowability, wettability and plasticity. The unique particle size and binder package provide excellent adhesion to the furnace substrate, improving density at the wall and minimizing rebound. This increases the durability of the material, which in turn reduces maintenance and increases furnace availability.

## THE TECHNOLOGY

### LaCam® Laserscanner

The 5th generation LaCam® laser scanner technology, with more than 10 million measurement points per scan in one furnace, makes it possible to determine wear with a very high degree of accuracy. The laserscanner (Fig. 2) is designed to measure the refractory lining from the inside of the metallurgical vessel, by inserting the laser head into the metallurgical vessel itself. A huge improvement is that the laser scanner is inserted into the metallurgical vessel and scans the wall and at the same time the bottom of the vessel with a 360° rotation. This reduces the overall measuring time to less than a minute. The laser scanner, using the Time-of-Flight principle (TOF), sends out a series of short laser pulses organised in a highly collimated beam, in a well-defined direction. The pulses are partially and diffusely reflected by

targets and the receiver gathers backscattered optical echo signals and converts them into electrical signals. The receiver's electronics detects the targets even in the presence of dust and smoke thanks to the echo digitization with full waveform analysis (DSP-Technology).

**Laserscanner Specifications**

**Real Number of Range Points per Scan:** <10 Million
**Measuring Time per Frame (360°/120°):** < 16 sec. (selectable)
**Scan Angle:** vertical 120°; horizontal 360°
**Scan Frequency:** <900 kHz
**Max. Surface Temperature:** 1700°C /3092°F
**Dual Wavelength Pyrometer for Temperature Detection of Lining**

*Figure 2: Technical specification of the 5th generation LaCam® laser scanner with protection enclosure*

As a result, the distance between the scanner and the target points is computed with high accuracy. Additional measurement values, like laser echo amplitude and surface heat radiation, are recorded for each measurement point too. The heat radiation is measured at two separate wavelengths, which allows to take the full advantage of the high measurement accuracy offered by the two-colour (ratio) pyrometry. In combination with a high-sensitivity long-wavelength channel, a wide temperature range between 500 °C (932°F) and 1700 °C (3092°F) can be measured accurately and displayed in the form of a high-resolution thermographic image. Using the measurement data, a program precisely calculates the critical areas that need to be repaired. It also suggests the quality and required quantity of repair spray material. The information thus obtained is used to automatically control a spraying robot for repairing the refractory lining. This machine applies the repair mixes exactly where they are needed in the furnace.

**MINSCAN™ Gunning Head**
The gunning head can perform a continuous 360° rotational and simultaneous vertical movement from the furnace centre to the upper edge of the furnace water-cooling panels. (Fig. 3). Incorporated inside the gunning head is an eccentric jet mixing Minteq®'s patented nozzle designed to thoroughly wet the material at high speeds whilst preventing clogging and pipe drip. The gunning Capabilities are up to 250 kg/min wet material and up to 350 kg/min dry material. Advanced cooling technique ensures that the maintenance operation can operate continuously without any temperature restrictions. Maintenance of EAF is possible immediately after tapping and even possible with remaining steel in the furnace. The system enables precise, efficient, safe, and fast application of the gunning material.

*Fig. 3 MINSCAN™ Gunning Head in operation*

**High Temperature Video cameras**
During the gunning process, four video cameras film the performance of the gunning mix application. All camera images are displayed on a monitor in the control station for continuous observation. This provides additional information for monitoring the quality of the spraying process.

**LaCam® - MINSCAN™ Manipulator**
Two types of design are available: A system where the laser scanner and the gunning head are mounted on the same manipulator arm, which is attached to a tower column (Fig. 4), and a solution where one tower column supports two independent manipulator arms. Depending on the location and available space the selection is made. In both alternatives is the tower column located next to the furnace on the ground. The one manipulator arm set up with main components is shown in Fig. 4. The compact design does not require a big footprint on the floor. All movements of the manipulator are detected by high-precision sensors to enable reproducible movement.
*Fig. 4: One manipulator arm set up*

**Interface between laser and manipulator: Scantrol™**
The SCANTROL™ interface module converts the measurement data from the laser scanner in such a way that this information is evaluated, and a maintenance strategy is derived from it to control the robotic maintenance unit (Fig.5).

**Evaluation**
The operator at the EAF triggers the measuring process. After the exact position of the furnace has been automatically determined from the laser measurement by means of 3D structure, the working lining measuring points are filtered out and transformed into a coordinate system for the furnace. The calculation of the residual brick thickness is based on a comparison profile (permanent lining).

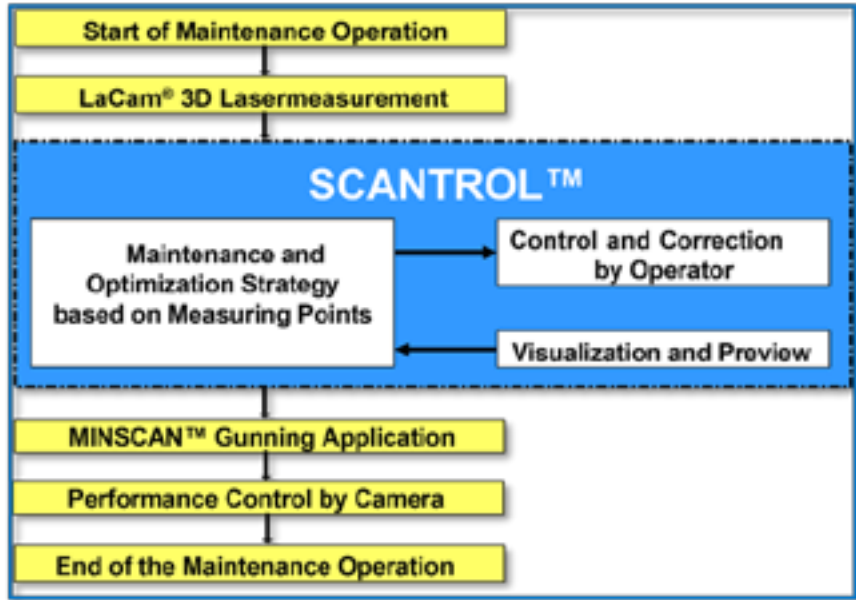

*Fig. 5 The maintenance process including Scantrol™*

The individual measurement points in high-resolution subfields, defined by cylindrical coordinates and evenly distributed over the area of the vessel potentially to be repaired, are then merged. The system determines the coordinates with minimum residual thickness in relation to sectors displayed in three dimensions. Based on thresholds defined by the operator for the allowable residual wall thicknesses per sector, the matrix of areas in need of repair is derived where the residual wall thickness is less than the respective threshold. The operator sets the optimisation sequence (duration, material consumption, degree of restoration) and starts the calculation of the optimised maintenance procedure so that the system carries out the maintenance automatically:
- Special matrix formulas combine the fragmented, high-resolution structures of the fields to be repaired into three-dimensionally coherent, compact structures.
- The size and sequence of the rectangular areas to be repaired, as well as the type of repair materials and the application quantity (application thickness), are determined using strategies for optimizing the time required, material consumption and degree of restoration,

and considering the physical properties of the mixtures used for the repair (application from bottom to top, setting time, maximum application thickness).
- The manipulator coordinates for the areas to be repaired are transmitted to the PLC unit of the MINSCAN™ system in the form of a telegram.
- The MINSCAN™ system performs its maintenance routine fully automatically, i.e., the correct product is applied "expertly" at the exact location in the desired layer thickness.

These parameters are integrated in the preventive maintenance programme, thereby harmonising consumption, and operating efficiency.

**Visualisation**

A monitor in the control pulpit is used for the visualisation of the measured residual refractory thicknesses and the parameters for the fully automatic maintenance process in the EAF. The measured residual refractory thicknesses are shown in the left-hand half of the display (Fig. 6). Visible on the right-hand side are the maintained areas or the thicknesses of the refractory after a pre-calculated, automatic maintenance process.

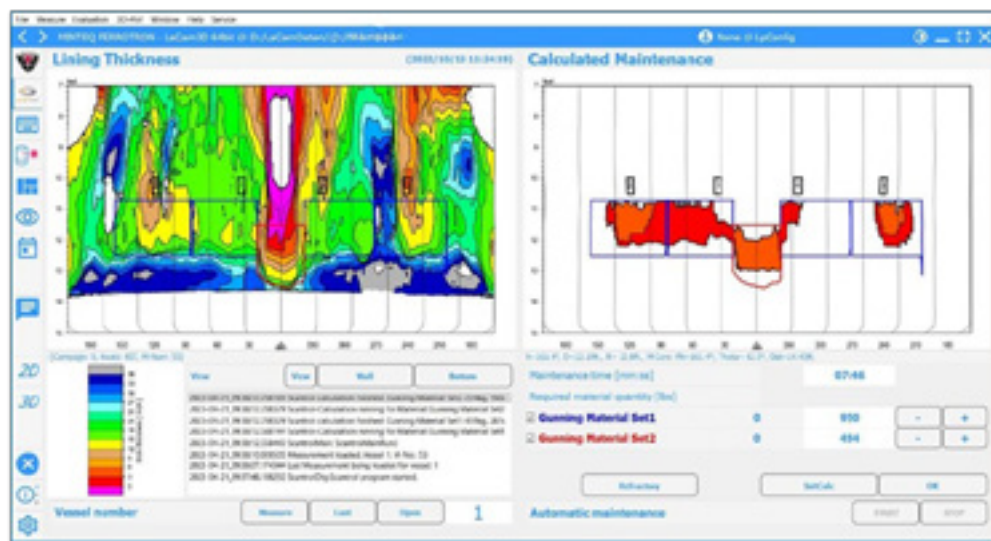

*Fig. 6 Main Screen of Scantrol™*

Here you can also read the proposed repair product, the required amount and the time needed for the application of the mass. The operator has the possibility at any time to adjust the maintenance process to the situation at the furnace. If he agrees with the proposed procedure, he can trigger the fully automatic repair from the control station. The exact measurements of the residual thickness in the whole furnace provide the operator with versatile information about the state of the refractory in wall and bottom. Profiles of the refractory wear in the EAF are being determined and evaluated online. The various colours symbolise the diverse residual thicknesses. Horizontal or vertical sectional images can be displayed at all angles. See Fig. 7

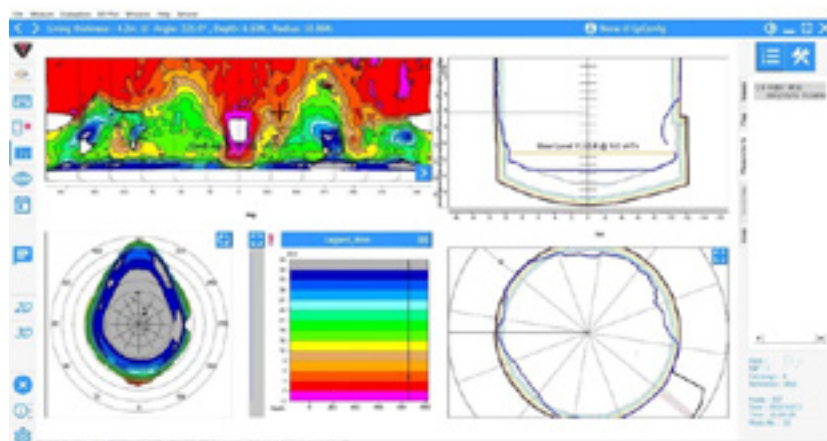

*Fig. 7 Presentation of measurement results (Wall, Bottom, Bathlevel) in different form*

**CONCLUSIONS**

The new generation of automatic and continuous refractory maintenance system SCANTROL™ 4.0 for the EAF takes subjectivity in gunning away from the operator as material applications governed by quantitative laser measurements. This more efficient refractory application reduces number of bricks relines and patches. It reduces the repairing time and refractory (kg/ton of steel) consumption. It provides increased furnace availability by reducing "Power Off" delays. Extra Power On time leads to increased heats and steel production. Due to remote operation safety conditions will improve – "NO PERSON ON THE FLOOR" Philosophy. Collecting and analyzing data from measurement systems and databases using the INDUSTRY 4.0 standards will allow steelplants to optimize production- and procurement processes to save on material-, energy- and $CO_2$ Emission-cost.

[2]TU Wien, Vienna, Austria

## ABSTRACT

Steelmaking is a highly complex and energy-intensive industry. With ever-increasing production demand, steel manufacturers must anticipate challenges and use innovative approaches to remain competitive while contributing to a sustainable future for the industry. Hence, leveraging advanced analytics tools has become vital to achieving more agile, integrated, optimized, and sustainable operations. Within the available tools, prescriptive analytics techniques can significantly enhance decision-making within steelmaking operations. In this context, one of the main levers to reduce the $CO_2$ emissions of steelmaking processes is to optimize the steel ladle logistics. We review current technologies and outline how advanced analytics can support this task.

Moreover, we discuss that to make good decisions on ladle deployment, precise predictions for the thermal state of the ladle for a given sequence of processing steps are required. Furthermore, the condition of the ladle lining and its remaining useful lifetime must be considered. A prescriptive analytics tool currently in development is presented. It enables the calculation of energy-efficient ladle schedules considering the lifetime and thermal state of the ladles. This initial contribution from the CESAREF European Project allows us to understand how to make better decisions and contribute toward more sustainable use of refractories in the steelmaking industry.

## INTRODUCTION

Steel ladles play an essential role in operating a steel plant, being responsible for moving hot metal from tapping at primary refining, undergoing secondary metallurgy treatment, and finally reaching the casting machines for producing the steel slabs. After casting, the ladles undergo several treatment processes until they are ready again to receive the hot metal. These operations define the so-called ladle cycle, depicted in Figure 1. Proper ladle availability and logistics management are critical aspects of the steelmaking process.

*Fig. 1: The steel ladle cycle*

Ladles are built with special refractory linings to transport molten steel at high temperatures. Three layers usually separate the molten steel from the ladle steel shell: the working, insulating, and safety linings. The working lining's choice of material and thickness is vital to achieving a trade-off between ladle capacity and its thermal capability [1]. The working lining is exposed to chemical, mechanical, and thermal sources of wear during its lifetime. This results in a reduction of its volume, which leads to different thermal properties over time. Thus, understanding the correlation between the remaining lifetime and heat-transfer mechanisms is a crucial aspect of achieving better control of the ladle's temperature and improving the overall energy efficiency of the steel plant.

## Motivation

The consideration of sustainability objectives, such as reducing the carbon footprint and energy consumption, has recently received much attention in industrial optimization applications [2]. In the steelmaking sector, optimizing the steel ladle logistics can be leveraged to improve energy efficiency. Inefficient ladle management can yield undesired results, such as (i) failure to achieve the production and quality targets, (ii) excessive energy losses, and (iii) reduction of the lifetime of the refractory lining. Hence, incorporating advanced analytics tools into the decision-making process is essential to achieve higher production demands while being energy efficient during the entire lifetime of the ladles.

## LITERATURE REVIEW

A relevant problem in the literature is the so-called steelmaking-continuous-casting (SSC) scheduling [3]. It can determine in what sequence, at what time, and on which device molten steel should be processed at the various production stages involved [4]. The usual formulation and solution of this problem are done within a static schedule for a given time horizon.

[3] presents a systematic review of the static SCC scheduling literature. The available methods differ mainly concerning the mathematical approach to their solution. They can be classified as:

1. Exact algorithms: These include branch & bound variants and decomposition approaches
2. Heuristics: These are mainly used to find a feasible solution quickly. It entails the use of greedy, local, and global search approaches.
3. Meta-heuristics: usually capable of obtaining good solutions, although they cannot guarantee optimality. Evolutionary computing techniques are often employed for this task.

Ladles are essential to the SCC scheduling problem since one must use them to transport the molten steel until it reaches the casting machines. However, the literature often overlooks their critical role in a steel plant [3]. Thus, more effort is required to advance the ladle scheduling problem, especially regarding energy efficiency. The most relevant ladle scheduling references are now briefly discussed. The SCC problem with ladle allocation decisions is described in [5]. Constraints regarding ladle maintenance, such as sanding and sliding plate change, are considered in the problem. A hybrid method that combines a meta-heuristic algorithm with a MIP solver was developed to tackle this problem. [6] presents an energy-efficient integrated SCC and ladle scheduling optimization problem. It considers the heating and waiting times during empty ladle operations. A tailor-made meta-heuristic was designed for its solution. [7] proposes and integrated planning and scheduling problem formulation. It includes a complete set of operational constraints and ladle allocation decisions. The Simulated Annealing (SA) algorithm is applied for its solution. Finally, [8] studies the ladle scheduling problem focusing on empty-ladle operations. It assumes that a production schedule is given and tries to optimize the allocation of ladles for that scenario. A genetic algorithm is proposed to solve the optimization problem.

## LADLE SCHEDULING OPTIMIZATION

A continuous-time mixed-integer linear programming (MILP) formulation of the ladle scheduling problem was developed to extend the existing related literature. It aims to minimize waiting times, heating times, and full ladle temperature losses while respecting the production plan and the stages a ladle must undergo after casting:

maintenance, warming, and waiting for tap. A steel ladle's reduced order model (ROM) calculates the refractory temperature. This model is an internal development of the Ceramics Research Center in Tata Steel IJmuiden, which has been extensively validated and is currently in use by other applications. The optimizer was developed using Python and the Pyomo modeling language [9]. Gurobi [10] is currently being employed for its solution. It requires a small amount of time to solve small to medium-sized instances. A web application was developed to allow the configuration and execution of different instances of the problem. It is then possible to evaluate other initial ladle conditions, such as the initial thermal state, lifetimes, and production plans. The application saves the optimization results of each instance in a database for later analysis.

A reporting section is also available, where users can quickly inspect the results of a single instance for the optimal schedule and predicted thermal profile of the ladles, as shown in Figure 2. For example, it is possible to identify the recommended operational practices within the resulting schedule and correlate them with the ladle temperature predictions. Moreover, constraints on the refractory temperature can be added to see how the logistics must be adapted to keep the refractory temperature in a particular range.

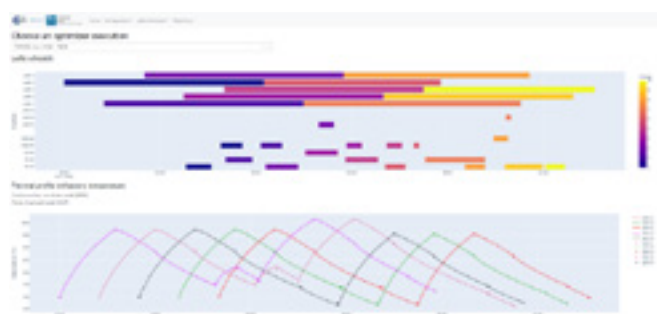

*Fig. 2: The schedule results view*

In a scenario comparison report (Figure 3), it is also possible to compare the potential savings between several instances regarding energy-efficiency metrics, such as heating times and ladle temperature losses. Furthermore, a visualization of the thermal model predictions enables the quick assessment of the ladle's average temperature over the scheduling horizon. Considering the current lifetime of a ladle fleet, it is possible to quickly compare the effect of the initial temperature and choose a ladle pre-heating practice that increases the process' energy efficiency.

*Fig. 3: The results comparison view*

## CONCLUSIONS

A prescriptive analytics tool to support the ladle scheduling was developed as an initial contribution of the CESAREF European Project. It solves a complex MILP scheduling problem incorporating the ladle's energy balance by leveraging a refractory temperature model developed in Tata Steel IJmuiden. Through a scenario-driven approach, evaluating and comparing the energy-efficiency metrics for different ladle configurations and production plans is possible. After this initial development, the tool already enables a step towards more sustainable ladle management regarding energy consumption and refractory usage. Future developments include improvements to the solution approach and User interface, optimization regarding

$CO_2$ emissions, and evaluation of the optimization model against production data.

**ABSTRACT**

With short service life from tens of minutes to a few months due to the harsh conditions in Iron and Steel (I&S) making process, the refractory material consumption is substantial, leaving companies with significant challenges in the use, recycling, and disposal of these materials. In the current context of the European Green Deal, a Concerted European action on Sustainable Applications of REFractories (Doctoral Network CESAREF, www.cesaref.eu), has been launched in 2022 [1]. In order to develop better knowledge around refractory materials with regards to the new operating conditions requested by the drastic reduction of greenhouse gas emissions, improved energy efficiency, and by life cycle assessment requirements. The presented PhD study aims to predict refractory materials' evolution in service and determine their reusability (to optimize material lifetime) and reduce operational costs. For that purpose, the existing online sensoring systems will help obtain real-time data. Whereas the non-destructive evaluation methodologies will obtain the thermo-chemical-mechanical properties through experimentation, both the collected data and the experimental data will be analyzed by machine-learning algorithm. The final global target of this new approach is to develop an artificial intelligence model that can assess the reusability and recyclability of refractory parts. Such tools can, in the future, assist the end user in planning regarding the 4Rs (Reduce, Reuse, Recycle and Replace).

**Keywords:** Non-destructive evaluation**,** machine learning (ML) refractories, recycling, sensoring, sustainability.

## INTRODUCTION

Digitization has become a prominent trend across various industries, driven by ongoing technological advancements. The steel industry is no exception, as digitalization has started playing a significant role in its operations. In high-temperature industries, such as steel production, refractory linings for industrial vessels serve as a vital foundation for its working. Each industrial revolution has progressively enhanced the overall industrial process, leaving a significant impact on our daily lives and work environments. Now, we stand at the brink of the fourth industrial revolution, known as Industry 4.0, which aims to leverage smart technology for automating traditional manufacturing and industrial activities. This concept is still in development but encompasses technologies like digital twins, the Internet of Things (IoT), big data analytics, advanced robotics, cloud computing, machine learning (ML), and artificial intelligence (AI) [2].

Steel is a broad category of iron alloys with carbon content ranging from 0.002 to 2.14 wt%. The casting process is used to create steel, and today continuous casting is the most used technique, accounting for more than 96% of all steel produced [3]. The ladle, the tundish, and the cooling zone are the three essential components of a contemporary continuous casting system. The ladle is a large container for liquid steel that may hold tens to hundreds of tons of steel and is used to pour the liquid steel into the tundish. One heat is equal to the weight of the ladle, and one sequence is equal to the amount of heats one tundish can accomplish. The tundish serves as a molten steel reservoir and disperses the liquid metal into several casting molds where steel solidification is initiated. In the steel industry, tundish, which are crucial for providing molten steel at high temperatures during the continuous casting process, require specific refractory linings. These linings typically consist of three layers: working lining, insulating lining, and safety lining, serving as a barrier between the molten steel and the tundish shell.

The tundish is used to control flow and provide a constant output from irregular inputs by holding a tiny amount of molten steel while dispersing some of it elsewhere. The tundish serves several crucial functions in the process of molten steel handling, including molten steel distribution, buffering, flow control, purification, and heat loss mitigation. To effectively fulfill these functions, various refractory materials are employed within the tundish:

o To control and homogenize the flow of liquid metal inside the tundish, refractories are used. These components include purging plugs, wires, impact pads, and dams that help regulate the flow of the molten steel.

o Using refractories reduces energy waste and oxidation during the secure transfer of steel between reservoirs. These parts, which ensure the steel flows smoothly, include submerged entrance nozzles, submerged entry shrouds, and sliding gates.

o To ensure safety and save energy, refractories are used to separate and isolate the exterior steel shell from the molten steel. These set of refractories, also known as lining refractories, which form a barrier between the environment and the molten steel in order to protect it.

Combining large-scale machine-to-machine communication and IoT enables improved automation, connectivity, and self-monitoring. The selection of the working lining's material and thickness is of utmost importance. Over its lifespan, the working lining undergoes wear due to thermal, mechanical, and chemical factors, resulting in a reduction in volume and changes in its thermal characteristics over time. To effectively control the tundish's temperature and enhance overall energy efficiency in a steel plant, understanding the relationship between the remaining lifespan of the working lining and heat-transfer processes becomes crucial.

## MOTIVATION

Industrial optimization programs have recently paid a lot of attention to environmental goals, such as reducing carbon footprints and energy usage [4]. In the steelmaking sector, predicting the parameters of tundish, which will be leveraged to improve energy efficiency. Refractories are essential in high-temperature operations in today's industrial environment, assuring the durability and effectiveness of furnaces. Refractories need to be checked and maintained because of the constant wear and tear they undergo during the process in order to increase their efficacy and a long lifespan. Our project's goals are to investigate various online sensing tools for refractories, apply cutting-edge A.I. methods to forecast

refractory wear, use non-destructive testing techniques for data collection, and use monitoring and modeling techniques to make educated decisions about reduction, reuse, recycling, and recreation in order to address this challenge. We want to transform refractory management methods and promote sustainability in industrial operations by integrating these multidisciplinary techniques.

*Fig. 1: Process methods.*

**Goal 1:** Non-Destructive Testing for Experimental Data Collection to augment the accuracy and reliability of our predictive models, our project will incorporate non-destructive testing (NDT) methods for data collection. Techniques such as ultrasonic testing, laser vibrometer and magnetic particle inspection will be employed to obtain crucial information about refractory properties, including microstructural changes, material integrity, and the presence of defects. By integrating NDT into our data collection processes, we aim to enhance the fidelity and comprehensiveness of our predictive models [5].

**Goal 2:** Understanding Different Online Sensing Instruments for Refractories the initial purpose of our study is to completely examine and comprehend the array of online sensing techniques available for monitoring refractory conditions. We will explore technologies such as infrared thermography, acoustic emission sensors, and optical coherence tomography, among others, to collect real-time data on refractory health and performance. By gaining a deep understanding of these tools, we aim to enhance our ability to capture accurate and timely information about refractory wear [6].

**Goal 3**: Implementation of A.I. for Refractory Wear Prediction Utilizing machine learning algorithms and artificial intelligence, our project seeks to develop predictive models for refractory wear. By training these models on historical data collected from online sensors and non-destructive testing, we aim to create accurate and reliable predictions of refractory degradation patterns. These predictive insights will empower operators to proactively plan maintenance activities, minimize downtime, and optimize the lifespan of refractory materials, leading to substantial cost savings and increased operational efficiency [7].

**Goal 4**: Monitoring and Modeling Techniques for Informed Decision-Making The final objective of our project revolves around leveraging advanced monitoring and modeling techniques to derive valuable insights for decision-making. By continuously monitoring refractory conditions and analyzing data collected from online sensors and NDT methods, we aim to generate actionable information regarding the reduction, reuse, recycling, and recreation of refractory materials. These insights will facilitate evidence-based decision-making processes, enabling industrial stakeholders to adopt sustainable practices, optimize resource utilization, and minimize environmental impact [8].

We hope to revolutionize refractory management through our initiative by utilizing online sensing, artificial intelligence, non-destructive testing, and sophisticated modeling methods. We aim to

transform conventional refractory management practices and promote sustainable approaches in industrial operations by gaining a thorough understanding of refractory conditions, accurately forecasting wear patterns, using NDT for data collection, and making informed decisions about reduction, reuse, recycling, and recreation. The results of our experiment might fundamentally alter how refractories are used, monitored, and maintained, ultimately leading to greater operational effectiveness, lower costs, and a more sustainable future.

## LITERATURE STUDY

Machine learning, a component of artificial intelligence, enables computer systems to think as people do by learning from the past and improving on it. It operates by investigating data, spotting patterns, and formulating hypotheses. Data-driven strategies are what are used to classify AI today [9]. Data availability and accessibility are a result of the expansion of our technological infrastructure, which includes sensors, system logs, user logs, storage availability, etc. This information might include an image, a sound, text, machine RPM, the thickness of the refractory lining, campaign lengths, chemical components, etc.

For instance, a smart factory may generate different photographs of the product parts that are categorized as normal or faulty. The residual thickness of the refractory, which can be measured with a laser, production parameters like tapping temperature, processing time, lancing time, blowing time, maintenance data like the amount of mix used during gunning, and refractory lining like the type of material used can all be considered as input data in the case of refractory maintenance. A typical AI/ML model follow the following steps as depicted below;

*Fig. 2: AI/ML Model.*

The quality of AI/ML outputs is determined by this crucial stage, which is highly significant. It controls how well the AI/ML model performs, determines its capacity to produce valuable insights, and ultimately determines how well the model can address the business issue.

Feature engineering is the following stage after data has been gathered and arranged in a certain way. The method of feature engineering, which draws on domain knowledge, is used to acquire features from unstructured data using data mining techniques. [10].

*Fig. 3: Sample data.*

In the context of refractory maintenance, characteristics of refractories like cold crushing strength at different temperatures, apparent porosity, bulk density, refractories, hot modulus of rupture, and thermal expansion of coefficient, workability, water addition percentage, Alkali resistance, and particular process parameters could be the features that have an impact on the refractory wear. The next step is to choose the appropriate machine learning algorithm model, where features are used as input data, such as linear classification, support vector machines (SVM), artificial neural

685

networks (ANN), convolution neural networks (CNN), logistic regression, K-mean, decision trees, random forests, etc [11].

*Fig. 4: Flowchart of proposed method.*

## RESEARCH FOCUS

Although the literature study describes several studies about the refractory from ladle and furnaces not from tundish, which gives us opportunity to explore through this project. The primary focus of this project is following:

1.  The use of Pearson's correlation coefficient assessment to lower the number of factors needed for tundish lining wear prediction to avoid data fitting.
2.  This doctoral study proposes an approach of the application of machine learning in the field of steelmaking industry.
3.  This study will end-up with an algorithm modal for evaluation of the online monitoring tool verified with an experimentation data for its accuracy.

## CONCLUSIONS

In order to meet the sustainability, circularity, and environmental impact objectives for 2050, the European Green Deal [12] has set significant technological and scientific challenges for the steel manufacturing industry. The CESAREF collaboration seeks to contribute to innovations in refractory materials for steelmaking that are transferable to other industries. The refractory materials used in the tundish linings will be the subject of this study. The determination of the crucial features to be evaluated in accordance with the criteria of the refractory application might be one of the potential solutions to address the European concerns while using the waste hierarchy as a reference point. This doctoral study focuses on the advancement of online sensing tools for refractories in the steel industry, utilizing artificial intelligence (AI) and machine learning techniques to develop a robust predictive model for refractory wear. The development of refractory wear models, accurate identification of the major wear affecting parameters, refractory benchmarking, and automated maintenance are all made possible by modern smart technologies. This model provides insights into the performance and lifespan of refractories, enabling proactive decision-making in reducing, reusing, recycling, or recreating refractory materials. Non-destructive testing techniques are also emphasized, providing

reliable and accurate data for informed analysis. The integration of monitoring and modeling tools enhances research findings, enabling informed decision-making processes. The findings have substantial implications for the sustainable operation of the steel industry, as predicting refractory wear and making well-informed decisions aligns with the industry's commitment to circular economy principles.

Maximizing refractory material utilization can boost resource efficiency and environmental performance. This increases safety, decreases refractory consumption, and enables plant operators to forecast the lifetime of the lining. These insights gained through monitoring and modeling approaches are help in deciding about the positive influence in decision-making processes, driving the transition towards a circular economy and responsible resource management.

# MICRO-MECHANICAL MODELLING OF HETEROGENOUS MATERIALS CONTAINING MICROCRACKS WITH DISCRETE ELEMENT METHOD

Q. Pledel; M. Huger, D. André

IRCER / University of Limoges, Limoges , France

Refractories are ceramic materials resistant to very high temperatures. Used in environments with harsh solicitations, a better understanding between the macroscopic physical properties and the micro structural aspects is necessary to optimize their use. This work proposes to focus on the resistance to thermal shocks by micro mechanical modelling.

To do this, numerical simulations are performed to model the microcracking caused by the thermal expansion mismatch between the constituents and its influence on the non linear stress strain behavior of such materials. The work has been performed with GranOO, a soft ware using the discrete element method (DEM), to which is added a periodic homogenization method to consider the phenomena at microscopic scale on the macroscopic properties. The damage process is studied during the cooling of refractories materials in order to reproduce a multi cracked state and to understand the mechanisms depending on parameters such as the proportion of the constituents, their thermal expansion anisotropies and the geometry of the model. From these simulations, the main macroscopic mechanical properti es involved in the resistance to thermal shocks can be analyzed and related to the microcracking state of the system. These results are then compared with analytical models and experimental results. These developments allow a better understanding between microstructure and macroscopic behavior. This work envisages the potential of the discrete element method to predict the thermome chanical behavior of microcracked media.

Keywords: Refractories, Microcracks, DEM modelling, Thermal shock, Periodic homogenisation.

# DEVELOPMENT OF AN ORTHOTROPIC ELASTIC–VISCO–PLASTIC BEHAVIOUR LAW FOR THE THERMOMECHANICAL MODELLING OF REFRACTORY MASONRIES

Z. El-Alami, T. Sayet, A. Gasser

*Univ. Orléans, Univ. Tours, INSA-CVL, LaMé (EA 7494), 45072 Orléans, France*

**ABSTRACT**

Some refractory linings that protect metallic vessels from the hot temperature of the products they contain are made of masonries with dry joints (*i.e.* without mortar). The presence of these joints makes the behaviour of the masonry non-linear and orthotropic, allowing a free expansion during the first part of the temperature increase, reducing the stresses in the masonries. Since bricks have an elastic-visco-plastic behaviour at high temperature, it is necessary to develop an orthotropic elastic-visco-plastic behaviour law for the homogeneous material that has a behaviour equivalent to that of the brick and dry joint assembly. This non-linear behaviour is the origin of creep, that could be represented at the mesoscopic scale (brick and joint scale) by the well-known Norton-Bailey creep law. This law was in a previous study adapted to the macroscopic scale (masonry scale) for orthotropic secondary creep (with a constant creep strain rate). This study presents the adaptation of this law to primary creep for which the strain rate is not constant. The parameters of this new law are determined by a non-linear full-field homogenization technique. The identified law is then validated by comparing the results obtained by meso-modelling (bricks and joints are simulated) and macro-modelling (bricks and joints are replaced by the equivalent material) of an elementary periodic cell subjected to different loads.

## I. INTRODUCTION

Refractory materials are the best candidates for application in steel ladles due to their low thermal conductivity and thermal, chemical, and mechanical stability at elevated temperatures. In order to meet the mechanical, thermal and operational requirements, various refractory layers are used for ladle construction. Each layer serves a specific function and possesses unique thermophysical and mechanical properties. The layers include a work lining, a safety lining (also known as a permanent lining) and a steel shell (see Fig. 1a). The working lining is often made of mortarless refractory masonry. The safety lining consists of two layers: a dense refractory masonry with a mortar joint layer with low thermal conductivity, and a porous layer with lower thermal conductivity (insulation layer).

**Fig. 1:** (a) Schematic of a simplified steel ladle showing the different layers. (b) Schematic of the four states of dry joints.

### 1. Joint states

In this work, we are interested in the study of the working layer of the steel ladle, which consists of hundreds of refractory bricks, which are arranged periodically forming a periodic masonry with dry joints separating the bricks from each other. Often, these joints result from the shape, dimensional tolerances, and irregularities of brick surfaces. Two types of joints can be defined according to their orientation: head joints, and bed joints. These joints can close and

reopen, making the mechanical response of the mortarless refractory masonry variable under cyclic loading and unloading.

In order to consider the impact of joint closure and reopening on the behaviour of the brick and joint assembly, four possible joint states are predefined according to the closure or opening of head and bed joints (see Fig. 1b): the 1st state is characterized by open head and bed joints, the 2nd state is characterized by open bed joints and closed head joints, the 3rd state is the opposite of the 2nd, and the 4th state corresponds to the closure of all joints.

Each case corresponds to a different periodic structure and therefore to a different equivalent macroscopic behaviour. It is necessary to determine this equivalent macroscopic behaviour for each state. There are three out of four states which are extremely easy to identify:

- The 1st state: there is no stiffness in the plan of the masonry, since all the joints are open. However, in the direction perpendicular to the plane, the stiffness of the brick is present since there is only one brick in the thickness.
- The 2nd state: there is no stiffness in the vertical direction, but there is stiffness in the horizontal direction, which is equal to that of the brick.
- The 4th state: since all the joints are closed, the behaviour of the equivalent homogeneous medium is simply the same as that of the brick.

The only state for which it is not trivial to identify all the material parameters of the equivalent homogeneous medium of the masonry, is the 3rd state for which it will be necessary to use a homogenization technique in order to determine the parameters of the equivalent homogeneous medium.

### 2. Scale of study

No matter what material is considered, there is always a scale where its structure is heterogeneous. Refractory masonry can be presented in three scales of size (macroscopic, mesoscopic, and microscopic) as indicated in Fig. 2:

- Microscopic scale: at this scale, the heterogeneity of the brick is considered.
- Mesoscopic scale: at this scale, the interaction between bricks and joints is investigated on the assumption that the brick is made of a continuous material.
- Macroscopic scale: at this scale, the refractory masonry is considered as a continuous material, it is then modelled by a homogeneous solid.

**Fig. 2:** The three characteristic scales of the studied masonry.

The benefit of the mesoscopic scale is that it can obtain both global results, such as the deformed state of the masonry, and local results, such as the deformations of bricks.

### 3. Full-field homogenization technique

When calculating a structure comprising a refractory masonry with dry joints and several hundreds or thousands of bricks, it is difficult to model every brick and every joint (problems of convergence and computation time). It is a homogenization technique that makes it possible to determine the behaviour of a homogeneous material that will have the same behaviour as all bricks and joints[1].

**Fig. 3:** Switch from meso to macro with full-field homogenization technique.

In order to study the homogeneous mechanical behaviour of refractory masonry in the 3$^{rd}$ state of dry joints (bed joints are closed and head joints open), the full-field homogenization technique based on the finite element method can be adopted. This homogenization technique allows us to go from meso-modelling (at the level of bricks and dry joints) to macro-modelling (at the level of the homogeneous medium equivalent to the studied masonry). It has the advantage of predicting both the effective properties of heterogeneous materials and the local-fields of stress and strain. This technique is based on the finite element simulation of a representative volume element (RVE).

First, we need to select a RVE of the masonry. In the case of a regular periodic masonry, the RVE is replaced by a unit cell (UC) which will reproduce periodically in both directions of the masonry plane (see Fig. 3). This unit cell is modelled using the meso-modelling approach (hence the need to describe the mechanical behaviour of the refractory brick) and subjected to boundary conditions resulting from the periodicity and a number of solicitations.

## II. CREEP MODELLING

In this section, the laws of creep behaviour in transient and steady state are presented in the form of the following two types of formulations:

- Local formulation: is used in meso-modelling to simulate the creep behaviour of the refractory brick for the purpose of identifying the parameters of the homogenized behaviour of the masonry.
- Macroscopic or homogenized formulation results from the full-field homogenization technique, it is used in the macro-modelling for simulating the behaviour of a homogeneous material equivalent to the set of bricks and joints.

### 1. Secondary creep
#### a. Local formulation

Secondary creep or steady-state creep is a period of time in which the rate of creep is constant. Bailey and Norton[2] have developed a model widely used to model secondary creep, which relates the creep strain rate $\dot{\varepsilon}_{ij}^{vp}$ to stresses using the following equation:

$$\dot{\bar{\bar{\varepsilon}}}^{vp} = \frac{3}{2}\bar{\bar{s}}\, A\, \sigma_{eq}^{n-1} \quad (1)$$

With $\dot{\varepsilon}_{ij}^{vp}$ is the viscoplastic strain rate

$\bar{\bar{s}}$ is the deviatoric component of the stress tensor $\bar{\bar{\sigma}}$

$\sigma_{eq}$ is the equivalent Von Mises stress

A, n are temperature-dependent material parameters

### b. Macroscopic or homogenized formulation

Due to the presence of open head joints, the macroscopic elastic-visco-plastic behaviour law of UC must be orthotropic. There is a homogenized orthotropic steady-state creep law of heterogeneous solids developed by Tsuda and al.[3]. The main advantage of this behaviour law is that by using the same creep parameters of the base material, the orthotropic homogenized viscoplastic behaviour of heterogeneous solids can be found. The behaviour law is obtained by averaging the local fields on the UC volume and using a stress concentration tensor based on the following equation:

$$\dot{\bar{\bar{E}}}^{vp} = \frac{1}{2}\,A\,(\Sigma_{eq})^{n-1}\bar{\bar{\bar{N}}}:\bar{\bar{\Sigma}} \quad (2)$$

Where A and n are the material parameters of the bricks, reported in Tab. 3, and:

$\bar{\bar{\Sigma}}$ is the macroscopic stress

$\Sigma_{eq}=\sqrt{\frac{1}{2}\,(\bar{\bar{\Sigma}})^{T}:\bar{\bar{\bar{N}}}:\bar{\bar{\Sigma}}}$ is the equivalent macroscopic stress

$\bar{\bar{\bar{N}}}$ is the stress concentration tensor that can be represented by a second order tensor $\bar{\bar{N}}$ using the vector notations of stress and strain tensors:

$$\bar{\bar{N}}=\begin{bmatrix} N_{11} & N_{12} & N_{13} & 0 & 0 & 0 \\ N_{12} & N_{22} & N_{23} & 0 & 0 & 0 \\ N_{13} & N_{23} & N_{33} & 0 & 0 & 0 \\ 0 & 0 & 0 & N_{44} & 0 & 0 \\ 0 & 0 & 0 & 0 & N_{55} & 0 \\ 0 & 0 & 0 & 0 & 0 & N_{66} \end{bmatrix} \quad (3)$$

The tensor $\bar{\bar{N}}$ is symmetric and is characterized by 9 non-zero components, which can be determined (Tab. 1) by combining the uniaxial tensile loads along the 3 directions of space and simple shear loads within the three planes of space.

**Tab. 1:** Expressions of concentration tensor $\bar{\bar{N}}$ constituents in secondary creep.

### 2. Primary creep
#### a. Local formulation

Primary or transient creep is a period in which the creep rate drops. Bailey and Norton have developed a model currently used to model

primary and secondary creep, which links the creep strain rate to the stresses by means of the following equation:

$$\overline{\dot{\varepsilon}}^{vp} = \frac{3}{2}\,\overline{\overline{s}}\,mA^{\frac{1}{m}}\,\sigma_{eq}^{\frac{n}{m}-1}\left(\int\sqrt{\frac{2}{3}\dot{\varepsilon}_{ij}^{vp}\dot{\varepsilon}_{ij}^{vp}}\,dt\right)^{\frac{m-1}{m}} \quad (4)$$

Where A, n and m are temperature-dependent material parameters (for the case of secondary creep, $m = 1$).

### b. Macroscopic or homogenized formulation

The behaviour law that has been developed at the LaMé laboratory to account for primary creep is written as follows:

$$\overline{\overline{E}}^{vp} = \frac{1}{2}\,mA^{\frac{1}{m}}\,(\Sigma_{eq})^{\frac{n}{m}-1}\overline{\overline{\overline{N}}}:\overline{\Sigma}\left(\int\sqrt{2\left(\overline{\overline{E}}^{vp}\right)^T:\left(\overline{\overline{\overline{N}}}\right)^{-1}:\overline{\overline{E}}^{vp}}\,dt\right)^{\frac{m-1}{m}} \quad (5)$$

With A, n and m are the material parameters of the bricks, reported in Tab. 3 (the secondary creep macroscopic formula may be recovered for m=1).

Tab. 2 summarizes the expressions of the tensor $\overline{\overline{\overline{N}}}$ components identified for each of the six applied loads, based on the macroscopic viscoplastic strain rate $\dot{E}_{ij}^{vp}$ and the macroscopic viscoplastic strains $E_{ij}^{vp}$.

**Tab. 2:** Expressions of concentration tensor $\overline{\overline{\overline{N}}}$ constituents in primary creep.

| Mechanical parameters of the brick forming the UC | | |
|---|---|---|
| Elasticity parameters | E=11000 MPa | υ=0.2 |
| Norton Bailey creep law parameters at 1000°C | A=2.77×10⁻⁸ s⁻¹ MPA⁻ⁿ | n=2.8 m=0.8 |

**Tab. 3:** Elasticity and creep parameters of the studied brick.

### 3. Principle of homogeneous formulation of primary and secondary creep

Considering that the local creep law of Norton Bailey only depends on the time and the applied stress, by analogy, the macroscopic creep law will also depend only on time and the applied macroscopic stress (see Fig. 4a).

The homogenization theory provides a tensor which links mesoscopic stresses to macroscopic stresses, called stress concentration tensor $\overline{\overline{\overline{N}}}$. This tensor has an orthotropic form since the masonry itself has an equivalent orthotropic behaviour due to the closure and opening of the head and bed joints. It should be noted

that the tensor $\overline{\overline{\overline{N}}}$ has 9 unknowns, which means that 9 loading cases need to be applied in order to identify its components.

However, the viscoplastic incompressibility condition of macroscopic viscoplastic strains ($\text{tr}\left(\overline{\overline{E}}^{vp}\right) = E_{11}^{vp} + E_{22}^{vp} + E_{33}^{vp} = 0$) makes it possible to reduce the number of unknowns from 9 to 6 (see Fig. 4b).

The viscoplastic incompressibility condition does not matter for pure

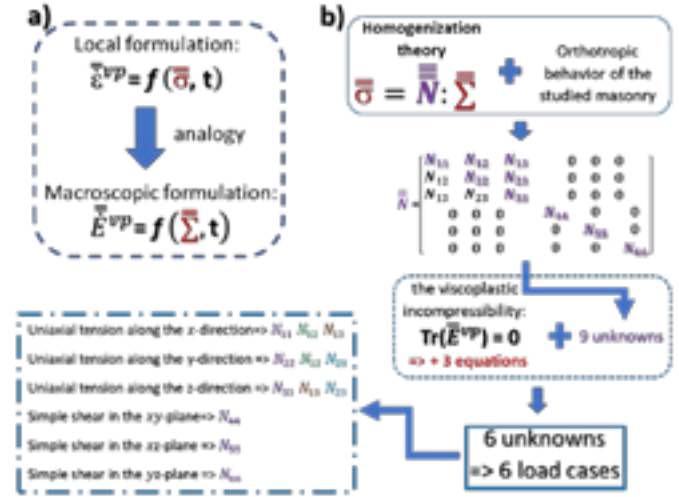

**Fig. 4:** (a) Similarity between local and homogenized creep formulations. (b) Principle of homogeneous formulation of primary and secondary creep.

shear tests. However, it must be checked and taken into account for uniaxial tensile tests in the 3 directions of space.

### 4. Methodology for evaluating effective meso-model behaviour

To implement the law of macroscopic creep in a finite element code, it is first necessary to determine by six load cases the 6 components of the tensor $\overline{\overline{\overline{N}}}$ for transient and permanent creep. All six load cases are simulated using meso-modelling (see Fig. 5a), with a UC subjected to the conditions resulting from the periodicity and a number of uniaxial stresses of 1.5MPa based on each of the six load cases.

The presence of open dry joints in the UC model leads to a discontinuity in the displacement field, given that the local strains within the placement of these joints are unknown (due to lack of viscosity and stiffness in the volume corresponding to dry joints). Therefore, the homogenized (or macro) strains $E_{ij}$ cannot be computed by integrating the local (or meso) strains $\varepsilon_{ij}$ over the volume of the unit cell ($V_{UC}$) according to [4]:

$$E_{ij} = \frac{1}{V_{UC}}\iiint \varepsilon_{ij}(x, y, z)\,dv \quad (6)$$

For this reason, in the current study, the homogenized strains are calculated from the average variation of the displacements of the corners of the UC [5], i.e. by dividing the variation of the displacements of the corners by the initial dimensions of the UC.

**Fig. 5:** UC geometry modelling: (a) Meso-model, (b) Macro-model.

Once the individual tensor $\overline{\overline{N}}$ components have been identified for both creep rates, macroscopic modelling can be used to simulate the equivalent homogeneous behaviour of the masonry (see Fig. 5b).

derivation have a considerable influence on the values of the stress concentration tensor components.

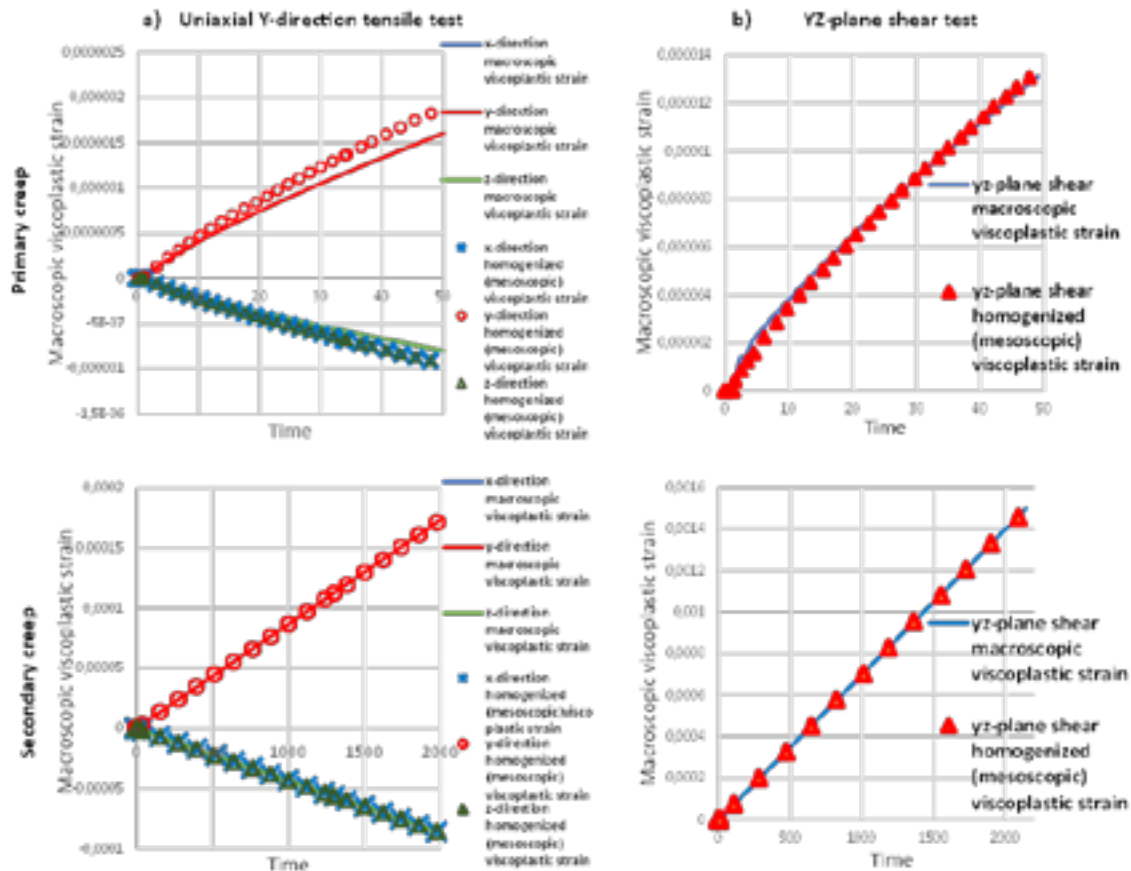

**Fig. 6:** Comparison of the macroscopic viscoplastic strain field between the Meso/Macro model for primary and secondary creep: (a) uniaxial Y-direction tensile test, (b) YZ-plane shear test.

## III. RESULTS AND DISCUSSION

With the aim of verifying the robustness and relevance of the macroscopic creep behaviour law in transient and stationary mode, a comparison is carried out between the simulation results of macro-modelling and meso-modelling for a uniaxial y-direction tensile test and an yz-plane simple shear test (see Fig. 6). By visualizing the curves obtained, it can be seen that the viscoplastic incompressibility is respected, and a very good correlations are obtained using the secondary macroscopic creep law, whereas less good correlations are obtained with the primary macroscopic creep law. This due to errors generated by the numerical derivation of homogenized viscoplastic strains $E_{ij}^{vp}$ in order to obtain homogenized viscoplastic strain rates $\dot{E}_{ij}^{vp}$. It should be noted that the numerical derivation problem was not encountered during the secondary creep simulation, because it is characterized by a steady rate of homogenized viscoplastic strain, whereas for primary creep, the homogenized viscoplastic strain rate gradually decreases over time. Subsequently, the error in the numerical derivation accumulates as time goes by, causing fluctuations of the identified components of the tensor $\overline{\overline{N}}$.

It must be noted that the tensor $\overline{\overline{N}}$ components are constant in secondary creep because they depend only on the macroscopic viscoplastic strain rate $\dot{E}_{ij}^{vp}$, which is constant during this period (Fig. 4). In addition, the tensor $\overline{\overline{N}}$ components evolve in the primary creep, because they depend on both the macroscopic viscoplastic strain $E_{ij}^{vp}$ and the macroscopic viscoplastic strain rate $\dot{E}_{ij}^{vp}$, which, in turn, change within that period (Tab. 2).

The error of the numerical derivation decreases as the simulation accuracy increases. It is a matter of finding the critical time step: $\Delta t_{crtical}$, above which the fluctuations caused by the numerical

## IV. CONCLUSIONS

A homogenized orthotropic creep behaviour law was proposed to model the primary and secondary creep behaviour of masonries without mortar at high temperature. It was identified using a meso-modelling of the periodic cell. The proposed law gives good correlations for primary creep and slightly poorer correlations for secondary creep. This is due to the fluctuations generated during the numerical derivation of the homogenized viscoplastic strain field, which are on the one hand high and increasing in primary creep, and on the other hand stable in secondary creep, because the viscoplastic strain rate is constant in the stationary creep regime and decreasing in the transient creep regime.

# FE MODELLING OF REFRACTORIES' MATERIAL PROPERTIES BASED ON 3D MICROSTRUCTURAL ANALYSIS

S. Pirkelmann, S. Sharba, G. Seifert, H. Friedrich, F. Raether
Fraunhofer HTL, Bayreuth, Germany

## ABSTRACT

This paper presents a simulation-based approach to evaluate the mechanical strength of refractory materials by investigating the influence of the material's structural composition on component failure. A neural network is trained and applied for image segmentation of 3D computed tomography images of refractory samples, enabling the identification of different material components. Structural properties, such as phase fractions, porosity, grain sizes, and their spatial distributions, are extracted from the segmented images. Finite element analyses are then conducted to assess the impact of mechanical loads on the material. The relationship between the identified structural properties and the probability of failure is evaluated, providing insights into material reliability. The approach is demonstrated using commercially available B80 and SP78 refractory materials.

## INTRODUCTION

The drive towards climate neutrality necessitates the quick optimization of thermal processes in terms of energy and material efficiency. Refractories play a crucial role in achieving these goals not only by enhancing functionality and prolonging service life but also by improving performance with reduced wear, and increased strength. These improvements enable the construction of lighter and more efficient structures, further contributing to energy savings and sustainability. In the systematic development of sustainable refractory materials, simulation-based methods offer significant advantages by reducing time and experimental effort. Consequently, understanding the behavior of refractory materials under stress becomes paramount, as it provides essential insights for optimizing their performance and reliability in a wide range of applications.

This paper aims to address the challenge of evaluating the mechanical strength of refractory materials by investigating the influence of material composition on component failure. By employing simulation-based techniques, it becomes possible to identify critical structural elements that contribute to component failure under various loads. The goal is to improve the reliability of new refractory materials by avoiding these critical elements.

The paper is structured as follows. The methodology begins with the acquisition of computed tomography (CT) imagery of refractory samples, allowing for non-destructive characterization of the material's microstructure. Subsequently, an image segmentation approach using a neural network is employed to accurately identify and classify the main structural components of the refractory material.

Following the segmentation, representative volume elements (RVEs) are extracted from the segmentation data and converted into meshes, enabling their utilization in finite element simulations. Finite element simulations are then conducted to analyze the stress increase within the RVEs when subjected to externally applied tensile strain, providing insights into the material's response to mechanical loading. Furthermore, macroscopic simulations of damage are performed using a 3-point bending simulation, allowing for an assessment of the material's behavior at a larger scale.

## NON-DESTRUCTIVE ANALYSIS OF REFRACTORY SAMPLES

### Computed Tomography imagery of B80 and SP78 refractories

We demonstrate our method using commercially available refractories: a dense refractory brick made of Bauxite B80 and a dense high alumina brick made of synthetic magnesia spinels with a high clay content Alurath SP 78. Cylindrical samples of 5 mm height and 33 mm diameter have been cut from the as-received refractory bricks. The resolution of the CT images is 24µm. Figure 1a) shows a slice through the CT image of a B80 material. The image clearly shows the very inhomogeneous microstructural compositions of the refractory material. The total volume of the samples is about 4.3cm$^3$ which is sufficiently large to be representative of the material at hand.

*Fig. 1a): Computed tomography image of a sample of B80 refractory material with a resolution of 1518 x 1483 x 276 voxels. A single slice of the image in the z-axis is displayed. b) Segmentation image as generated by nnUNet algorithm. Different colors indicate the distinct structural components of the material: pores are shown in red, course-grained inclusions in blue, fine-grained matrix in green, background in black.*

### Material analysis and 3D-image segmentation using convolutional neural networks

From the CT images, three main structural components of the refractory samples can be distinguished: pores (dark regions), coarse-grained inclusions (distinct light regions), and a fine-grained matrix in between. The structural and chemical composition of the various components of the B80 refractory was determined through scanning electron microscope (SEM) and X-ray diffraction (XRD) analysis. The analysis revealed that the B80 material consists of 61.8% Al2O3 (Corundum), 33.5% 3Al2O3-2SiO2 (Mullite), 4.6% Al2TiO5 (Tialite), with traces of other compounds. The material exhibits a complex structural composition, with distinct coarse grains made up primarily of Corundum with inclusions of either Mullite or Tialite, and varying degree of porosity. The matrix phase essentially shares the same composition but has a high degree of micro-porosity below the threshold resolution of the CT imaging.

A convolutional neural network has been trained to automate the process of generating 3D-segmentations of the CT images, assigning to each voxel of the input image a corresponding class (background, pore, distinct coarse grain, or matrix). nnUNet has been chosen for its proven effectiveness in image segmentation tasks [1]. The algorithm was trained using manually generated training data from a single B80 image, consisting of a volume of 1152×1152×64 voxels. Despite the relatively small training volume, the implementation of data augmentation strategies in nnUNet ensured the generation of high-quality segmentations. Additionally, custom variations of the input data were incorporated to replicate common CT image artifacts, enhancing the algorithm's robustness to diverse imaging conditions. The resulting segmentation, showcased in Figure 1b), demonstrates the effectiveness of the approach in accurately identifying and classifying the structural components within the B80 refractory material. The segmentation model was also applied to CT

images of the SP78 material. Despite not being specifically trained on this material, the model demonstrates excellent segmentation performance, yielding accurate results.

**Analysis of structural composition**

The segmentation data is used to analyze the structural composition of refractory materials. We can derive various quantities from the segmentation results such as the volume fractions of grains, pores and matrix phase, the size and local distribution of inclusions, and the orientation of particles within the matrix phase. This information can be used to compare different samples and materials based on their microstructure. To illustrate this, Figure 2 shows the volume fractions, porosity and average grain size for the B80 and SP78 samples, respectively. Note that the reported porosity only includes critical macroscopic pores that are detectable in the CT images and does not capture the much higher micro-porosity of > 10% according to density measurements.

*Fig. 2: Volume fractions of pores, distinct coarse grains and matrix for B80 and SP78 material.*

Homogenized mechanical properties of the main structural components of the B80 material were estimated using mixture rules, as listed in Table 1. to ensure the accurate modelling of the material's behaviour under stress in the simulations.

*Tab. 1: Material data used in microstructure simulations as estimated by mixture rules based on input data from the Material Property Database (MPDB) [2].*

| Component | Young's modulus [GPa] | Poisson ratio |
|---|---|---|
| Coarse grains | 320 | 0.22 |
| Matrix phase | 95 | 0.22 |

**FINITE-ELEMENT-BASED CHARACTERIZATION OF MATERIAL STRENGTH**

To quantify the failure probability of a given refractory material under external load we apply finite element simulations. The analysis is focused on the B80 material, but similar investigations could be conducted for SP78.

We follow a multi-scale approach: on the micro-scale we calculate an approximate distribution of fracture stress using microstructure simulations based on representative volume elements (RVEs) extracted from the CT image segmentation data from above. The resulting distribution then serves as an input to a macro-scale simulation of a three-point bending experiment from which we can estimate the failure probability of the material.

**Mesh generation from volumetric data**

For the simulations on the micro-scale, we cut out numerous RVEs with a resolution of 125 x 125 x 125 voxels, each corresponding to a volume of 27 mm³, from the segmentation image of the refractory, cf. Figure 3. For each RVE, the volumetric data is converted to a mesh for use in finite element (FE) analysis using the CGAL library [3] and subsequent simulation in Ansys APDL.

*Fig. 3: Illustration of multiple representative volume elements cut from the segmented CT image of a B80 sample.*

**Tensile strain simulations on micro-scale**

For each RVE, finite element simulations of linear elasticity were performed to determine the relative stress-increase factor compared to a defined external stress. In these simulations, a specified tensile strain was applied to the RVE, corresponding to a reference stress of 1 MPa. If structural defects such as pores are present within the RVE, the surrounding material has to bear the additional stress, resulting in localized regions of elevated stress within the material. To quantify the stress increase, the 99th percentile of the volume-weighted first principal stress in the matrix phase of each RVE was measured. This value was then used to compute a local stress increase factor by calculating the ratio between this percentile and the reference stress. In addition to the stress increase, an equivalent local stiffness is calculated for each RVE structure. By employing automated scripting, this procedure was iteratively applied to all RVEs, enabling the computation of a representative distribution of local stress increases across the material. Figure 4 shows the resulting distribution of stress increase from the simulation of approx. 400 RVEs of the B80 material.

The distribution of local stress increase is mapped to a distribution of fracture stresses which is used in damage simulations as discussed in the following section.

*Fig. 4: Histogram of the stress increase of individual RVEs when applying an external tensile strain corresponding to a stress of 1 MPa to opposite faces of the RVE.*

**Macro-scale simulation of 3-point-bending**

The scatter of bending strength of the refractory material is evaluated using a virtual three-point bending test as illustrated in Figure 5. The bending strength is computed using finite element analysis (FEA) with the goal of comparing it with experiments and eventually using FEA directly to evaluate the failure distribution of complex structures. The model accounts for microscopic elasticity via coupling the effective properties of the microscopic representative volume elements with a macroscopic model of a three-point bending test.

*Fig. 5: Illustration of a finite element model of the three-point bending test.*

On the macroscopic scale, an isotropic damage model that influences the stress-strain relationship is implemented as a user programmable feature (UPF) in Ansys [4, 5, 6]. The stress-strain relation is represented as

$$\boldsymbol{\sigma} = (1 - D)\,\mathbb{C}\,\boldsymbol{\varepsilon}\,,$$

where $\boldsymbol{\sigma}$ is the Cauchy stress tensor, $\boldsymbol{\varepsilon}$ denotes the strain tensor, $\mathbb{C}$ represents the fourth-order elasticity tensor and $D \in [0,1]$ is the damage variable, $D = 0$ corresponds to the undamaged state and $D = 1$ represents the fully damaged states.

The damage evolution is implicitly expressed by the following equation:

$$D(\kappa) = 1 - \frac{\kappa_0}{\kappa} e^{-\frac{\sigma_F h_e}{G_F}(\kappa - \kappa_0)},$$

where $\kappa$ is the maximum value of the equivalent strain experienced during the loading history, $\kappa_0$ represents the critical equivalent strain beyond which damage is initiated, $h_e$ represents the characteristic length associated with the element size in the FEA, $\sigma_F$ represents the fracture stress, and $G_F$ represents the fracture energy. A key point here is to use a modified equivalent von Mises strain from [5, 7] to evaluate $\kappa$. The modified version differentiates between tensile and compressive scenarios on the top and lower surfaces of the beam. This strain is given by the following expression:

$$\kappa = \frac{k-1}{2k(1-2v)} I_1 + \frac{1}{2k}\sqrt{\left(\frac{k-1}{1-2v} I_1\right)^2 + \frac{12k}{(1+v)^2} J_2}\,,$$

where $v$ represents the Poisson ratio, $k$ represents the ratio of tensile to compressive strength, $I_1$ represents the first invariant of the strain tensor, and $J_2$ represents the second invariant of the deviatoric strain tensor. Moreover, the critical equivalent strain $\kappa_0$ is determined by

$$\kappa_0 = \sigma_F \frac{(1+v)(1-2v)}{E(1-v)}.$$

*Fig. 6): a, b) fracture stress distribution of two randomly chosen beam models, where fracture stress in each element is coming from the underlying RVE. c, d) the corresponding damage evolution pattern given identical loading conditions.*

To study the scatter of the bending strength and the effect of the microstructure on this scatter, various simulations are carried out with RVEs assigned in a random manner to each element of the beam model in order to reflect the inhomogeneous material/pore distribution. In other words, the material properties of each element come from a pool of RVEs resulting in beams with different fracture stress distributions, as seen in Figure 6a and Figure 6b.

Examining the corresponding damage distribution and crack path in Figure 6c and Figure 6d, the effect of the fracture stress distribution on the failure pattern and consequently on the bending strength (15.2 MPa and 14.9 MPa) can be seen. The fracture stress distribution around the center of the lower surface has a profound effect on the results as this is the location of the highest tensile stress. The simulation is run 45 times to allow statistical evaluation of the results. A Weibull distribution is fitted to the resulting bending stresses with a mean of 14.6 MPa and a standard deviation of 0.66 MPa. The mean is in good agreement with experimentally observed values of 14.8 MPa from in-house data. However, the standard deviation is further away from the experimental value of 1.25 MPa. The difference may be due to a limited fracture stress distribution that does not fully reflect reality. Further investigation could, for example, directly calculate the fracture stress in each RVE by simulation, thus reducing the dependence on the available experimental data.

**CONCLUSIONS**

We have presented a simulation-based approach to evaluating the failure probability of refractories for mechanical loads based on their microstructure composition. Using this method, it becomes possible to rapidly compare different refractory materials based on data from CT imagery, eliminating the need for costly and time-consuming destructive testing. This will enable more rapid iterations when designing new refractory materials. In a future work, more detailed investigation on the scatter of bending strength will be carried out and then the resulting failure distribution obtained using FEA will be validated against an experimental setup.

**ABSTRACT**
Refractories interacting with molten slags and gaseous process environments can be unexpectedly compromised with respect to their durability and display complex failure modes. We focus particularly on degradation mechanisms resulting in catastrophic refractory brick failure due to formation of multiple reaction zones and chemical reactivity taking place within its respective microstructure. In order to address this complex micromechanism, we propose and demonstrate a multiscale modeling approach which accounts for the various mechanistic couplings between the material and the operating environment at the scale of the material microstructure. Focus of the work is in full field representation of material microstructure that is seen critical in order to be able to reproduce the observed failure mechanisms computationally. Use case work with bricks seen use in flash smelting operation is presented and the modeling results are compared to experimental and characterization results, the outcome is seen to be overall in compliance and comparable to the respective findings. The work demonstrates how addressing the refractory degradation modeling problem as a multiphysical and multiscale one yields improved ability to evaluate performance against challenging durability and lifetime limiting process conditions.

**INTRODUCTION**
Degradation of refractory materials in pyrometallurgical processes involves a complex set of mechanisms including loadings that are typically multiphysical in nature, from a modeling perspective it can involve chemo-transport, thermomechanics and material damage in a strongly coupled manner over the refractory lining's lifetime. Similarly, the problem can be argued to be multiscale, several of the mechanisms and resulting effects having their origins in the microstructural scale of the materials. However, presently the most successful approaches in addressing refractories interacting with molten slags or gaseous process environments are typically based on thermodynamical Calphad methods, which albeit have proven reliable in estimating, e.g., chemical wear behavior, are forced to simplify the problem considerably as far as accounting for the complex interplay of different physical phenomena at different scales. In order to be able to address complex failure models and investigate the interactions between the different coupled phenomena, we present a full field modeling concept and toolset which can incorporate many of the features typically neglected by thermodynamical equilibrium approaches. The aim the work is to improve the prediction of refractory degradation and failure and followingly provide a sound basis for refractory selection for new designs and process conditions.

695

**COMPUTATIONAL METHODS**
The concept of the multiscale modeling framework is summarized in Fig. 1. The objective is to enable the implementation and deployment of numerical high-performance computing (HPC) workflows which are able to address refractory degradation in a multiscale and multiphysical context. In this sense, it means that coupled problems can be addressed which involve interactions between transport, chemistry, thermomechanics and degradation (e.g., by cracking) of refractories in conditions of relevance to industrial processes. The implementation of the respective material behaviors and evolution laws is performed in a full field microstructural setting, by making use of microstructural modeling toolsets presented in more detail in [1-2]. Fig. 1 if interpreted as a sequential modeling workflow presents the simplest analysis scenario where no complex interrelations between the solutions steps are present, but the analysis is in essentially a sequence of data transfers between the modeling solvers addressing the differing physical phenomena. If divided to such a sequence, typically the analysis initiates from the evaluation of transport mechanisms, chemistry and phase transformations taking place within the refractory domain. Process conditions and their evolution in time, i.e., the conditions at the outer surface of the brick exposed to the respective environment and thermal histories arising from operation, are considered given by either other types of models or measurements.

*Fig. 1: Modeling concept and simplified sequential analysis sequence between the different physical phenomena.*

As a tightly coupled problem the thermal solution is typically performed for process initial and boundary conditions and over the smelter wall to establish the respective conditions influencing the transport problem. The transport problem is addressed as a multi-phase one as all the other steps as well, i.e., microstructural and phase specific characteristics are included. During the solution of the transport problem, local elemental concentrations are utilized to address phase changes and formation of new compounds due to process species interacting with the refractory phases. Parallel to addressing the evolution and transport within the microstructure, the thermomechanical problem is solved to address thermally induced stresses and those arising from mechanical loading. This solution is updated and fed into the effects arising from the solution of the chemo-transport problem. This stage necessitates typically a coupling to experimental work to address the mechanical properties of the updated microstructure, typically by way of incorporating the results of small scale mechanical tests (or alternatively, lower scale model couplings). Followingly, damage and possible cracking are addressed, typically by way of cleavage fracture models seen compatible with the behavior of the rather brittle ceramic phases. If nucleation and growth of cracks is predicted, this typically necessitates a model update as cracks couple strongly to the chemo-transport and thermomechanical problems. This is carried out by adaptively remeshing the solution domain and remapping the last time increment results to the new, modified, material microstructure. In practise, the model update can be done in steps by specifying criteria for model changes or updates over time which constitute significant enough couplings to push interactions within the co-simulation (e.g., coupling the selection to species and thermal diffusivity).

Typically, this form of modeling where the degradation process is interpreted as a unidirectional sequence of events is not sufficient to consider the degradation process with the necessary physical consistency, but rather, interactions between chemo-transport, phase transformations and the formation of new compounds, thermomechanics and degradation via crack nucleation and growth arise. For example, it is easy to see that if new compounds are formed this influences the respective properties across the physics being solved, or, if cracking takes place, it significantly influences transport mechanisms within the microstructure, let alone further accumulation of damage. To enable the solution of the degradation problem in a sufficiently realistic setting, the different physics-solutions can be coupled and time-integrated differently in time. This can mean direct coupling of solvers (although this leads to a prohibitively costly numerical computation) or a co-simulation type of an approach adopted in current work, where the different solutions are propagated in time and enabled to frequently interact during the solution process. As an example, the phase distribution arising from the solution of chemo-transport and evolving over solution is updated for the thermomechanical solution to capture the respective effects to, e.g., mechanical behavior of the refractory microstructure. The toolset is implemented primarily by making use of the Moose framework [3] as a basis, which as a multiphysical and adaptive mesh refinement finite element (FE) development environment enables one to develop different levels and types of couplings making also use of its build-in capabilities for linking different physics kernels. Computational workflows can be executed sequentially or with stronger degrees of coupling and concurrency. The outcomes can be upscaled to engineering material properties by way of, e.g., numerical homogenization methods as in present work, and data from lower scale methods can be included to specifics of microstructure scale models if seen of benefit. Methods such as Calphad calculations can be coupled directly or indirectly by making use of the APIs of the respective tools, current implementation interfaces to [4-5]. With respect to many of the inputs, thermodynamical and mobility databases are utilized [4-5] for the solid phases, additionally, the influence of the pore network is accounted for. In addition, the experimental and characterization activities contributing the current work are summarized in [6-7].

## RESULTS AND DISCUSSION

The studied magnesia-chromite refractory and its microstructure obtained by way of micro-computed tomography (µCT) imaging is presented in Fig. 2, further details of the characterization are provided in [6-7]. The primary phases that are resolved by segmenting the µCT image with the aid of scanning electron microscopy (SEM) and X-ray diffraction (XRD) results are the magnesia MgO and spinel $(Mg,Fe)(Al,Cr)_2O_4$ phases. Additionally, porosity is included explicitly in the imaging-based models as in the µCT results. Multiples of the microstructure are utilized in modeling as synthetic microstructures to obtain domains of large enough in size to extract results comparable to experimental ones.

*Fig. 2: Segmented model input of magnesia-chromite refractory based on µCT results.*

The aim of the simulation is to evaluate the degradation and failure of refractories, in current case addressing particularly a case where gaseous species from process atmosphere can exhibit transport over the microstructure and pores particularly considering sulfur dioxide, leading to the formation of reactions zones consisting of calcium and magnesium sulfates. Different analysis cases have been investigated: loading of the refractories at operational temperatures uniformly and investigating failure behavior, assessing the infiltration and development of reaction zones within the brick, and lastly, assessing fracture of reacted bricks subjected to the gaseous atmosphere during fast thermal cycling. The results for micromechanical modeling of refractory failure and the development of reaction zones are summarized in following. For comparing the reaction zones and distribution of compounds across the refractory a process boundary condition is defined exposing the microstructure to a gaseous environment and the changes within the microstructural domain can subsequently be investigated.

Firstly, results are presented in Fig. 3 when the refractory is loaded at an operational temperature of 1350°C (corresponding roughly to, e.g., copper and nickel flash smelting furnaces) by uniform applied tensile loading. The mismatch in properties between the magnesia and spinel phases yields a heterogeneous distribution of stress within the microstructure (stresses given in MPa). It is also noted that the pores within the refractory contribute to the local stress concentrations, as can be expected. The damage in current case is particularly promoted by the pore network in relation to the spinel phases running across the refractory microstructure and contributing to the localization of damage. Results of an analysis simulating the formation of reaction zones is presented in Fig. 4, the chemo-transport and resulting microstructure infiltration leading to a formation of calcium and magnesium sulfates. The outermost region is considered to primary correspond to a reaction zone already within the refractory brick, as the formation of the outer deposit layer visible in experiments [6-7] and containing elements of the feed materials is partially neglected with the current set of initial and boundary conditions.

*Fig. 3: Uniform loading of the refractory at a temperature of 1350°C: equivalent stress (top), first principal stress (middle) and damage when reaching failure (bottom).*

*Fig. 4: Simulating the formation of reaction zone and the respective evolution as a function of time (final figure segmentation of the sulfate containing reaction zone).*

The experimental work related to measurement of reaction zone dimensions from the studied refractory system is presented in Fig. 5 related to work in [6-7]. The numerical values are homogenized over full field microstructures to yield comparable values and zones are differentiated by changes in elemental chemistry and the specific phases, although the segmentation of phase distributions over the experimental and computational results is a source of uncertainty. What is deemed zone 3 is best aligned with the experimental work and model formulation as far as the comparison is concerned as it includes the formation of new phases. Zone 1, the face of the brick open to the

gas-space of the smelter, is underestimated in the model compared to experiments, although as the elements and richer deposit chemistry is not accounted for thoroughly in the model as is this is to be expected. Thus, the computational results for the gas-space end are lower than the most comparable experimental findings. For the zone 3, where the formation of calcium and magnesium sulfates is the primary difference, the model yields a bit of a lower bound for the zone thickness, although the results are comparable to what has been obtained experimentally. For zone 2 the changes in the brick are rather limited based on experimental findings, the model produces somewhat greater dimensions to this region over the experimental results.

*Fig. 5: Comparison of the three reaction zone thicknesses: simulation (solid lines) vs. experimental measurements (triangles which correspond to different furnace measurement locations).*

## SUMMARY AND CONCLUSIONS

We present a multiphysical and multiscale modeling concept for assessing the degradation mechanisms of refractories interacting with molten slags and gaseous process environments. The focus is particularly on degradation mechanisms resulting in catastrophic refractory brick failure due to formation of multiple reaction zones and chemical reactions taking place within its respective microstructure. We emphasize the full field representation of material microstructure to be able to reproduce complex failure mechanisms and study interactions with industrial process environments and various multiphysical behaviors taking place within the refractory microstructure.

The performed use case work against experimental findings focusing on refractory bricks seen use in flash smelting operation suggests the proposed approach appears viable and can address scenarios beyond classical chemical wear models, although further work is required to perform comparisons to experimental and characterization results in order to establish proper validation of the computational approaches. The comparisons as far as the principal refractory behavior are concerned are promising as the findings for the reaction zones are similar, but the model sensitivities and quality of inputs needs to be investigated further to ensure the predictive abilities being targeted can be reached. The work demonstrates how formulating the refractory degradation as a multiscale and multiphysical problem enables better evaluation of the performance against challenging durability and lifetime limiting process conditions. This is foreseen as an important step towards better evaluating the performance of refractories in novel and complex process environments, which is to enable the systematic design and selection of the respective material solutions by making the most out of state-of-the-art computational methods.

# ESTIMATION OF REFRACTORY CASTABLE THERMAL CONDUCTIVITY: A MANUFACTURER'S PERSPECTIVE

Chia-Yuan Chang
China Ecotek Corporation, Kaohsiung, Taiwan

**ABSTRACT**
Thermal conductivity ($\lambda$) is one of the most important parameters for refractory lining. We have purposed a practical procedure by following existing models to estimate thermal conductivity of castable. The results showed for room temperature estimation, the maximum deviation is less than 30%. By considering factors which might affect the estimation, the accuracy of estimation could be further improved.

**BACKGROUD**
**Ribaud's expression**
Among different models for $\lambda$ estimation, Ribaud's expression has been found fairly accurate and relatively simple [1][2]. According to the expression, apparent porosity (A.P.) and thermal conductivity of mass ($\lambda_s$) are the only needed parameters (1).

$$\lambda = (1-P^{2/3}) \lambda_s + (P^{1/3}) \lambda_g \qquad (1)$$

in (1) where, $P$(%):apparent porosity of castable; $\lambda_s$(W/mK):thermal conductivity of mass; $\lambda_g$(W/mK):thermal conductivity of air, which value can be found at relevant literature.

**Geometric mean model**
As a refractory manufacture, quality control is extremely critical for castable production. Therefore, apparatus for A.P. measuring might not be a problem. On the other hand, $\lambda_s$ in Ribaud's expression is difficult to know.

By introducing Geometric mean model (2), $\lambda_s$ of castable can be calculated by its raw materials [3]. However, since volume fraction of constituent is inconvenient for manufacture, we purposed to replace volume fraction to weight fraction. Therefore, Geometric mean model can be used easily (3).

$$\lambda s = \Pi \lambda_i^{voli} \qquad (2)$$

$$\lambda s = \Pi \lambda_i^{wi} \qquad (3)$$

where, $\Pi$ is notation of repeated multiplication; $\lambda_i$(W/mK) is the conductivity of ith constituent (solid); $voli$ is the volume fraction of constituent; $wi$ is the weight fraction of raw material.

**PROCEDURE**
**Case A: $\lambda_s$ of all raw materials of castable are known**
To begin with, the proportion of raw materials of castable should be listed. Then, according to the weight proportion of raw materials, using Geometric mean model to calculated $\lambda_s$ of castable. Additionally, refer to ISO 1927-6:2012 measuring the castable's A.P.. Finally, according to Ribaud's expression, the $\lambda$ of castable can be estimated.

**Case B: $\lambda_s$ of raw materials are unknown**
When confronted with this situation, the database of $\lambda_s$ of each raw material should be established first. Only at here, the thermal conductivity measuring meter is required.

First of all, $\lambda_s$ of binder (ex: cement) is an entry point. By mixing binder with suitable water, after forming, measuring it's $\lambda$ at desired temperature. Then, following ISO 1927-6:2012 measuring the mixture's A.P..

Secondly, transposed Ribaud's expression, $\lambda_s$ of binder can be found. Thirdly, mixing previous binder with 1st raw material (same weight of binder and 1st raw material is suggested), then adding suitable water. After forming, measuring this mixture's $\lambda$ at desired temperature. Lastly, following ISO 1927-6:2012 measuring the mixture's A.P..

So far, 1st raw material's $\lambda_s$ can be calculated by transposed Geometric mean model with Ribaud's expression. The procedures are simplified listed as follow (4-6).

transposed of Ribaud's expression:
$$\lambda_{s\ of\ binder} = [\lambda - (P^{1/3}) \lambda_g] / (1 - P^{2/3}) \qquad (4)$$
$$\lambda_{s\ of\ 1st\ raw\ material\ with\ binder} = [\lambda - (P^{1/3}) \lambda_g] / (1 - P^{2/3}) \qquad (5)$$
transposed Geometric mean model with same weight of binder and raw materials:
$$\lambda_{s\ of\ 1st\ raw\ material} = (\lambda_{s\ of\ 1st\ raw\ material\ with\ binder} / \lambda_{s\ of\ binder}^{0.5})^2 \qquad (6)$$

Repeated with previous step, until all raw materials $\lambda_s$ have been found. Then, follow case A situation. The details can be referred to figure 1.

*Fig. 1: Procedure of $\lambda$ estimation.*

**DISCUSSIONS**
According to the procedure as we purposed, the database of $\lambda_s$ of each raw material at different temperature has been constructed (not shown at here). In addition, by using Ribaud's expression to estimate $\lambda$ of castable, the actual $\lambda$ has been measured by thermal conductivity meter as well. The deviations are listed at Table 1

Tab. 1: Results of λ estimation and actual value.

| | Estimation λ | 0.85 | | 0.94 | | | | | |
| | Deviation(%) | -28.6 | | -23.0 | | | | | |
| Sintered 600°C measured at room[1] | Actual λ | 1.15 | 25.6 | 1.01 | 30.3 | 1.26 | 32.0 | 2.11 | 29.2 |
| | Estimation λ | 0.93 | | 0.86 | | 1.33 | | 1.71 | |
| | Deviation(%) | -19.1 | | -14.9 | | +5.6 | | -19.0 | |

1: The sample has been either sintered at 600 or 1000°C*3hr then furnace cooling, λ is measured at room temperature.
2: Measured by thermal conductivity meter QTM-710.
3: Calculated by Ribaud's expression, trace additives are neglected.
4: [(Estimation λ)-(Actual λ)]/(Actual λ)

As the results shown, for room temperature, the deviation between estimation and actual λ is small. The maximum deviation is -28.6% for commercial castable after sintered at 1000°C. This might be the effects of low melting elements, trace additives we neglected for calculation or other reasons. Nevertheless, for manufacturer, this deviation should be acceptable and can be improved by knowing the factors which might affect the results.

Moreover, the density difference of raw materials might also influence the results. As Table 1 listed, the FCWFA and AWFA both containing white fused alumina (WFA) and flint clay (F.C.). Since we have modified Geometric mean model from volume fraction to weight fraction, the density difference of ingredients might be non-negligible. Furthermore, concentration difference should also be considered. For Table 2, over diluted castable, its λ might be overestimated. On the other hand, castable with less water content, its λ might be underestimated. In sum, despite lots of factors might affect the results, the estimation method we purposed is still be considered as a good approximation for λ of real castable.

**CONCLUSIONS**
1. By combining Ribaud's expression and modified Geometric mean model, a relatively simple and accurate method has been provided for λ estimation.
2. Once the database of $\lambda_s$ has been created, the thermal conductivity meter is no longer needed. Only A.P. apparatus and simple calculation are needed for λ estimation.
3. The estimated value might be affected by temperature, concentration and density weight difference of raw materials.
4. This method is worth to be promoted due to simplicity, low cost and high accuracy.

## ABSTRACT
The CESAREF project is a Doctoral Network (DN), supported by the European Commission, to generate a Concerted European action on Sustainable Applications of REFractories. In the current context of the European Green Deal, this ambitious project has been launched in 2022 in order to develop a better knowledge around refractory materials with regards to the new operating conditions requested by the drastic reduction of greenhouse gas emissions, improved energy efficiency, and by life cycle assessment requirements. The present PhD study is focused on developments of numerical tools based on the discrete element method (DEM) for investigation of the relationships between microstructure and thermomechanical properties of model materials. This original numerical approach includes debounding, thermomechanical coupling, crack-closure and anisotropic behaviours. These developments will lead to a "virtual numerical lab" able to provide tensile, dilatometry, fracture mechanics or thermal shock virtual tests for virtual characterizations. The related achievements will be integrated to the free DEM software GranOO. Obtained numerical results will be validated in regard to experimental observations in terms of (i) mesoscopic thermomechanical quantities such as CTE, Young's modulus, Poisson's ratio, stress-strain law and fracture energy and (ii) microscopic observations such as fracture coalescence under thermal and mechanical loadings dynamically observed in SEM.
Keywords: Discrete Element Method (DEM), Microstructure, Refractories and Thermomechanics

## INTRODUCTION
Refractory materials are advanced materials with high thermomechanical properties and chemical stabilities. Refractory materials are used as insulating linings of equipment in steel, glass, and cement manufacturing. When exposed to an environment with fast temperature variations, refractory materials experience thermal shocks leading to thermal stress introduced over the material's surface, which causes critical failures of the material leading to environmental damage and pollution.

Past researchers have summarised that the critical failure of refractory materials can be enhanced by improving the material's Thermal Shock Resistance (TRS). According to several experimental studies, introducing thermal expansion mismatches between constituents of a refractory material can increase its thermal shock resistance. Micro-cracks promoted by an imbalance in thermal expansion might result in a refractory material exhibiting a non-linear mechanical behavior (figure 1a) [4].

On the other hand, past Doctorates Asadi [1] and Nguyen [2] have incorporated modelling platforms to give experimental insights for improving TSR. The modelling field has not yet fully covered every aspect of study regarding thermo-mechanical behavior for refractory materials. Modelling the complex behaviors of refractory has become an objective and the current Ph.D. focuses on investigating the relationship between microstructure and thermomechanical properties of model materials using the Discrete Element Method (DEM).

The developed tool will set up a virtual lab to characterize the material failure virtually. The numerical tool will help us perform the process from 3➔4 in the Youngs modulus evolution graph (Figure 1b). In this paper, we will address the basics of DEM, choice of model material of interest, boundary conditions and material routines to achieve the first set of results.

*Fig. 1: a) The non-linear stress-strain curve with microcrack promotion [4] b) Youngs modulus evolution w.r.t temperature [2]*

## DISCRETE ELEMENT METHOD (DEM)
The DEM is widely used for investigating the discontinuity behaviors in rocks, ceramics, and refractories [6]. The principles of discrete elements method are described as follows:
- The elements are rigid body that can move freely in a defined 3D space;
- The interaction between the elements is defined using interaction laws;
- It incorporates explicit numerical technique;
- The elements can have a translational and rotational movement determined using Newton's second law.

The benefits of incorporating DEM are listed down below ([1], [5] & [7]):
- It allows considering overlapping of the discrete elements; it is computationally efficient in GPU aspects, and the elements have mass and geometry as shown in figure 2a;
- It helps us perform mesoscale analysis of quasi-brittle failure, preserve real natural phenomena using rheology (example: spring), and simulate multiple crack nucleation, propagation, branching, and failure analysis, as shown in figure 2b.

*Fig. 2: a) The realistic phenomena is preserved [8], b) Multiple crack nucleation and propagation c) Flat joint [1], Beam model [2] & Cohesive beam [3]*

## PROBLEM STATEMENT
Past doctorate had chosen different interaction models like a cohesive beam [2], Flat joint [1], and beam models [3] (figure 2c) with discrete elements of spherical form.

The current Ph.D. incorporate the lattice spring model (figure 4a) generated using the voronoi tessellation technique. The computational study of the model can be performed by directly using the continuum mechanics laws, and the crack surface is visible, as shown in figure 4b. In addition, the lattice model does not require a calibration step as the continuum laws are well established [7].

Fig. 4: Description of a) Lattice spring model b) Surface crack with polyhedral element [7]

## Preprocessor

The Voronoi discretization technique is generated using the granoo preprocessing package named cook-project.

## Model Material

Incorporating complex microstructures of refractories (figure 6a) to study the relationship of its microstructure with thermomechanical properties, computationally is difficult. The ideology of defining a simplistic model material was the primary objective of the current study. The model material of interest is as defined below:

1. Model material 1:
   - Single-phase system (figure 6b);
   - 1-set of material parameters;
   - Homogenic system with just the matrix material.
2. Model material 2:
   - Bi-phase system (figure 6c);
   - 2-set of material parameters;
   - FCC packing will be incorporated to have very low anisotropy.
3. Model material 3:
   - Polycrystalline system (figure 6d);
   - n-sets of material parameters;
   - High in anisotropy → more related to realistic refractory behavior.

Fig 6: Description of the material model a) Example microstructure [4] b) Single-phase system [1] c) Bi-phase system [1] d) Polycrystalline system [3]

## Boundary conditions

The homogenization aspect of the study in DEM is still not as familiar as in the FEM. Recent past doctorate students have shown that applying the periodic boundary condition (figure 7a) will give us better results than the Free boundary condition [1]. The model material is chosen as the Representative Volume Element (RVE), and the copy of the RVE is arranged around the master element to bring the most simplistic microstructure arrangement replicating the realistic microstructure. The free boundary condition (figure 7b) is also incorporated for the following study to cross-verify the proven study by past doctorate students.

Fig. 7: Boundary condition a) Free boundary [8] b) Periodic boundary [1]

## Material routines

In the current Ph.D., the Elastic model and Fracture model are incorporated.

Local failure criteria: $\sigma_{(I)} \geq \sigma_{(max)}$

## Failure test

The current Ph.D. study focuses on the refractory material's tensile loading and mode-I fracture analysis.

## Validation

The developed numerical tool will be quantitatively validated using the results (experimental data) of a colleague from the CESAREF group. In addition, analytical solutions are also utilized as supportive data for the current Ph.D.

## CONCLUSIONS

The following Ph.D. incorporates further study by using:

a) Discretization technique: Voronoi tessellation DEM model
b) Boundary conditions: Free boundary model and periodic boundary model
c) Model/systems: Single-phase, bi-phase and polycrystalline system
d) Material routine: Elastic and Fracture model (Mode I)
e) Thermomechanical model with tensile loading

# COMBUSTION CHARACTERISTICS OF METHANE AIR PREMIXED FUEL IN ORDERED POROUS BURNERS

Liping PAN [1,2*], Yawei LI [1], Xiong Liang [1], Bowen XU[1]

[1]Wuhan University of Science and Technology, The State Key Laboratory of Refractories and Metallurgy, Wuhan 430081, China
[2]Geotechnical Institute, TU Bergakademie Freiberg, Freiberg 09596, Germany

**ABSTRACT**
Inside porous medium burners, the holes exhibit a variable size due to the sponge template, leading to uneven combustion intensity and exacerbating thermal shock damage. With the equivalent cell, an ordered lattice structure is proposed as a replacement for the disordered structure of the sponge template. By incorporating the two-step reaction mechanism of $CH_4$/air, radiative heat transfer and turbulence models, comprehensive calculations are performed to analyze the combustion kinetics and heat transfer within both solid and gaseous domains. The finite volume method is utilized to fully simulate the impact of cell structure parameters on fluid flow and combustion characteristics in porous media. The results indicate that increasing the cell side length while reducing the pore diameter enhances the porosity of the porous medium, resulting in reduced pressure resistance. Moreover, this adjustment leads to a more uniform temperature distribution, contributing to improved combustion efficiency, higher $CH_4$ conversion rate, and reduced CO emissions.

## 1 Introduction

Porous Media Combustion (PMC) technology involves combustion of fuel and oxidizer within a three-dimensional porous medium, resulting in high combustion efficiency, low emissions, and uniform heat release. However, traditional porous materials, like foam ceramics, have uncontrolled pore structures, limiting their application in low-calorific value fuels. To overcome this limitation, this study utilizes 3D-printed porous resin templates to design and optimize the cell body structure of the porous medium. By investigating the influence of the cell body structure on stress and flow fields, as well as studying the correlation between cell body structure and combustion characteristics, this research aims to optimize the parameters for enhanced combustion efficiency in porous media combustors.

## 2 Experimental and Simulation Methods

The complex structure of foam material (Fig. 1(a)) is geometrically simplified using a simplified equivalent unit channel (single cell), resulting in a cubic framework structure (Fig. 1(b)). The calculation of porosity in the lattice cell structure is as follows:

$$\varepsilon_c = \frac{V_p}{V} = \frac{a^3 - \frac{3\pi d^2}{4}(a - 0.6d)}{a^3} \tag{1}$$

$\varepsilon_c$, $V_p$ and $V$ represents porosity, pore volume, and cell volume, respectively. $a$ means the edge length of the cell, and $d$ is the diameter of the cell.

The modified momentum equation takes into consideration the porous structure and seepage effects. It can be expressed as:

$$\frac{\partial(\rho_m\varepsilon)}{\partial\tau} + \nabla\cdot(\rho_m\varepsilon\vec{v}_m) = \nabla\cdot[(\mu_m + \rho_m C_\mu\frac{k^2}{\varepsilon\sigma_\varepsilon})\nabla\cdot\varepsilon] \tag{2}$$

$$+ \rho_m C_1\nabla\vec{v}_m\varepsilon - \rho_m C_2\frac{\varepsilon^2}{k + \sqrt{v_m\varepsilon}}$$

where $\rho_m$ is the density of the fluid, $\vec{v}_m$ is the velocity vector, t is time, $k$ is the turbulent kinetic energy, $\varepsilon$ is the turbulent dissipation rate, $v_m$ is the dynamic viscosity coefficient of the mixture gas $\sigma_k$ =1.0, $\sigma_\varepsilon$ =1.2, $C_\mu$ =0.09, $C_1$ =0.43 and $C_2$ =1.9.

*Fig.1: PMC Diagram: (a) Foam type, (b) Lattice cell type.*

To investigate the relationship between cell structureparameters, porosity, and combustion characteristics, a structure was designed with different edge lengths (a=4-8mm) and a regular hexahedron shape (D=2R=0.25-0.9mm). Mechanical simulation analysis was conducted to evaluate the strength of the lattice cell structure, and a model was established to analyse its flow characteristics in the combustion field. The designed structure was 3D-printed using porous resin material, and a two-step process involving slurry coating and vacuum impregnation was used to prepare ordered SiC porous ceramics. Combustion experiments were conducted to study their combustion characteristics. Temperature measurements were conducted by an infrared thermal imager and a flue gas analyser after the methane combustion experiment, which was at an equivalence ratio of 0.65 ($CH_4$%= 6.4%), the methane flow rate of 0.82 NL/min, and air flow rate of 12 NL/min.

## 3 Results and discussion

The variation in pore size during the impregnation process is shown in Fig.2. The results indicate that as the cell edge length decreases from 8 mm to 4 mm, the increment in pore size (ΔR) gradually diminishes. This trend highlights the increasing difficulty of reducing porosity during the slurry coating process with smaller cell dimensions.

*Fig.2: The variation in pore size during the impregnation process.*

The analysis revealed significant relationships between the geometric parameters of the lattice cell and both porosity and pressure drop, as depicted in the graph. Increasing the lattice cell edge length led to higher porosity, while increasing the strut radius resulted in lower porosity. Interestingly, as the cell edge length decreased, the impact of increasing strut radius on porosity became more pronounced. For instance, with an increase in edge length from a=4 mm to a=8 mm, the difference in porosity for a strut radius of R=0.25 mm was only 2.74%. However, as the strut radius increased to 0.9 mm, the porosity difference soared to 24.45%.

*Fig.3: The porosity and pressure drop with cell size.*

Regarding pressure drop, larger lattice cell edge lengths were associated with reduced pressure drop, whereas increasing strut radius led to higher pressure drop. Notably, as the cell edge length decreased, the influence of increasing strut radius on pressure drops intensified. For example, as the edge length increased from a=4 mm to a=8 mm, the difference in pressure drops for a strut radius of R=0.25 mm was merely 0.68 Pa/m. However, with an increase in strut radius to 0.9 mm, the pressure drop difference surged to 4.19 Pa/m. It is worth highlighting that when the strut radius exceeded

0.5 mm, the impact of cell edge length and pore size on porosity and pressure drop became even more pronounced.

*Fig.4: The equivalent stress and strain with cell size.*

The investigation of H-system ordered cell structures subjected to a 0.02 mm (0.1% strain) displacement loading highlighted important findings. It was observed that larger cell edge lengths contributed to reduced maximum equivalent stress and strain within the structure, while larger pore sizes led to increased stress and strain. Remarkably, based on the critical flexural strength of SiC (CMOR = 41.9 MPa), optimal design dimensions for structural stability were identified: a cell edge length of 4 mm required a pore radius (R) below 0.45 mm, a cell edge length of 6 mm necessitated R to be below 0.5 mm or equal to 0.6 mm, and a cell edge length of 8 mm demanded an R below 0.9 mm.

*Fig.5: Temperature distribution of different structures.*

The temperature distribution within the combustion chamber was uniform, as shown in Fig.5. Notably, the combustor with a strut radius (R) of 0.5 mm and a cell length (a) of 8 mm exhibited the highest peak temperature, reaching 784°C. In contrast, the combustor with a cell length of 4 mm had the lowest peak temperature, a significant 337.9°C lower than the maximum temperature observed in the combustor. This disparity in temperature arises from incomplete combustion at a cell length of 4 mm, leading to considerably lower temperatures compared to conditions of complete combustion.

*Fig.6: Static pressure distribution along the flow direction.*

Tab. 1: Pollunt products of *different structures*.

| | $H_{8\_0.3}$ | $H_{8\_0.5}$ | $H_{6\_0.3}$ | $H_{6\_0.5}$ | $H_{4\_0.3}$ | $H_{4\_0.5}$ |
|---|---|---|---|---|---|---|
| CO/ppm | 100 | 106 | 203 | 284 | 253 | 872 |
| NO/ppm | 0 | 0 | 0 | 0 | 0 | 0 |
| NO$_2$/ppm | 0 | 0 | 0 | 0.3 | 0 | 0.2 |
| NO$_X$/ppm | 0 | 0 | 0 | 0.3 | 0 | 0.2 |
| 烟温/°C | 310.6 | 272.7 | 348.9 | 329.9 | 324.7 | 312.6 |

The sufficient combustion of gas in PMC significantly reduces pollutant emissions. The exhaust gas composition during stable combustion is summarized in Table 1. Generally, lower CO content in the exhaust gas signifies a higher degree of combustion. It is worth noting that the cell structure with a=8 mm enhances the combustion of fuel gases within the combustor, resulting in more complete combustion compared to a=6 mm and a=4 mm. Regarding NOx emissions, four of the combustors showed no NOx production, while the remaining two had low emissions of approximately 0.2-0.3 ppm, significantly below those of randomly distributed porous media combustors. These findings indicate that, at a constant strut radius (R), a decrease in cell pore length reduces porosity and diminishes the combustion performance of silicon carbide porous ceramics.

## CONCLUSIONS

The irregularity of hole sizes caused by the sponge template leads to uneven combustion intensity and increased thermal shock damage in PMC. An ordered lattice structure is proposed as a substitute for the disordered sponge template. The findings of the present study reveal that increasing the cell side length and reducing the pore diameter enhance the porosity of the porous medium, resulting in reduced pressure resistance. Additionally, this adjustment leads to a more uniform temperature distribution, ultimately improving combustion efficiency, increasing the conversion rate of CH$_4$, and reducing CO emissions. These results demonstrate the significance of optimizing cell structure parameters in achieving enhanced combustion performance in PMB.

# TRANSMISSION CONDITIONS ACROSS A THIN THERMOELASTIC INTERPHASE

Shubhra Pade[1]; Andrea Piccolroaz[2]; Séverine Romero Baivier[3]

[1]Università degli Studi di Trento, Tento, Italy; [2]University of Trento, Department of Civil, Environmental and Mechanical Engineering, Trento, Italy; [3]Vesuvius group plc, Department of Advanced Refractories, Ghlin, Belgium

Refractory devices composed of ceramics are employed wherever there is contact with molten metals as in crucible, filters, furnaces or systems for flow control. These devices are composed as a mixture of two or more materials, and thus have varying elastic and thermal properties. As these devices operate at very high temperatures, the mixture undergoes thermal expansion at different rates, which can lead to crack initiation, and ultimately the failure of the materials.

The work mainly focuses on the development of transmission conditions across a thin thermoelastic interphase. The interphase is modeled as a thin, „spring-type" elastic layer of constant thickness, whose properties are different from those of the surrounding media, and is subjected to a high thermal load. This interphase is then reduced to „zero thickness" leading to imperfect interface conditions. An asymptotic approach is used to derive the non-linear transmission conditions across the interface, and results are analyzed using finite element methods.

# REIMAGINING REFRACTORIES: HOW PROFESSIONAL SOCIETIES INFLUENCE THE PERCEPTION OF REFRACTORY TECHNOLOGY AND ENGINEERING

Eileen J. De Guire, Mark J. Mecklenborg

The American Ceramic Society, Westerville, Ohio, USA

## ABSTRACT

Refractory ceramics are essential to industrial heat-intensive processes but generally are used in environments that hide them from view. However, they fill a vital role in achieving sustainable manufacturing, improving efficiency, reducing carbon emissions, adapting to hydrogen fuels, adapting to new high-performance alloy compositions, and more. As such, the refractory industry offers straight-to-the-bottom line opportunities for engineers to impact today's grand challenges. However, the industry competes for talent with emerging materials science technologies, and it suffers from an outdated perception as a dusty, staid industry. The American Ceramic Society and its Refractory Ceramics Division have taken on the challenge of raising the visibility of this "invisible" industry and of presenting the industry as an innovative discipline that solves urgent problems with global impact.

## INTRODUCTION

According to the World Refractories Association (WRA), 70% of all refractory products are sold to the steel industry. Thus, as the steel industry goes, so also goes the refractory industry. [1]

The steel industry is changing, as are other processing industries that rely on heat and heat-treatment processes. Energy-intensive industries are embracing their roles as global citizens, acknowledging their corporate responsibility to mitigate climate change by transitioning to sustainable production methods, among other steps. Plus, these companies' customers are challenging them to make not just refractory products sustainably but also to develop new products that will help the customers make their own products sustainably. For example, automakers need high-strength, lightweight steel alloys that will reduce the weight of cars and thereby make room for large battery packs in electric vehicles.

New steel, aluminum, glass, etc. compositions change the hot face reaction chemistries inside furnaces. Additionally, experiments with hydrogen fuel by steelmakers, glassmakers, and others change the combustion chamber chemistries and melt–refractory reactions.

The refractory industry, as the literal "holders of the heat," is an essential partner in the drive toward sustainable manufacturing. And, in turn, refractory manufacturers are embracing sustainable manufacturing of their products across the entire value chain.

The UNITECR 2022 and 2023 programs point to some of the new science, engineering, and skills that the refractory industry needs: nanoscale microstructure engineering, modelling and artificial intelligence, recycling, slag and mine tailing reclamation, and more.

Despite the essential role refractories have in all heat processing—from steelmaking to glassmaking to pizza ovens—they have low visibility. Few people entering their career decision-making pathway are aware of refractories.

The refractory industry faces stiff competition for engineering talent. Based on data the Society of Women Engineers compiled from the United States Bureau of Labor Statistics job outlook for engineers, between 2021–2031, demand for materials engineers in the U.S. is expected to grow 6.1%. Demand also will increase for other manufacturing-related engineering disciplines: chemical, health and safety, industrial, and mechanical engineers. [2]

Within the refractory ceramic engineering subdiscipline, other end uses such as hypersonic vehicles compete for materials scientists trained in high-temperature ceramic materials, their synthesis, properties, and applications.

However, for those motivated by the urgency of the impact they can have—and the speed at which they can affect that impact—a refractory engineering career offers a rewarding pathway.

Many factors influence career choice. This paper presents some actions The American Ceramic Society is taking to promote STEM careers broadly and careers in the ceramic and glass industry specifically through outreach, community building, publications, multi-media communications, and workforce development. Several examples that pertain specifically to refractory engineering careers will be presented.

## CAREER DECISIONS START EARLY

Young children are often asked what they want to be when they grow up. As students approach the end of their secondary school years, they are asked again, but this time the question carries more importance. Students who choose university are asked to refine the question further: What major will you study? Will you go to graduate school, medical school, law school, etc.?

Recent research shows that the first inquiry—what you want to be when you grow up—may be the most important gateway.

In 2020 Ph.D. research [3], Ralph C. Tillinghast asked about 2,500 working science and engineering professionals the following questions:

1. In what grade did you first become interested in science and/or engineering?
2. In what grade did you first see yourself as a scientist and/or engineer?
3. In what grade did you decide to become a scientist or engineer?
The responses, summarized in Figure 1, show that awareness and interest start in the preschool years. Interest declines in first and second grade, but by third grade—the age at which most students have become skilled readers—interest in science and engineering undergoes a steep increase. The incidence of first interest in science and engineering is approximately constant through sixth grade, when it starts to wane in middle school and high school. Presumably, as students advance through the elementary and middle school curriculum, most will have been introduced to science and/or engineering (S&E).

The orange line represents the grade at which students first imagined the possibility of becoming scientists or engineers. This line shows that students first begin to consider S&E careers in third grade—the same age at which a more informed awareness of S&E begins. Students' openness to S&E careers continues to increase into high school and begins to decline as students make career path decisions during the second half of high school. This research shows that there are key points at which outreach and intervention will take root.

The Ceramic and Glass Industry Foundation (CGIF) was established by ACerS in 2014 to advance the educational outreach of the American Ceramic Society and serve as ACerS's philanthropic arm. Its mission is to "attract, inspire, and support the next generation of ceramic and glass professionals," which it does through the outreach activities listed in Table 1. [4]

CGIF's programs intervene at key points on the career pathway: K–12, undergraduate, and graduate levels. The CGIF Materials Science Classroom Kits (Figure 2) and Mini Materials Kits leverage the natural curiosity of young students in the context of materials. Undergraduate and graduate students are supported by scholarships, travel grants, and professional development programs. The reach of these programs is significant, as highlighted in the table.

Tab. 1: CGIF outreach programs

| Program | Target audience | Program goal | 2022 impact |
|---|---|---|---|

*Fig. 2: The "Hot or Not" lesson in CGIF's Materials Science Classroom Kit teaches K–12 students about refractories. Teachers can learn how to teach MSE concepts using the kits by attending a teacher workshop or by watching YouTube demonstrations. All kits come with Next Generation Science Standards aligned lesson plans.*

## COMMUNITY BUILDING

ACerS' Refractory Ceramics Division (RCD) is among the oldest of the Society's 11 Divisions. In collaboration with ACerS St. Louis Section (SLS), RCD has organized the Refractory Ceramics Symposium for 52 consecutive years. Recent themes and presentations reflect the evolving grand challenge issues for refractory engineers to solve: sustainability, hydrogen firing, recycling, nanoscale effects, and more. RCD and the SLS intentionally recruit and nurture young professionals to organize the symposium and give presentations. Nearly 40% of the 200 people who attended the 2023 Symposium were attending for the first time. Anecdotally, many of those first-timers were early career engineers (Figure 3). RCD also organizes sessions at ACerS Annual Meeting at MS&T and is a founding member of UNITECR.

Taylor Perrey and Austin Scheer, both of Zircoa, are representative of the new generation of refractory engineers attending the Refractories Symposium.

Anthony Williamson of Morgan Advanced Ceramics recently earned a B.S. in chemical engineering before entering the refractoryindustry.

*Fig. 3: The proportion of young professionals attending the St. Louis Section/Refractory Ceramics Division meeting has increased in recent years. About 40% of attendees at the 2023 Symposium were first-timers.*

## CONTENT

The Society has published authoritative content in the form of books, journals, and magazines for more than 100 years. Modern internet and social media tools provide new opportunities to showcase the refractory industry. ACerS's *Ceramic Tech Chat* podcast, for example, which is hosted by *ACerS Bulletin* editors, showcases leaders in ceramic and glass science, including the refractory industry. The refractory professionals talk about the industry, as well as their personal career stories (Table 2). Additionally, the High Temperature Times podcast, which is published by HarbisonWalker International and promoted on the ACerS website, provides an excellent insight into the refractory industry. [5]

Each March issue of the *ACerS Bulletin* magazine focuses on refractories. Themes, which come from ACerS members in the refractory industry, reflect the evolution of refractory technology as the industry responds to new requirements. Some recent themes include Refractory solutions for sustainability, Innovations in refractory technology, Going green: Ceramics in renewable energy, Refractory lifecycles, and Refractories as engineered ceramics for industry. The Society promotes *Bulletin* content through email to a global audience of 13,000. The audience expands with promotion of *Bulletin* content over LinkedIn, Facebook, and Twitter. The new digital-based *Bulletin* ensures optimal discoverability of *Bulletin* content. This publishing format allows collection of metrics and will allow *Bulletin* editors to tailor future content.

The Society publishes a thrice-weekly blog called *Ceramic Tech Today* (*CTT*). Through *CTT*, the Society curates content from around the world for the ceramic and glass community. In addition, each issue contains original reporting on developments in the industry. *CTT* is distributed to a global audience of about 11,000, which provides excellent visibility of topics to a targeted audience. Recent blog posts related to refractory topics include

- Effects of expanded graphite content on the performance of magnesia carbon bricks,
- Singling out discrepancies: The effect of magnesium source on a ceramic's final properties,
- New test method for aluminosilicate refractories offers better insight into real-world alkali attack mechanisms,
- Ensuring safe production of metal goods: A review of alumina spinel castables for steel ladles,
- Ceramics processing—are we using the correct sintering and creep models?
- Refractories Symposium resumes in St. Louis with sustainability theme.

Tab. 2: *Ceramic Tech Chat* podcast guests and topics relevant to the refractory industry

| Guest | Affiliation | Podcast topic |
|---|---|---|
| Dana Goski | Allied Mineral Products | Why we like two-year tech degrees |
| Matt Creedon | Washington Mills | Local manufacturing in a global economy |
| Carol Jackson | HWI (formerly) and WRA (formerly) | Leading a global refractories company |

| Christopher Berndt | Swinburne University of Technology, Australia | Engineering surfaces using thermal spray |
| Jürgen Rödel | Technical University of Darmstad, Germany | Actions for a sustainable future |
| Rita Baranwal | Westinghouse Electric | New technologies for nuclear energy |

## WORKFORCE DEVELOPMENT

Many engineers entering the refractory industry today have general MSE or nonmaterials backgrounds. ACerS partnered with the Edward Orton Jr. Ceramic Foundation to create two certificate programs to train new hires; up-skill non-MSE engineers; and train technicians, production staff, and other personnel, such as purchasing agents and sales engineers.

The Basic Refractory Technology and Intermediate Refractory Technology certificate programs are taught primarily online and conclude with an onsite, hands-on course. Table 3 summarizes the certificate curricula, plus additional refractory courses. Participants may take the full sequence of courses to earn a certificate, or they may enroll in individual courses to build specific skills. Students may purchase a prerecorded course option if attending a live course is impractical. [6]

Since establishing the program in 2020, eight courses have been taught to 180 students, with about one-fourth attending from outside the U.S. Students have said, "It helped me make connections to the work I do daily and understand the background of the materials I work with" and "It was great that the course attacks the knowledge from first principles. Exactly what I needed to help my understanding of refractory. Magnifique."

Tab. 3: Orton–ACerS Refractory Technology program courses.

**SUMMARY**

As a professional society, The American Ceramic Society has many tools in its arsenal for promoting careers in STEM and for highlighting careers in the refractory industry. Outreach through student programs, podcast interviews, and publications (blog, magazine, journals, books) communicates the impact of refractory engineering careers to address urgent grand challenges in impactful ways. ACerS's workforce partnership with the Edward Orton Jr. Ceramic Foundation provides practical, immediate, high-quality education for the refractory industry's incumbent workforce and for those new to the industry.

# ON REFRACTORY ENGINEERING EDUCATION EVOLUTION

Michel Rigaud, Ecole Polytechnique, Montreal, Canada

Jacques Poirier, CEMHTI-CNRS, University Orleans, France

**ABSTRACT**

This paper provides answers to stay tune with the "Conceptual Age" refractory producers, users and service providers are already facing for the coming years. This New Age is a major change of paradigm.

Some answers are given to consider how the new research and innovations for new refractory solutions should be conducted with the adequate human resources required for the purposes.

After a review of the education tools now available, those to be the further developed are

then presented, which will involve the participation of all the refractory constituency.

## 1. INTRODUCTION

It took two centuries for the factory workers to outnumber the farmer workers, but then less than one century for the knowledge worker to become the predominant ones.

To-day many of the changes in our societies are propelled by the technological efficiency of the communication networks, to facilitate technology transfers to support the commercial exchanges and the global economy. Just realize how fast the use of the Artificial Intelligence(A.I) and the CHAT-GPT have spread!

This is impacting the entire educational system. Yes, the refractory engineering education has evolved. However, to provide the required knowledge workers with the required technical expertise, it is required to train more engineers to become ''creators" of long term solutions, with a broad vision of our contemporary world.

After a brief review about the FIRE network as a starting block, the needs for innovations and innovators, then of creators will be clarified, so that the need to extend the CDIO approach will be made apparent. To conceive the future with a positively built-thinking mind, acting in a competitive spirit (i.e., keeping competition and collaboration in balance) will lead to the conclusion. It is a matter of education and collaboration.

## 2. THE FIRE'S NETWORK

Fire has been able to develop into a non-bricks and mortars network with 10 academic institutions (Austria, Brazil, China, France (2), Germany (2), Korea, Spain, United-States) with 14 industrial partners. Details of the FIRE mission, goals, research, and education programs have been described at different times of its evolution [1-2-3]and presented on its web-page (http://fire-refractory.org). In short FIRE does fund international studies and research activities associated to allow graduate students to obtain a degree in refractory materials. FIRE pools the expertise, the experience and the

712

willingness of some worldwide most competent persons and the availability of their installations to tackle some innovative research programs at the precompetitive level. In the last 15 years, FIRE has delivered over 50 diplomas to FIRE'S alumni, most of them still strongly related to our industrial sector, including manufacturers, raw materials providers, all others service providers, and users of refractories.

## 3. INNOVATIONS AND INNOVATORS

To appreciate fully what innovations involved, it is important to deal with patent rights, technology transfer limits, business laws, foreign exchanges policies, technology forecasting, strategic planning, including the economical, environmental and ethical aspects.

From an educational point of view to train 'innovator' this constitute an immense challenge to learn, to learn to learn, to teach, to use in a rapidly changing world.  But there is no reason not to tackle the task, challenging partners, and the students to develop bit by bit some of the needed innovations at our disposal right now: such as better high temperature insulting materials, others with ultra high temperature corrosion and erosion resistance, and for to-morrow refractories for new carbon free processes, and also near-net-shaped casting of steels. FIRE'S contribution into such projects as ATHOR and CESAREF [4] are valuable steps forward in that direction.

## 4. CREATORS

In order to benefit from technical innovations such as robotization, virtual reality, artificial intelligence, etc.…to bring the trained refractory engineers to be more at ease into the 'Conceptual Age' [5] it is time to educate new potential refractory leaders to realize that the human cultural values are deeply influenced by the objects being manufactures in our surroundings. It does require to develop candidates with personal and interpersonal skills.

Then FIRE'S students should be confronted with different aspects of: i) knowledge discovery along with data mining, ii) system thinking and discussion about the abstraction necessary to define and model systems and to use metaphoric thoughts, taking on account that the brain rules, iii) professional skills and the attitudes to assert the social and technical impact of new discoveries and innovations.

To incorporate such preoccupations into a graduate a cursus on refractories do require team-teaching with colleagues of cognitive sciences faculties such psychology of learning and/or sociology. The goal is to facilitate the development of the right side of our brain. To distinguish between objective (left-brain) and subjective (right-brain) knowledges, in order to move into 'Conceptual Age' had been considered recently with other academic refractory colleagues (4) in some more details.

## 5. THE CDIO APPROACH IN THE FUTURE

CDIO approach stands for Conceive, Design, Implement and Organize. This is a road-map well defined, in details, in [6]. FIRE'S alumni have been trained. as graduate students, at the M.Sc. and Ph.D. levels, to accomplished experimental research projects focus on industrial needs, defined collaboratively in within the FIRE network. In order to meet perceivable future needs, more emphasis on imaginative rationality must be implemented.

At the end, FIRE alumni should have learned how to implement efficient changes at 4 levels: i) the technical efficiency based on solid STEM core, ii) the production efficiency based on pragmatism and memorable experiences, iii) the organizational efficiency based on some management know-how, iv) the economical efficiency based on financial and political analysis.

It is necessary to insist on the personal and interpersonal skills required to grasp the impact of new technological innovations and a certain awareness of the discovers made by the human cognitive sciences.

To finally benefit from such an approach, for the immediate future, it would still be necessary to conclude an evaluation procedure, to be followed by the academic institutions with the accepted standards, approved by the network members, to provide the proper feed-back, to appreciate the evolution over time.

## 6. CONCLUSION

Under the hospices of the Unified Technical Conference on Refractories it is good to notice that since 2003, Education has always been considered as an issue of concern. It is essential to keep such an interest on educational aspects to be able to seduce and recruit the human ressources required to surf on the E-waves. E for economy, E for ethic (a key determinant in the 'Conceptual Age' we do need to adjust to).

All our leaders need to coordinate their efforts and join forces to induce university administrators and politicians at all levels, to sustain refractory engineering education as a needed activity in the globalized world education system.

It is essential to define broad enough vision to allow for new initiatives to emerge. And yes networking in a competitive way is surely a way to prosper. Again, it is a matter of education and collaboration.

## future – systemrelevant – sustainable – unique

### Knowledge – Education – Training

The Integrated Refractory Education System (IRES) supports the development of young school leavers across all levels of vocational education and training, from basic apprenticeship courses through to graduate and doctorate programmes. The Koblenz University of Applied Sciences offers a complementary vocational programme that leads to the qualification of Ceramic Technician ("Keramiktechniker") as well as an academic programme leading to the degree of Bachelor of Engineering which, in cooperation with the University of Koblenz and Landau, can be crowned with the degree of Master of Ceramic Science and Engineering. This cluster of expertise in conjunction with the close collaborative relationship maintained with the University and the Ceramics Education and Research Centre (Bildungs- und Forschungszentrums Keramik e.V. / BFZK) enables the wealth of knowledge about refractory products, their manufacture and use to be imparted and shared in a well-condensed way across all levels, up to the university-awarded doctoral degree.

**European Centre for Refractories**

### Bildungs- und Forschungszentrum Keramik (BFZK)

BFZK offers with its 8 institutes in Höhr-Grenzhausen a combination of facilities that is unique in the world, all of which deal with the topic of training and further education as well as research within ceramics. The Montabaur vocational school, with its ceramics branch, is one of the dual partners in ceramics initial training and teaches the necessary theoretical knowledge for successful completion as a skilled worker in industry or as a journeyman in the trade. Further training as a ceramics technician or ceramics designer at the technical colleges for ceramics technology and ceramics design is then just as possible as studying for a bachelor's or master's degree in engineering – materials engineering, ceramics and glass – on the Westerwald Campus. Furthermore, with the Bachelor or Master of Fine Arts at the Institute for Artistic Ceramics and Glass, which also belongs to the Koblenz University of Applied Sciences, there are opportunities for further training in areas of art. Information about the 8 members of the education and research center: www.bfzk.de

# The European Center of Refractories

## Study Guide "Materials Engineering Glass & Ceramics"

**NEW**

The Koblenz University of Applied Sciences offers an application-oriented, engineering Bachelor of Engineering, Bachelor of Engineering dual, Ceramics Industrial Engineer and a consecutive Master of Ceramic Science and Engineering on the Westerwald campus. The range of courses: broadly based, clearly focused on ceramics and glass, unique. The location can look back on a 150-year tradition in training and is the oldest location of the Koblenz University of Applied Sciences. Together with the local research institutions, the European Center for Refractories (ECREF) and the Research Institute for Inorganic Materials-Glass-Ceramics (FGK), the location forms a unique concentration of training and research in a small radius. All those involved benefit from research and teaching, which also directly benefit training through joint projects with industry-related research. Due to the close and exceptionally good networking with the refractory or ceramic industry, contacts are made at an early stage, which enables the students to write their theses in the companies where they later find their professional start. Both bachelor's and master's students have excellent opportunities on the job market.

## Master's degree "Refractory Engineering" Tandem professorship at Koblenz University of Applied Sciences

**Prof. Dr. Amin El Gammal**

The German refractory industry is a world leader in product quality and in the application areas of high-temperature processes for steel, cement or glass. The processing of refractory materials is of particular importance. That is why the German refractory industry is supporting the establishment of a professorship "Refractory Engineering" at the Koblenz University of Applied Sciences.as an industrial partner. On the professorship Dr. Amin El Gammal appointed. This tandem professorship between the Koblenz University and the refractory industry will be connected in the European Refractory Center and the Westerwald-Campus and organized by ECREF gGmbH. The development of the part-time English-language master's degree program "Refractory Engineering" is aimed in particular at international bachelor's graduates in materials science or civil engineering who are about to or after starting their business careers. The content will be divided into the three areas of "Refractory Engineering", "Refractory Materials" and "Services". Aspects such as building law, construction site management or approval procedures are also dealt with in the curriculum.

# EU ATHOR PROJECT (2017–2022) – DIRECT IMPACTS ON INTERNATIONAL REFRACTORY COMMUNITY

Marc HUGER, University of Limoges, Institute of Research for Ceramics (IRCER), UMR 7315, Limoges, France

**ABSTRACT**

ATHOR (Advanced THermomechanical multiscale mOdelling of Refractory linings) was an innovative, collaborative and interdisciplinary European project that brought together 6 academic beneficiaries and 8 private partners. The main objective was to develop high-end engineering technologies in material engineering and numerical simulations thanks to an intensive cooperation between academia, raw materials suppliers, refractory producers and end-users. Starting from material characterization, all significant properties were investigated, including fracture behaviour, tension and compression creep behaviour, corrosion and thermal shock resistance. The interdisciplinary aspects have been addressed thanks to a multiscale approach looking at the influences of micro-, meso- and macro-characteristics on each other. To conduct their research and interlink the different topics, the 15 recruited researchers have taken advantage of the most sophisticated numerical tools to model, design and predict the life of different lining configurations in critical operation conditions. The ATHOR network was deeply committed to provide a combination of research and training activities which has supported and strengthened the initiative of the Federation for International Refractory Research and Education (FIRE). The different key impacts, achieved on several levels in the international refractory community, of this EU project, will be highlighted here.

## INTRODUCTION

Refractories are heat-resistant materials used as inner linings of high temperature furnaces, reactors and processing units. Unique and advanced ceramic materials, refractories sustain complex combinations of thermomechanical stresses and chemical/physical wear generated by fluids and chemical agents used during high temperature fluid processing. As the only low-cost family of materials able to sustain operating conditions, at temperatures typically above 1000°C, refractories are widely used in energy intensive industries such as Iron and Steel production. Vessels commonly lined with refractories include the steel ladle which, due to the harsh environment, typically require the lining to be changed every 8 weeks. Extending the lifetime of refractories under such conditions is thus of importance both economically and environmentally.

ATHOR was a H2020 MSCA European Training Network combining seven academic and eight industrial partners across Europe. The project, which has run from October 2017 to March 2022, focussed on the training of 15 young researchers in multi engineering required fields for a better understanding of thermomechanical behaviour of refractory linings. The research was aimed at the design of more robust and reliable refractory linings, undertaken through the combination of advance numerical modelling with both small- and large-scale laboratory research (from the micro to the 10-meter scale). This will allow the development of innovative numerical simulations that will form the basis of future research as well as monitoring form a safe location. Ultimately, it represents a reduction of the refractory costs, an increase of the equipment's availability and an enhanced process control. In total, 16 milestones have been past, and 43 deliverables have been submitted to the European Commission. This paper is an overview of the project, the achieved results and the socio-economic impact.

## ATHOR APPROACH TO REFRACTORIES RESEARCH

The European steel industry is a world leader in innovation and environmental sustainability. A constant engineering of refractories is needed to cope with new and more demanding requirements in the steel making process. The steel ladle forms the hearth of the steel making process and is a major refractory using facility accounting for about ¼ of all refractory consumption. Dependent on its purpose and position in the steel ladle, the requirements for the refractory materials are various ranging from high thermal stability to high erosion resistance, high corrosion resistance, penetration resistance, thermomechanical stability, impact resistance, flexibility and creep resistance. The concerted work in the ATHOR program was therefore be focused on the steel ladle as model installation.

The main scientific goals of ATHOR were to adapt and develop the most advanced modelling strategies and experimental technologies to the refractories field such that reliable computations and measurements, in the temperature range of the applications of these materials, could be performed. ATHOR targets the development of high-end engineering technologies in the fields of material's science and numerical simulations to give a substantial contribution through the design of more robust and reliable refractory linings.

The main training objective was to prepare the 15 Early-Stage Researchers (ESRs) to be the next generation of highly employable scientists and engineers in the refractory and related sectors. With the evolution of industry towards digital twins and the use of advanced numerical simulations based on real world data, the ESRs needed a basis in both numerical simulations and fundamental materials science. This was achieved through a series of Refractory Training Courses (RTCs) and online webinars, which were recorded and stored in a database such that future interested PhD students can benefit from the time and energy given by the ATHOR industrial and academic experts. The highly interconnected and international nature of this project meant that the ESRs were required to communicate extremely precisely with each other as well as the industrial and academic partners to determine the exact nature of the data required for the numerical simulations and the parameters used in the lab to generate this information. Communications skills were thus also developed as well as soft-skills important for the future employability of the ESRs such as leadership skills. The training was provided at both the local universities and via centrally organised activities.

The specific objectives of the ATHOR network were defined as:
- Deliver the best training to young researchers to reach a scientific level by addressing their scientific and transversal needs.
- Enable young researchers, through their tailored training and regular mobility, to "cross-pollinate" industry and academia;
- Give the young researchers the opportunity to be close to the industry and to face the actual engineering challenges;
- Support the development of new characterization devices and modelling methods to offer solutions to current S/T challenges;
- Create a multidisciplinary environment where industries and academia can share ideas and find solutions together.
- Explore the capability of advanced numerical modelling in order to design better materials and better refractory linings, consequently improving energy efficiency and thermomechanical properties of products.
- Assist the European refractory and steelmaking industries to identify technological improvements by providing high performance characterization and modelling tools which can improve their competitiveness.

To guarantee a maximum economic impact when ATHOR methodologies were implemented in practice, the consortium decided to carry out research on different refractory materials, in well organised Work Packages. These Work Packages:
- involved materials with different chemical composition and microstructure so as to cover a wide diversity of end-user applications;
- involved different key scientific topics sufficiently critical and/or of economically importance;

717

- were sufficiently generic for the European market to cover the different current interests of the industrial partners.

## ORGANISATION OF THE SCIENTIFIC WPS

The ATHOR project brought together 7 academic and 8 industrial partners to carry out cutting-edge research, using state-of-the-art technology, in highly specialized areas including materials science, structural engineering and numerical modelling. Research ranged from, the development of techniques to initiate, track and analyse small scale crack formation, to the construction and analysis of large-scale structures, such as a 3D pilot steel ladle, which were subjected to various heating and loading regimes.

The scientific work program consisted of 4 highly interconnected, scientific Work Packages, Figure 1.

*Figure 1 : The four highly interconnected, scientific Work Packages of the ATHOR project.*

WP1 was dedicated to the improvement of measurements tools through the development of experimental methods (contactless optical techniques, high temperature strain gauges…). These tools were then employed in the collection of the mechanical data necessary to study refractory materials in service conditions (temperature up to 1500°C, large structures, industrial environment). Previously, these techniques were mainly used for different materials in a laboratory environment up to 500 °C and for small structures. The aim of WP1 was thus to improve these experimental optical methods in order to accurately quantify low level of strain fields and to make measurements possible in extreme conditions associated with the environment of in service refractory materials.

WP2 was dedicated to the characterization of selected materials, at room and elevated temperatures, in a virgin or corroded state by conventional and specific experimental techniques. This WP has provided all the experimental results needed for characterisation and understanding of the materials behaviour. Furthermore, the input parameters for the finite element simulation have been determined for the modelling from micro to macro scale. WP2 took advantage of the ATHOR network to apply the most appropriate experimental device to each task. Where available, different methods within the ATHOR network were used to validate the experimental results and improve the testing procedures.

WP3 was dedicated to the production of dedicated modelling methods and numerical tools to optimize the design of industrial refractory linings. The different proposed approaches cover all the scales that impact the thermomechanical refractory lining behaviour: from the material scale (i.e. microstructure) to the industrial lining (structural computation). The multiscale approach was developed from micro to macro to establish the models and then, inversely, from macro to micro to optimize each scale from the final vessel requirements point of view.

WP4 was dedicate to advanced measurements for numerical validation. As such, it closely interacted with WP1 and WP3, the improved and newly developed methodologies for thermal and mechanical characterization of refractories within WP1 were used in WP4. Using a multiscale approach, measurements were performed to validate the advanced numerical models developed in WP3.

## KEY SCIENTIFIC RESULTS

### Improvement of measurements tools

Expertise developed by ATHOR partners, for example on Digital Image Correlation, mark tracking in 2D and stereovision configuration, were applied to monitor deformation and temperature of the steel shell of the industrial ladle to validate the results of numerical modelling based on mesoscopic characterization. Moreover, a bi-axial high temperature testing device, for a 1 m² masonry wall, available through ATHOR network, was improved thanks to additional instrumentation. A second laboratory pilot device, at around 2 m in diameter, was designed to reproduce the stress state induce by the cylindrical shape of industrial vessels. They were used to validate, at mesoscopic level, the results of numerical modelling based on new mathematical and numerical method taking into account mesoscopic materials and contact properties. All the different experimental technologies used for the characterization of individual materials, subsystems (e.g. bricks with or without mortar, castable-based linings, bed joints…) and the overall thermomechanical behaviour of selected industrial devices, were strongly enhanced through WP1. These included thermal and strain fields instrumentation as well as devices for thermo-physical properties characterisation, thermomechanical characterisation and validation of masonry and vessels.

### Advanced characterization of raw materials, refractories and joints

The experimental results, of the refractory materials under investigation, that were required to characterise and understand the materials behaviour were obtained here. The microstructure and its evolution were described, thermal and mechanical characterisations were carried out, fundamental corrosion mechanisms were described as well as the mechanical characterisation of corroded samples and finally the behaviour of the joints was defined. Thermal expansion and thermal conductivity were tested by laser flash or hot wire method, Young's modulus by ultrasonic echography or by Resonance Frequency and Damping Analyser (RFDA), damage monitoring by acoustic emission, stress-strain and creep laws were determined for tension and compression and work of fracture by wedge splitting test.

### Innovative modelling from microstructure to industrial scale

Different modelling techniques were used depending on the material being modelled. The Discrete Element Method (DEM) was used for the modelling of the microstructure and thermomechanical behaviour. When regarding the modelling of bricks and joints, the multi-surface plasticity theory and nonlinear homogenisation method were used and compared. For the full-scale industrial steel ladle, the simulation of a representative volume element was also compared with the multi-surface plasticity theory and nonlinear homogenisation method.

### Advanced measurements for numerical validation

Refractory masonries were characterized experimentally, in order to obtain data for the validation of advanced analysis methods, as well as for subsequent simulation of industrial problems to allow industrial device optimization. The selected materials and structures were characterized under different conditions, and their thermal and mechanical properties investigated under complex limit conditions. A large and comprehensive experimental campaign was implemented, wallets were constructed and subjected to uniaxial and biaxial loading from room temperature to high temperature. A 3D pilot steel ladle was designed, constructed and tested. The 3D pilot scale and the full-scale models investigated have provided unique and valuable data for the calibration and validation of the advanced numerical macro-models developed in WP3.

## RESULTS DISSEMINATION AND EXPLOITATION

As part of the ATHOR training program, the 15 ESRs have had the opportunity to disseminate the results of their cutting-edge research through workshops, summer schools, international journals and

international conferences across the globe. The ATHOR ESRs have participated in conferences in Japan, China, America and Europe and have published their work in Rank A journals such as the Journal of the European Ceramic Society, Ceramics International and the International Journal of Mechanical Sciences. These published results are openly available via the ATHOR website and on the Zenodo platform, the list of published articles is presented below:

This list of publications will continue to be added to as the ESRs finalise their PhDs which is standard for this type of project. However, while the PhDs have come to an end, the work that has been produced during ATHOR will continue to be exploited. For example, measurement tools that have been developed and improved, such as the ATHORNA device, bi-axial press and 3D pilot plant, will continue to be used by the industrial partners to generate data for future projects. A database of thermomechanical behaviour of large-scale specimens has also been developed for different testing configurations. The advanced characterisation of raw materials, refractories and joints has led to a plethora of information being made available to partners to use as a baseline against which future products can be compared. This work also demonstrated how microstructures can improve resistance against thermomechanical loads by, for example, inducing a dedicated microcrack formation. This phenomenon has the potential to be exploited in other refractory applications such-as in the aluminum, foundry, cement and petrochemical industries. Several numerical models have been developed over the course of ATHOR to determine material parameters and simulate the thermomechanical behaviour of refractory materials. These models are now being employed in both academic and industrial partners in various ongoing projects.

**SOCIO-ECONOMIC IMPACT OF THE PROJECT**
ATHOR was built on an international network of academic and industrial institutes (Federation for International Refractory research and Education - FIRE) focused on the development of the refractory industry. This network aims to promote the refractories industry and provide training to young researchers. This solid basis for the ATHOR project has led to a free-flowing exchange between the

partners from the very beginning of the project and this strong foundation has enabled the consortium to adjust to the changes to the initial planning due to the COVID-19 pandemic. This has limited the effect the pandemic has had on the project and resulted in high impact achievements on several levels.

**Direct impact of ATHOR on the ESRs**
The employability of the ATHOR ESRs has been greatly impacted through participation in this project. They have received training on cutting-edge research projects using state-of-the-art technology, and on transferable skills. Simultaneously, the ESRs have developed an international network and have gained experience working in an interdisciplinary and intercultural environment. This was achieved, for example, by the completion of at least one secondment, per ESR, with a project partner. Currently 11 out of 15 ESRs are employed as postdocs, engineers or R&D professionals with the four remaining ESRs writing their theses.

The communication skills of the ESRs have also benefitted from ATHOR in several ways. The ESRs have all presented work at international conferences and "ATHOR industrial feedback events" to scientific audiences, improving their presentation skills and increasing their networks at the same time. On top of this, communication with the general public was achieved through making personal videos for the website, as well as contributing to a short video, drawmylife and a short documentary produced by the BBC. ESRs were also face-to-face with the general public in events such-as the European researchers night and during the presentation of the ATHOR travelling exhibition "CeramiK".

The "CeramiK" exhibition is aimed at 11-18 year old students and combines technical concepts, presented in plain language (English and the corresponding translation depending on the location), visually impressive imagery and hands-on experiments and games. The ESRs were all implicated to some extent in the production of the text, images and suggestions of experiments that could capture the imagination of younger students.

All of these activities have enhanced different aspects of the ESRs communication skills while at the same time increasing the visibility of the project on both the scientific stage and to the general public.

Over the course of the project, eight ESRs were also chosen by their peers to represent the ESRs on the ATHOR Supervisory board. This provided ESRs with first-hand experience on how an international, interdisciplinary and intercultural project is managed as well as actively participating in the decisions and actions that were addressed.

**The impact of ATHOR at a local level**
The refractories industry is known within the industry as the "hidden industry". This is because, while refractories are fundamental to the production of materials at high temperature (steel, cement, glass etc.) the general public are unaware of their existence. The lack of visibility has resulted in difficulties recruiting talented research engineers who are required to modernise a business that is relied on by industries across Europe. As such, 15 ATHOR ESRs have been trained with the skills needed to directly respond to this need for high quality engineers in the short term and the visibility of the industry amongst future R&D engineers has been increased to respond to this need over the long term.

This new group of highly skilled, young professionals will induce a new movement in the industry towards new technologies and scientific approaches. They will act as light-towers, multiplicators through their social networks, and be the ambassadors to attract new talents to the refractory industry in the near future. The training received by the ESRs, at the ATHOR Refractory Training Courses and a series of webinars by academic and industrial experts, was recorded and stored on the database ELEANOR. Different levels of access can be granted (ranging from "general public" to "ATHOR consortium only" depending on the preference of the author of the content) that can be accessed by future refractories students free of charge. Thus, local universities have access to high quality,

industrially relevant teaching materials, which will continue to be updated after ATHOR, to provide to future students. It will also be used in an industrial context to train new generations of researchers, engineers, and for those who want to refresh their knowledge.

Regarding the long-term, two main tools were developed during the project, the dedicated videos and the "CeramiK" exhibition. These tools will be used to attract new students in the domain of refractory materials and structures. They will most likely be the best marketing tools to attract people far beyond the four years of the project itself. They will give visibility of the refractory industry to all levels of the society including policy makers, young talent looking to choose their career paths, and to researchers and engineers in industries beyond refractories. Those tools will definitely facilitate the attraction of excellent talent to join the relatively unknown and small refractory community that is so essential to all high temperature processes and to our daily lives.

**The impact of ATHOR on a scientific level**
From refractory producers through to end users, all sections of the refractories value chain have benefitted from the research carried out during the ATHOR project.

New and improved measurement tools have been developed including the ATHORNA device, a bi-axial high temperature testing device and a 3D pilot steel ladle. These were used to validate, at mesoscopic level, the results of numerical modelling based on new mathematical and numerical method taking into account mesoscopic materials and contact properties. Both the measurement tools and models will continue to be exploited by both the industrial and academic partners.

A large database of data, generated from the advanced characterisation of raw materials, used in refractories manufacture has been developed. This will remain available to the project partners for future use.

The optimisation of industrial devices will be made possible through future simulations of industrial problems. In order to obtain data for the validation of advanced analysis methods, refractory masonries were characterized experimentally under different, complex conditions. A large and comprehensive experimental campaign was implemented, wallets were constructed and subjected to uniaxial and biaxial loading from room temperature to high temperature. A 3D pilot steel ladle was designed, constructed and tested. The 3D pilot scale and the full-scale models investigated have provided unique and valuable data for the calibration and validation of the advanced numerical macro-models developed and will continue to be exploited by our partners.

One of the most significant and direct impacts is without a doubt that made by the direct employment of ERSs by the industrial partners. With their expertise on modelling and characterization, the ESRs will be part of new development activities to reduce cost and time required for the development of new materials and technologies.

The scientific and technical exchanges in the ATHOR consortium will continue beyond the life of the project and will facilitate future cooperation between refractory suppliers and steel producers. In addition, having some academic partners beyond the classical ceramic/refractory domain was very useful as the transfer of knowledge was possible and very efficient, specifically in the case of expertise on joints and mortar from the civil engineering field. New ideas have been triggered by the mix of expertise.

This network has already and will continue to foster collaboration and procurement of funding towards the development of other research projects. For example, the recently awarded Horizon Europe MSCA-DN-ID project CESAREF has several original partners from the ATHOR project.

# EU CESAREF PROJECT (2022–2026) – A COMING CONTRIBUTION TO EUROPEAN GREEN DEAL

Marc HUGER, University of Limoges, Institute of Research for Ceramics (IRCER), UMR 7315, Limoges, France

## ABSTRACT

The movement of the Iron & Steelmaking (I&S) industry towards Net-Zero emissions and digitalized processes through disruptive, breakthrough technologies will be achieved through the use of Hydrogen. The biggest challenge for the refractory industry is to continue to meet the performance expectations while, at the same time, moving to a more sustainable production direction. The complexity and urgency of these technological changes, highlighted by the European Green Deal, requires a Concerted European Action on Sustainable Applications of REFractories (CESAREF). A consorted and coordinated European network, with steel, refractory and raw material producers collaborating with key academic poles, will tackle the following key topics: efficient use of raw materials and recycling, microstructure design for increased sustainability, anticipation of hydrogen steelmaking, energy efficiency and durability.

While creating new developments in the I&S and refractory industries, the network will train highly skilled doctoral candidates capable of communicating and disseminating their acquired knowledge. CESAREF will create a core team across the European refractory value chain, accelerating the drive of the European refractory industries towards sustainable materials and processes, as well as Net-Zero emission steel production. This will help to create and secure sustainable employment in the European refractory and I&S industries.

## INTRODUCTION

Refractories are unique ceramic materials used in vessel linings and components to contain and process fluids, solids and/or gases at high temperature. They can sustain complex combinations of thermomechanical stresses and chemical/physical wear generated by fluids and chemical agents. Being the only materials able to sustain operation conditions at temperatures typically above 1000 °C, refractories are identified as advanced materials and key enablers of the production of essential products for everybody's daily life across Europe.

CESAREF (Concerted European action on Sustainable Applications of REFractories) is a Horizon Europe MSCA Doctoral Network combining nine academic and fourteen industrial partners across Europe. The project, which will run from October 2022 to September 2026, aims firstly to train researchers in multi-engineering areas and expose them to the academic and non-academic sectors through international and inter-sectoral mobility combined with an innovation-oriented mind-set. They will receive a combination of research-related and transferable competences in the full production-to-the-end-of-life cycle of refractory materials applied to I&S processes. These processes include new operation conditions required to reduce GHG emissions drastically, improved energy efficiency and life cycle assessment requirements. An important part of the project will be dedicated to the sustainability of refractories, including recycling issues, using the Life Cycle Assessment (LCA) methodology. The 15 doctoral candidates (PhDs) recruited will take advantage of the most sophisticated numerical tools and laboratory equipment to model, design and predict the life of refractory materials in critical operational conditions. Being trained in scientific, technical, and transferable skills, these PhDs are the next generation of highly employable scientists and engineers in the refractory sector and related areas. New testing methods and models will be developed to address the Scientific/Technological (S/T) challenges for these applications and help to design better performing and sustainable refractory materials and linings.

## CESAREF APPROACH TO REFRACTORIES RESEARCH

Steel, cement, glass and super alloys are essential materials of our society. The competition in and out of the European territory is intense. Due to rising costs related to $CO_2$ emissions and to the European Green Deal, the urgent challenge for the industry is to stay competitive and invest in breakthrough technologies for decarbonization.[1,2] The European Iron & Steel (I&S) industry is a world leader in innovation, environmental sustainability and a pioneer in the development of new technical solutions to enhance resource efficiency and meet the "Net-Zero emission of Green House Gas" (GHG) target by 2050.[3,4] 84 % of the European Steel producers have already committed themselves to be fully Net Zero by 2050, compared to 67 % in Japan and 19 % in China.[5] Steel production is very highly energy intensive and accounts for 25 % of Europe's industrial $CO_2$ emissions and 7 % of the global industrial GHG emissions. Every ton of steel produced in 2018 emitted on average 1.85 tons of $CO_2$. As shown in Figure 2, Net-Zero emissions by 2050 entails alternative breakthrough technologies and processes. The European I&S industry has numerous decarbonisation projects in the works, at various levels of technical readiness, either on the Smart Carbon Usage and/or the Direct Carbon Avoidance technological pathways. By dealing with energy efficiency through new refractory materials and technologies, the CESAREF network will target research topics not presently covered. Other key initiatives are dedicated to steelmaking by enlarging the use of hydrogen based-Direct Reduced Iron (DRI) as feeding material in Electric Arc Furnaces or by developing low-carbon footprint iron production technologies.[6] The conversion from carbon-based fuels to clean burning hydrogen-based mixes is a major change in the industry. DRI is expected to be a major decarbonization lever and offers the potential for truly green steel, particularly in Europe where 70 % of steel is still produced through integrated process. However, the current refractory materials are not designed to perform as well with such new operation practices.[7]

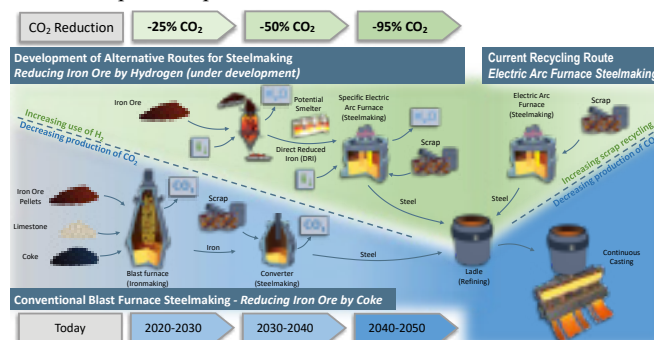

*Figure 1: Overview of upcoming evolutions in steelmaking.*

Competitiveness must also be based on innovative technologies like advanced analytics, digitalization, and digital twin. Simulations don't benefit from having real-time data. On the other hand, digital twins are designed around a two-way flow of data and can itself run any number of simulations to study multiple processes and reach a global effectiveness. Model-based optimization for efficient use of resources and energy have started to be developed but not directly related to the refractory performances yet.[8] In this context, the European Refractory industry is a vital pillar of the European I&S industry. The raw material suppliers and refractory producers are part of the global production cycle of steel and a key part of the solution to reach Net-Zero emissions.

## ORGANISATION OF THE SCIENTIFIC WPS

CESAREF's objectives are identified through four scientific WPs presented Figure 2.

*Figure 2: Overarching research and industrial objectives of CESAREF within the circular economy challenges and using a multiscale approach.*

**WP 1 - Efficient use of mineral resources and recycling** will deal with the 4 challenges associated with circular economy: feed the loop, design the loop, slow down the loop and close the loop. The Life Cycle Assessment methodology (LCA), which has become a standard environmental evaluation tool (ISO 14040 - 14044:2006), will play a key role in this WP. Feeding the loop in a sustainable way requires knowledge about raw materials extraction (including secondary raw materials) to build robust inventory databases. Designing the loop means having access to relevant production routes of several types of refractories (bricks, precast blocks, unshaped products), to optimize them in an eco-design perspective. Slowing down the loop refers to the value of the environmental footprint of the refractories once applied in the steel industry. The impact of several operating parameters has to be assessed to both reduce the environmental impact and costs associated to refractories for the steel industry. Closing the loop means working on recycling routes and the associated environmental impacts, including the recycling process and re-use of secondary materials, relying namely on model material systems. WP1 will benefit from the CESAREF industrial network, to access the required primary resources allowing relevant inventory databases to be built, calculate the environmental impacts (climate change and resource depletion among many others), and propose eco-design strategies so the sector contributes to the EU Green objectives.

**WP 2 - Microstructure design for increased sustainability** will deal with the characterization of selected materials at room and high temperature in virgin state, after service, or after exposure to $H_2$ or other combustion atmospheres. Conventional and specific experimental techniques, based on the use of European large-scale facilities such as synchrotron radiation sources, will be used to determine the relationships between structure, microstructure and macroscopic properties. Alongside thermal expansion, thermal conductivity will be tested, as well as the Young's modulus by ultrasonic echography or the resonant frequency method. X-ray tomography and diffraction under synchrotron radiation source will be applied to investigate structural and microstructural evolutions of refractories in service or due to $H_2$ containing atmospheres. Stress-strain relationships and creep laws will be determined from tension and compression tests and work of fracture by wedge splitting tests. WP2 will take advantage of the CESAREF network to apply complementary experimental devices useful for each task. If different methods are available within the network, the most appropriate will be used to obtained key experimental results and improve the global outputs of the project.

**WP 3 - Anticipation of Hydrogen Steel Making** will deal with the acquisition of science-based knowledge on the long-term behaviour of refractory materials in the new emission-free processes. The conversion to emission free industrial processes, as requested by the European Green Deal, will lead to the replacement of carbon-based by hydrogen-based fuels. Several options for hydrogen-based ironmaking are presently being tested on a pilot scale level. The most promising breakthrough technologies need to be tested and implemented on an industrial scale between 2020 and 2030 and beyond.[9] The time pressure to ensure the process changes, and consequently change enabling process parameters such as refractories, is enormous and research is needed. The application of refractories has to be revised due to drastically changed process conditions in both iron- and steelmaking, and in more downstream processes. Extensive characterization of the relevant refractories materials (WP2) is urgently needed, and the results thereof will form the backbone of this work package.

**WP 4 - Energy efficiency and durability** will deal with leveraging advanced digital methods to reduce heat losses in the steel making process and prolong the useful lifetime of refractory linings and components. The basis for the novel methods to be developed in WP4, is accurate real-time data on the thermal state of steel ladles and the condition of the refractory lining. To collect the required data new monitoring methods aided by machine learning and data driven approaches will be developed. Experimental data will be augmented with data from detailed simulation models. The insights gained from these monitoring and modelling methods will be transferred to the steelmaking process to support the decision making regarding reduce/reuse/recycle/recreate and employing the steel ladles. To incorporate the process perspective in the decision support, an optimization model for the ladle logistics is set up, which not only takes the thermal state and the remaining useful lifetime of the refractory lining into account, but also considers the limitations of the steel making process. Incorporating this new information in the decision-making process will result in a reduction of resource consumption (gas, refractories, hot metal) and greenhouse gas emissions, thus directly contributing to the objectives of the European Green Deal. For validation, dedicated experiments in a steelmaking plant will be conducted.

## TRAINING ASPECTS, DISSEMINATION AND OUTREACH

Being built on an interdisciplinary and inter-sectoral approach, the CESAREF value chain (cf. Figure 3) will dramatically increase the transfer of scientific knowledge to the refractory users in EU, ensuring their progress on societal, economic, and environmental aspects.

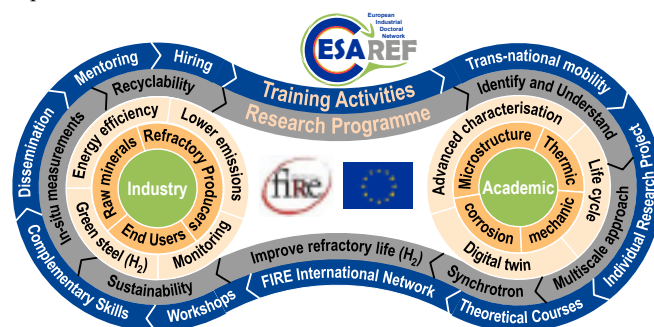

*Figure 3: CESAREF value chain global overview.*

CESAREF targets the development of high-end engineering technologies in the fields of material's science and numerical simulations to give a substantial contribution through the design of more sustainable, robust, and reliable refractory linings. Ultimately, it represents a reduction of the refractory costs, an increase of the equipment's availability and enhanced process control. In addition to the significant energy savings that meet the interest of the industrial partners, CESAREF contributes to tackling environmental issues, namely through the focus on refractory recycling at their end of life, in a circular economy perspective.

### Overview of the doctoral training programme

Today, refractory companies experience ever-expanding economic and environmental challenges that hinder the continuous development of innovative approaches in material design, process,

and product functionality. Their competitiveness and sustainability are related to the availability of industrial-oriented, well-educated young engineers whose inter-disciplinary and inter-sectoral skills drive the development and improvement of refractories as advanced materials enabling essential material production, e.g., steel, cement, or glass. CESAREF will provide unique training of 15 PhDs for 540 researcher months. WP 5, dedicated to training, mobility, sustainable recruitment, and transfer of knowledge, will offer them continuous and discrete training activities that contribute to the development of refractories science globally and the innovation system for the I&S industry. The 15 PhD positions are distributed among 15 Beneficiaries (6 academics and 9 industrials) in 6 countries. In total, CESAREF represents 9 countries with 15 Beneficiaries and 10 Associated Partners, most of whom are members of the Federation for International Refractory Research and Education (FIRE). This worldwide network constitutes a valuable assembly of complementary expertise for these training activities. All CESAREF academic partners have extensive expertise in post-graduate and post-doctorate research training. The PhDs will be fully integrated in the existing local research teams and related activities. Thus, each PhD participates in local Doctoral training programs (scientific and transversal lectures) and also benefits from the integration activities (welcome parties, administrative help and language courses) which are regularly organised for foreign students. A member of the academic research team will be appointed as the primary supervisor for each PhD. The supervision will be managed by both academic supervisors as well as one dedicated industrial supervisor. Thus, each PhD capitalizes on the interdisciplinary expertise available. To meet the objective of increasing the training level of European researchers in the field of Refractories, and thus their employability, CESAREF will provide advanced training in research methods and engineering skills, as well as industrial experience. The PhDs will develop their own network, during events and promote collaboration between academia and the industry. This combination of research-related and transferable competencies will enhance career perspectives in both academic and non-academic sectors.

The 13 companies of the network, in collaboration with FIRE, will contribute to interdisciplinary and intersectoral research training and to outreach activities (talks at internal and external events, organisation of training lectures and webinars, and industrial site visits, etc.). They will identify main industrial needs and regularly inform the consortium. They will provide materials and relevant data to facilitate the successful completion of the Individual Research Projects. All will participate in network-wide training events and/or host secondments. They will also guide training through participation in the Industrial Advisory Committee (IAC) and Steering Board (SB) meetings. They will play a vital role in strengthening the connections between academia and industry, and in accelerating knowledge transfer and adoption of innovative solutions. Every 6 months, the CESAREF network will organise 2 days of scientific virtual workshop during which PhDs are expected to prepare dedicated oral presentations to present their work progress and results to the overall consortium. Such a training program will foster interaction of the trainees with a truly exceptional inter-sectoral community to arm them with all the skills required to realise their professional life and their entrepreneurial ambitions.

**Dissemination activities**

Considering the impact of the activities under the scope of this network, the dissemination and exploitation of the results obtained throughout the project is of paramount importance. Measures will be implemented within a WP6 dedicated to "Dissemination and proactive knowledge transfer to industry" led by S. Sinnema (TATASTEEL/FIRE). The Plan for Exploitation and Dissemination of Results (PEDR) is outlined below.

Depending on the targeted audiences, the dissemination of CESAREF results will comprise many different channels. The communication to the industrial sector will be based on the strong capability of FIRE as a multiplier to disseminate among its network's members and beyond. In parallel, CESAREF is expecting to organize regular dedicated scientific workshops and two specialist industry seminars to promote knowledge transfer. These events will allow to present/discuss and develop a knowledge database for the expertise generated within the consortium.

Another far-reaching platform for the dissemination of CESAREF (especially for WP4) will be the IEA IETS Annex XVIII[10] on "Digitalization, Artificial Intelligence and Related Technologies for Energy Efficiency and GHG Emissions Reduction in Industry", which is a worldwide network of academia and industry. In Annex XVIII, TU Wien leads Task 2 on "Methods and Applications of Digital Twins" and TataSteel leads Task 4 "Road mapping the implementation of digitalization in the energy-intensive process industries".

High-performance refractory materials and applications are not typically used directly by the general public. Thus, CESAREF PhDs and their supervisors will also ensure that research activities are made known to society at large in ways that they can be understood by non-specialists, thereby improving the public's understanding of science.

CESAREF Website: dedicated to non-confidential research and network-related communications will target three types of audience: general public without a strong technical background, experts in the field interested in the project results, and participants of the project. PhDs and all the network partners will be encouraged to contribute to the website, which will also feature a social networking portal, blogs, forums, a "FAQ" section and wikis for the general public. A dedicated section with restricted access will serve for internal communication to the project partners. Information such as S&T field of activity, patents, publications, and positions will be regularly updated for every PhD. The website will thus be an excellent indicator of the success of the initial training of the PhDs, connecting them and promoting careers in refractory products. The coordinating institution is responsible for the website's design and maintenance (until at least 8 years after the end of the project).

During the first year of the project, a short video project will be produced in which the CESAREF's goals, the team and the collaborating partners will be presented in a comprehensive way. This video will be accessible via YouTube as well as via CESAREF and FIRE websites. During the last 6 months of the project, other promotional videos will be made to showcase the project results.

In close collaboration with Centre Sciences[11] an interactive exhibition called "Cerami°K" dedicated to "The World of High Temperature Science" (in the context of European Green Deal) will be used at each academic pole for general public awareness (notably for secondary schools) at the occasion of yearly open days at universities. Interviews in mass media will be organized to target the general public through the local press.

A newsletter will be published every semester in the CESAREF website and disseminated by email. This will be directed to the general public, but links will be given to the website for experts to obtain further technical information. Researchers' informal wikis and monthly blogs to showcase their research work to a non-technical audience. Specialised Press releases and joint articles will be submitted to magazines and websites linked to the refractory industries. Advice and contacts with existing stakeholder groups (e.g. potential investors, advisory groups, competitiveness clusters, etc.) will be sought to prepare at least one broad audience article published in each country represented in the CESAREF consortium. Regular Press releases, through the collaboration of the communication offices of CESAREF partner institutions, will be published on the network results.

Scientific results will be disseminated through oral communications during international congress and publications in rank A international peer reviewed journals. The organization of dedicated sessions in selected conferences will also be promoted to show the project results to large audiences. Since academic partners in CESAREF are editors of relevant journals and/or organizers of key conferences, the dissemination will be highly efficient. An average

723

target of three Open-Access, peer-reviewed papers per PhD is expected.

## EXPECTED IMPACTS

### Contribution to the European Doctoral Training structuration

Industrial partners in CESAREF participate at the highest level of the training programme and are directly (and strongly) involved in the supervision of all the PhDs (Industrial Doctorate) and can be additionally involved by specific mentoring (closely monitoring an area of a given PhD work) in case of secondments. CESAREF fosters a tight interconnection of cutting-edge European research institutions, several world leading scientists and leading companies in the fields of raw minerals, refractory materials producers, and end-users (in steelmaking or superalloy casting). The inputs of industrial partners in the training activities will enable the creation of a pool of well-trained researchers. At the end of the project, this industry will be looking to recruit them.

The CESAREF network covers the full supply chain for these critical materials required in steel-making industries, which urgently need to drastically change their industrial process (increasing hydrogen use) to reduce $CO_2$ emissions. The industrial partners will also be able to lead research activities and ensure that the research projects are relevant to the refractory applications. They will be able to directly use the results of the CESAREF projects and exploit them to increase their competitiveness in the EU and the international market. The reputation of the industrial partners will also be improved by their participation in CESAREF as this will increase their visibility, both within the Network's academic partnership, and out of the Network. Long lasting collaborations are expected to be developed between industry and academia during the four years of the network.

Furthermore, the results obtained in CESAREF are transferrable to other essential domains like cement or glass. CESAREF assembles expertise within the EU, leading to scientific exchange and knowledge transfer, thereby overcoming fragmentation within European research. In this fruitful collaborative context, PhDs are offered the rare possibility for international, interdisciplinary and intersectoral training, characterised by 1) an individual, scientifically ambitious, research project well connected to other researchers and disciplines, 2) close collaboration with academic and industrial partner labs working in a complementary research field where they are supervised for a period of 18 months (9 months at the beginning and end of the PhD), and 3) training in core and advanced research skills and transferrable skills. The non-academic partners will participate in the courses (WP5) via presentations and case studies. Industrial site visits and direct access to R&D facilities will be provided. This structured training stimulates the creativity and entrepreneurial mindset of researchers at a doctoral level.

### Expected scientific impact(s)

Scientific impact is expected through materials development triggered by the combined application of methods such as synchrotron radiation sources, thermochemical simulation and advanced material testing at temperatures up to 1600 °C. In addition, life cycle analysis, in conjunction with simulation methods, will show further potential for developments. The research on life cycle analysis will address some of the key recommendations recently published by a working group of members from the "task force mineral resources" participating in the "global guidance for LCIA indicators and methods"[12] hosted by UN Environment. CESAREF will significantly contribute to covering a broader range of inventory flows which are currently under-represented, namely minerals and aggregates. It will also develop characterization models including both natural stocks and anthropogenic stocks (secondary resources). The depletion of resources considered in CESAREF will also consider flows of material ending up in tailings, waste rock, or as emissions to nature. It will promote the identification of "dissipative resource use". Some PhD students will be strongly involved in the use of synchrotron radiation sources, use of such facilities and a related training period will be built-up. Due to the very high X-ray flux and the tunability of the beam energy, synchrotron radiation allows in-situ and operando diffraction and tomography measurements that are not possible without these types of sources. At the end of the project, PhDs able to use, for industrial purpose, such equipment will disseminate their knowledge to the industrial community. Building scientific relationships with other users of such facilities, they will be able to lead industrial projects including the use of such facilities.

### Expected economic/technological impact(s)

The industrial partners will directly benefit from the training of the network and the dedicated industrial doctorate programs ensuring that the research projects are relevant to the refractory and steel industries as well as others committed to Net-Zero emissions. Their inputs in the training activities and supervision of the PhDs will enable the creation of a pool of well-trained, highly employable researchers. The industrial partners will make direct use of the obtained results during the project and increase their competitiveness by implementing new technological solutions. On completion of CESAREF the industrial partners will be bolstered by life cycle analysis, refractory design for hydrogen technology and enhanced energy efficiency by using advanced digitalization methods. This will enable the realisation of maximum recyclability, zero $CO_2$ emissions and lower energy consumption. The visibility, and thus reputation, of the industrial partners' will be improved by their participation to the project, increasing the potential for future collaborations leading to continued innovation and/or patents for the years to come. The proposed network will help to establish long-term partnerships between the researchers and industry in the areas of research, training and development, which will promote the creation of new refractory solutions. The structured training programme will create synergies from the expertise of all participants and can only be offered through a network such as the one proposed. The network will also reinforce the critical mass of researchers in the European Research Area able to compete with other international actors.

### Expected societal impact(s)

CESAREF will contribute to circularity, energy efficiency and $CO_2$ reduction and as such contribute to environmental and social well-being. The collective willingness to put the energy transition into operation as soon as possible has led to this urgent concerted action of all academic and industrial partners. With the attention on development of robust refractory materials, unwanted breakouts of installations can be prevented, leading to safer working conditions. Educating PhD's on themes with high environmental added value will also lead to a generation of researchers and future decision makers with enhanced awareness of social responsibility.

**ABSTRACT**

The wettability between refractory and slag is a crucial property for assessing their resistance to slag. This study investigates the slag wetting behavior of magnesia refractories with varying basicity (C/S ratio), magnetic induction intensity and different atmospheres. It aims to uncover the influence of weak static magnetic field on the wetting behavior of the slags. The findings reveal that the reaction involving superoxide radical significantly impacts the contact angle between the slags and magnesia under different atmospheric conditions. Moreover, the application of a weak static magnetic field can effectively suppress the free radical reaction, leading to an improved contact angle between the slags and magnesia, and can enhance the slag resistance of magnesia refractories.

Keywords: magnesia refractory; molten slag; static magnetic field; superoxide radical

## 1. INTRODUCTION

Magnesia refractory not only has high refractoriness, strong resistance to the corrosion of alkaline slag and high iron slag, but also has the ability to purify molten steel without pollution. Because of these properties, it is widely used in oxygen converters, electric furnaces, off-furnace secondary refining, ladles and other industrial vessels [1]. Lao et al. [2] studied the wettability between CaO-Al₂O₃-SiO₂-(MgO) slags and magnesia. It was found that a high C/S ratio in the slag and a higher MgO content could help enhance the slag resistance.

With the development of electromagnetic metallurgy technology, the application of external electric and magnetic fields to the interface reactions between slags and refractory materials has attracted the attention of researchers. Christos G et al. [3] found that applying an electric field can change the wettability between the slag and magnesium oxide, promote electron transfer and exchange, thus promoting the interfacial reaction and accelerating the dissolution of magnesium oxide in the slag. Wang et al. [4] found that the effect of alternating electromagnetic field increased the diffusion coefficient of $Fe^{2+/3+}$ and $Mn^{2+}$, as well as the substitution ability with $Mg^{2+}$ in magnesia, which contributed to the formation of solid solution of magnesium oxide and iron oxide or manganese oxide, and intensified the corrosion of magnesia carbon refractory by slag. Ren et al. [5-6] investigated different magnesia-based refractories (MgO-MgAl₂O₄, MgO-CaO, and MgO-C) under static slag resistance and dynamic rotational corrosion tests in a vacuum electromagnetic field environment. Both types of slag corrosion tests demonstrated that the electromagnetic field can promote interface reactions between slags and refractory materials, accelerating the corrosion and infiltration of slags into the refractories. Lian et al. [7] found that under a static magnetic field, the viscosity and contact angle of the slag increase with the increase of magnetic induction intensity, and electromagnetic damping phenomenon can be formed to inhibit the penetration of the slag. Zou et al. [8] discovered a "magnetic braking effect" on slag under a static magnetic field, reducing the wettability between slag and magnesia-based refractories. The introduction of alternating magnetic fields exacerbates refractory corrosion, while a static magnetic field can effectively inhibit slag infiltration corrosion. Moreover, weak static magnetic fields have important prospects for application in high-temperature smelting processes due to their adjustability and cost-effectiveness. However, there is

still a lack of in-depth research on the wetting behavior of slag on magnesia refractories under high-temperature weak magnetic fields. This paper aims to investigate the wetting phenomenon between slag and magnesia refractories under weak static magnetic field conditions, elucidating the influence of magnetic induction intensity, temperature, and slag composition on the wetting behavior of slag. It provides a theoretical basis for the application of high-temperature weak static magnetic fields in regulating and improving the resistance of magnesia refractories to slag corrosion.

## 2. EXPERIMENTAL

### 2.1 Experimental materials

Large crystalline fused magnesia (average crystallite size is 283 μm, chemical composition is shown in Table 1) was used in the wetting experiment. Al₂O₃ powder (analytical pure, Al₂O₃≥99 wt%), CaO powder (analytical pure, CaO≥98 wt%) and SiO₂ powder (analytical pure, SiO₂≥98 wt%) were used for synthetic slag (following the mass ratio shown in Table 1). Alumina ceramic balls were used as the mixing medium. CaO-Al₂O₃-SiO₂ oxide powders with different C/S ratio were prepared by mixing and grinding.

After the oxide powders were evenly mixed following the specifications in Table 2, they were pre-melted in an induction furnace for 15 min, quenched, and then placed in a Muffle furnace for 8 h at 1000 ℃ for decarbonization. Subsequently, the powders were finely ground into slag powder and pressed into small cylindrical samples with a height and diameter of 3 mm.

Tab. 1: Chemical composition of the fused magnesia (wt%)

| MgO | CaO | SiO₂ | Al₂O₃ | LOI |
|---|---|---|---|---|
| 97.81 | 0.60 | 0.65 | 0.18 | 0.34 |

Tab. 2: Chemical composition of the synthetic slags (wt%)

| No. | CaO | Al₂O₃ | SiO₂ | C/S ratio |
|---|---|---|---|---|
| S1 | 32.5 | 35 | 32.5 | 1 |
| S2 | 48.75 | 35 | 16.25 | 3 |
| S3 | 54.16 | 35 | 10.84 | 5 |

### 2.2 Experimental process

The wetting behavior experiment was carried out with the ultra high temperature confocal laser observation system VL200DX-SVF18SP. The polished fused magnesia samples were successively polished with 200, 400, 800, 1000, 1200, and 1500 grit sandpaper. The samples were placed in alumina crucibles, and a cylindrical slag sample was placed in the center of the magnesia surface before being placed in the furnace.

The heating regime was as follows: the temperature was raised to 1600 ℃ at a heating rate of 50 ℃/min from room temperature ~200 ℃, 300 ℃/min from 200 ℃ ~1400 ℃, and 50 ℃/min from 1400~1500 (1550 and 1600 ℃), and then decreased to room temperature at 200℃/min. At the same time, the furnace chamber was subjected to different static magnetic intensities: no static magnetic field, as well as static magnetic fields of 0.5 mT, 1.0 mT and 1.5 mT. After the experiment was completed, the sample was photographed using an optical microscope, and the apparent wetting angle between molten slag and fused magnesia was analyzed using Image J software (National Institutes of Health, America). Subsequently, the samples were quenched, cut along the

center line of the slag, polished, gold-plated through vacuum ion sputtering, and analyzed using scanning electron microscopy (SEM; JSM-6610, JEOL, Tokyo, Japan) and Energy Spectrometer (EDX; QUANTAX, Bruker, Berlin, Germany) for comparative analysis of the interfacial microstructure and composition of the slag and fused magnesia.

The slag was ground into fine powder with a particle size below 0.074mm, and electron spin resonance spectroscopy (ESR, A300, Bruker, Salbrucken, Germany) was used to quantitatively measure superoxide radicals in a light-free environment. The ESR settings were as follows: central magnetic field 3500.00 G, field sweep width 150.00 G, sweep time 30.00 s; microwave power 3.99 mW, modulation amplitude 1.000 G; conversion time 40.0 ms, using DMPO as the trapping agent.

## 3. RESULTS AND DISCUSSION
### 3.1 Effect of slag basicity and static magnetic field under air

*Fig. 1 Apparent contact angle of slag with different basicity under temperature variation situation and air*

It can be seen from Fig.1 that at 1450 ℃, the contact angle between slag S1 and magnesia is much lower than that between slag S2 and S3. This discrepancy can be attributed to the low basicity and acidic nature of slag S1, which easily corrodes and penetrates magnesia and certain basic refractories. Consequently, the contact angle of S1 is much smaller than that of S2 and S3 slags. At 1600 ℃, the contact angle of S2 is greater than that of S3. This variation occurs due to the reaction between S2 slag and magnesia, resulting in the formation of spinel (as depicted in Fig.2). The spinel formation inhibits further penetration and corrosion of the slag, thereby increasing the contact angle.

*Fig. 2 Thermodynamic simulation of the amount of spinel generated by the reaction between slag S2 and S3 and magnesia (Alpha is the ratio, when it is 0, it is the pure slag, when it is 1, it is the pure fused magnesia)*

From the Fig.3, it can be observed that the application of a static magnetic field has a significant effect on the contact angle between the slags and the magnesia. Within the temperature range of 1425 to 1462.5 ℃, the introduction of a static magnetic field of 1.0 and 1.5 mT results in a notable decrease in the contact angle between slag S1 and magnesia. However, at 1450 and 1462.5 ℃, a static magnetic field of 0.5 mT can increase the contact angle. Specifically, at 1450 ℃, the contact angle is 23.7° with a magnetic field, while without the magnetic field, the contact angle is 15.7°, indicating an increase of up to 50.8%. For the contact angle between S2 slag and magnesia, it initially decreases and then stabilizes as the temperature rises. The magnetic field can reduce the contact angle between S2 slag and magnesia. Additionally, at 0.5 mT, the effect of accelerating slag infiltration and corrosion is the greatest. The contact angle between S3 slag and magnesia gradually decreases with increasing temperature. At temperatures between 1450 to 1550 ℃, the application of a 1.5 mT static magnetic field increases the contact angle. At 1500 ℃, the contact angle is 45 ° at 1.5 mT, compared to 36.2 ° at 0 mT, representing an increase of 24.3%. Conversely, st 0.5 mT and 1mT, the contact angle decreases. At 1600 ℃, the external static magnetic field has little effect on the contact angle.

*Fig. 3 The apparent contact angle of the slags with different basicity and the magnesia under air*

### 3.2 Effect of atmosphere and temperature

From the results of the contact angle between the slags with different basicity and magnesia, it can be observed that the contact angle of slag S3 is reduced by applying a static magnetic field. Additionally, slag S1 exhibits high permeability, making it difficult to investigate its wetting behavior with fused magnesia at higher temperatures. As a result, the experiment on wetting behavior under different atmospheres selected slag S3.

*Fig. 4 The apparent contact angle between slag S3 and magnesia varying with atmosphere and temperature*

As shown in Fig.4, in the temperature range of 1500~1600 ℃, the contact angle between air and argon is consistently larger than that under vacuum condition. Specifically, at 1500 and 1550 ℃, the contact angle in air is greater than that under argon atmosphere. However, when the temperature reaches 1600 ℃, the contact angle between air and argon shows no significant difference.

### 3.3 Effect of atmosphere and temperature under static magnetic field

It can be seen from Fig. 5 that with the increase of temperature in the air, the contact angle between slag S3 and magnesia gradually decreases, and the degree of wetting gradually increases. The

introduction of a static magnetic field will change the wetting behavior between the slags and magnesia. The static magnetic field with an intensity of 0.5 mT and 1.0 mT results in a smaller contact angle compared to the contact angle without a magnetic field. However, a static magnetic field with an intensity of 1.5 mT significantly improves the contact angle between the two materials at 1500 ℃ and 1550 ℃. At 1500 ℃, the contact angle is 45° with the magnetic field, whereas it is 36.2° without the magnetic field, representing a 24.3% increase. At 1550 ℃, the contact angle is 35.6° with the magnetic field, while it is 31° without the magnetic field, resulting in a 15.1% increase. As the temperature increases further, reaching 1600 ℃, the contact angle without a magnetic field becomes similar to that with a 1.5 mT magnetic field. Under vacuum conditions, the static magnetic field with intensities of 0.5 mT and 1.0 mT effectively improves the contact angle at 1500 ℃ and 1550 ℃. The contact angle of 1.0 mT at 1500 ℃ is the highest, measuring 26.3°, which is a 37.7% increase compared to the contact angle of 19.1° without a magnetic field. Similarly, at 1550 ℃, the contact angle of 0.5 mT is the highest at 23.1°, representing a 21.5% increase compared to the contact angle of 19° without a magnetic field. However, at 1600 ℃, the contact angle of 0.5 mT becomes significantly smaller than that without a magnetic field. Under argon atmosphere at 1500 ℃, applying a static magnetic field with intensities of 0.5 mT and 1.5 mT can improve the contact angle. The contact angle with a 0.5 mT magnetic field is the largest, measuring 39.7°, while the contact angle without a magnetic field is 28.8°, resulting in a 37.9% increase. However, applying a static magnetic field at higher temperatures has little effect on the contact angle.

*Fig. 5 The apparent contact angle of S3 slag and magnesia in different atmospheres*

## 3.4 Microstructure and analysis of the interface

One control group was selected for microstructure analysis. The group was subjected to a vacuum atmosphere of 1550 ℃, a static magnetic field of 1.0 mT, and another group without a static magnetic field (0 mT). Analysis of Fig. 6 reveals that under the vacuum atmosphere of 1550 ℃ and a static magnetic field of 1.0 mT, there is weaker slag corrosion between magnesia particles compared to conditions without a magnetic field. Furthermore, the corrosion between particles is reduced, and there is no difference in composition between the slag and particles under both 1.0 mT and 0 mT. The primary components identified are calcium aluminite and cacoclasite phases (Table 3).

*Fig. 6 Microstructure and composition of the interface between slag and magnesia under vacuum atmosphere in 1550 ℃*

Tab. 3: EDS analysis results (at%)

| Element | Ca | Al | Si | Mg | O |
|---------|-------|-------|------|------|-------|
| Area 1 | 20.94 | 14.8 | 3.59 | 3.29 | 57.38 |
| Area 2 | 19.71 | 14.30 | 3.39 | 2.48 | 60.12 |
| Area 3 | 20.90 | 13.84 | 4.41 | 2.23 | 58.62 |
| Area 4 | 22.36 | 15.48 | 3.69 | 2.20 | 56.27 |

The influence of the static magnetic field at the Gauss level on the energy change of the reaction process can be ignored [9,10] , However, it is believed that the magnetic field at this intensity may have an effect on the reaction rate. Li et al. [11-13] proposed that there are abundant superoxide radicals in oxide smelt, and expounded their formation mechanism. The static magnetic field of Gauss level may inhibit the free radical reaction.

*Fig. 7 ESR/EPR test results of S3 slag after quenching*

The ESR/EPR spectrum of slag S3 after quenching at 1600 ℃ is shown in Fig.7. There are 6 absorption peaks in the spectrum, among which the peak intensity at 1, 2, 4, and 6 is higher, and the peak intensity at 3 and 5 is lower, with a g value of about 2.006. The detection result shows that they are superoxide radicals, indicating the existence of superoxide radicals in the slag. In high-temperature air, $O_2$ melts into the slag to form singlet oxygen, and then superoxide radical (see equation (1) and (2)) [14]. In the melt, non-brig oxygen (NBO) will react with ion clusters to form superoxide radicals (see equation (3)) [15]. With the participation of $O_2$, the concentration of superoxide radical will be greater. The advancement of equation (3) is impeded under high-temperature air conditions, resulting in a reduction in the degree of

reaction between the slag and magnesia. As a consequence, the contact angle at 1500 ℃ and 1550 ℃ is decreased. However, at 1600 ℃, the accelerated diffusion rate leads to an intensified free radical pair bonding reaction. As a result, the contact angle under air is not much different from that in argon. Due to the vacuum environment, the oxygen generated in the reaction is continuously pumped away, which prevents the equilibrium between free radicals and oxygen conversion reaction from being reached. As a result, the reaction proceeds towards oxygen generation, intensifying slag corrosion and reducing the contact angle.

$$O_2 \rightleftarrows {}^1O_2 \tag{1}$$
$$O_2 + A^- \rightleftarrows O_2^{\cdot -} + A \tag{2}$$
$$M^{2+} + 2O^- \rightleftarrows M^{\cdot +} + O_2^{\cdot -} \tag{3}$$

Where ${}^1O_2$ is singlet oxygen, $O_2^{\cdot -}$ is superoxide radical, $O^-$ is NBO, $A^-$ is on cluster : $[SiO_4]^{4-}$, $[Si_2O_7]^{6-}$, $[Si_2O_6]^{4-}$, $[Si_2O_5]^{2-}$, $[AlO_4]^{5-}$, etc. $M^{2+}$ is Mg, Ca, etc.

*Fig. 8 Mechanism of free radical reaction under air, where O(3P) is Triplet oxygen.*

Superoxide radicals are mainly involved in reactions as shown in Fig. 8 under air. With the increase of magnetic induction intensity, the contact angle decreases first and then increases. This is because magnetic field makes the triplet states ($T_+$ and $T_-$) and singlet state (S state) level become non-degenerate. The probability of S→$T_±$ intersystem channeling is reduced, so the total S→T intersystem channeling rate decreases with the increase of the magnetic induction intensity [10,16] , thus inhibiting the transformation of singlet oxygen to triplet oxygen, increasing the concentration of singlet oxygen, promoting the reaction with ion clusters in the slag to generate more superoxide radicals, and facilitating the reaction wetting. When the magnetic induction intensity reaches 1.5 mT, The degree of magnetic field inhibiting free radical reaction is greater than the degree of promoting reaction wetting. Thus, the contact angle is increased to inhibit the corrosion and penetration of slag. But the static magnetic field has a certain threshold for inhibiting the bond of free radical pairs, the inhibition effect of 0.5mT is the best when the vacuum and argon are 1550 ℃. When the temperature reaches 1600 ℃, the increase of diffusion rate will reduce the recombination probability of free radicals, so the effect of magnetic field on the apparent contact angle of slag will gradually decrease, and magnetic field will also accelerate the reaction wetting to reduce the contact angle.

## CONCLUSION

The wetting behavior of the magnesia was analyzed and studied with variations in slag C/S ratio, atmospheres, and magnetic induction intensity. Based on the research, the following conclusions were drawn:
(1) The contact angle of S1 is much smaller than that of S2 and S3 slags. The spinel formation inhibits further penetration and corrosion of the slag, thereby increasing the contact angle. The influence of the weak static magnetic field on the wettability of the slags with different C/S ratio and magnesia is completely different, weak static magnetic field has a significant impact in the temperature below 1600 ℃.
(2) The atmosphere was found to have a significant influence on the apparent contact angle between slag and magnesia. In vacuum environment, the conversion reaction from free radicals to oxygen intensifies the slag corrosion and reduces the contact angle.
(3) The magnetic field affects the reaction degree between slag and refractory by inhibiting the reaction of free radicals, thereby

reducing the reaction rate between slag and magnesia, and improving the contact angle and reducing the wettability of the slags to magnesia refractory especially in vacuum condition.

# FROM UNPOPULAR MATTER TO SMART SUBJECT:
# PUBLIC FUNDING OF REFRACTORY RESEARCH AND PHD EDUCATION BY DFG RESEARCH PROGRAMS AT TU FREIBERG

Patrick Gehre*, Jana Hubálková, Christos G. Aneziris

TU Bergakademie Freiberg, Institute of Ceramics, Refractories and Composite Materials, Freiberg, Germany

## ABSTRACT

The imparting of knowledge, as well as hard and soft skills to young PhD scientists by close supervision as well as by workshops and training courses, are important instruments for acquiring not only scientific and technical but also social competencies in the environment of interdisciplinary research work. The German Research Foundation DFG has established long-term research programs such as the Collaborative Research Center CRC 920, the Research Unit FOR 3010, and the Research Training Group GRK 2802 at the TU Freiberg, in which more than 60 PhD students explore basics framing multiple actual challenges in the field of refractory materials such as the manufacturing and interaction of ceramic foam filters with steel and aluminium melts for cleaner metal parts, electrically heatable refractory composites based on refractory metals and refractory oxides, and the recycling of MgO-C in new bricks the and upcycling of metal-ceramics as carbon-free electrodes. But also team and leadership competence questions were educated to the PhD students. For an interdisciplinary, international, and industrial-related education, all the research programs involve mentors from the industry, foreign universities, and three departments of Freiberg University (plasto-mechanics, fluid dynamics, iron and steel, and materials science), who guide the PhD students during workshops, internships, and bilateral discussions. The presentation will summarise key scientific outputs and will give insights into the tools and experience of more than ten years of activities in focused research programs and structured training strategies of PhD students.

## COLLABORATIVE RESEARCH CENTER CRC 920: MULTI-FUNCTIONAL FILTERS FOR METAL MELT FILTRATION - A CONTRIBUTION TOWARDS ZERO DEFECT MATERIALS

### Vision

There are increasing requirements in the metal-making and metal-using industry to remove solid and liquid inclusions such as deoxidation products, sulfides, nitrides, carbides etc., and thereby improve metal cleanliness. It is well known that the size, type and distribution of non-metallic inclusions in metal exert considerable effects on the mechanical properties of the cast products. The vision of the collaborative research centre (CRC) 920 is to create a new generation of metal qualities via melt filtration with superior mechanical properties for use in lightweight structures and high-demand construction materials. The aim of the collaborative research centre is an enormous reduction of non-metallic inclusions in the metal matrix by the use of intelligent filter materials as well as filter systems with a functionalised filter surface. Especially in the third funding period, a new generation of combined refining filter systems will be the focus. The metal melt comes first in contact with a reactive filter which generates gas bubbles in the melt as well as activates gas bubbles on the surface of the inclusions. As a result, a kind of flotation of the inclusions towards the slag on the surface of the melt takes place. Further, the high reactivity, as well as the gas bubbles, contribute to the agglomeration of the fine inclusions to big clusters, which flow due to buoyancy forces to the surface of the melt or are filtrated on the surface of active filters, which do not form gas bubbles but provide on their functionalised surfaces the same chemistry as the inclusions for a sufficient adhesion and as a result for a sufficient filtration of the inclusions. With this approach, a purification higher than 95 % can be achieved. The modelling focuses mainly on the several contributions of the gas bubbles and on the in situ formed reactive layers on the surface of the reactive filters as well as they generate codes with respect to the thermomechanical and functional properties of the filters for a 3D-printing of filter structures which are then end shaped with the aid of a robot-assisted flame spraying technique. The dynamic flow conditions in the filter during casting are of great importance for the proper design of the filter macrostructure. A material, as well as a flow computer-aided micro- and macrostructure filter design based on investigated filtration mechanisms, will lead to high purification efficiencies with superior properties – strength, fracture toughness, fatigue- of the cast steel, iron, aluminium and magnesium components. In addition, other applications, such as the electronic industry via filtration of copper or thin aluminium foil production, will profit from the scientific results. The target for higher material efficiency and reduction of energy and $CO_2$ emissions is coming closer in the near future.

*Fig. 1: Research program of the CRC 920*

### Project areas

The CRC 920 is divided into three project areas, which include 19 scientific subprojects (figure 1). There is also a graduate program, three service projects, transfer projects and a central administration project. The three project areas of CRC 920 are constantly interacting with each other in terms of exchanging information about their results. Together they create an innovative cycle of research, material design and understanding of the main mechanisms of active and reactive filter materials. This cycle enables the CRC to transfer the results on other metal melts to the point of their application.

Project area A - Filter materials - consisting of 6 subprojects, researches active filter materials. Especially the surface tension at the junction of the filter wall - solid inclusion - metallic melt is set up. The main goal is to raise the filter efficiency for primary and secondary inclusions with a size of 1 to 100 μm from currently about 70 % for steel melts and about 75 % for aluminium melts to over 90 %. Another focus of this project area is the examination of the reaction mechanism and the filtering potential of reactive filter materials. That means that the filter material reacts with the gases which are included within the melt. This can help to reduce the primary and secondary inclusions but also can be a substantial contribution to reducing tertiary and quaternary inclusions. Project area B - Modelling of filter structures and filter systems - consisting of 5 subprojects, is considered to be a prerequisite both for a precise geometrical and material design of filter structures and the evaluation of the material behaviour under operation conditions. Understanding the micro-processes of particle deposition, meaning inclusions, on an active and reactive inner surface of a functional cavity is the main focus of this project area. To understand the effects of filter mechanisms as a function of filter structure, filter process and filter systems, physical and stochastic models are developed. Those models include deposition, agglomeration and heat conduction. Based on those models, simulations are being run. The stochastic distribution of inclusions within the melt has to be

determined to allow a theoretical prediction of the probability of occurrence of those inclusions. Project area C - Filter efficiency and material properties - consisting of five subprojects, researches the efficiency of the produced filter materials. With the now improved mechanical properties, this project area will demonstrate how these new filters will help to create new generations of highly stressable cast iron parts. Filter technologies and efficiencies, as well as the properties of the filtered end product, a metal cast iron part, will be examined extensively within the course of this project area. Based on these examinations, conclusions can be drawn considering the filter materials (project area A) and structural filter design (project area B). An important aspect is the creep resistance of ceramic filter bodies in mould casting under extreme temperature changes. This project area will also determine the necessary material parameters that are essential for the modelling in project area B and are also important for designing and dimensioning.

## RESEARCH UNIT FOR 3010 - MULTIFUNCTIONAL, COARSE-GRAINED, REFRACTORY COMPOSITES AND MATERIAL COMPOUND FOR LARGE-VOLUME KEY COMPONENTS IN HIGH-TEMPERATURE PROCESSES
### Motivation

Materials for high-temperature applications contribute essentially to our society. Without them, there would be no light, no car, no turbine, and no wind and solar energy. They are not seen, but they are directly or indirectly needed everywhere. The increasing demands on environmentally friendly and resource-saving processes as well as on higher efficiency lead to increasing requirements regarding high-temperature materials. The Research Unit FOR 3010, supported by the German Research Foundation DFG, has the aim to research and develop a new generation of coarse-grained refractory composites based on pre-synthesised aggregates from refractory metals and refractory ceramics.

Limited resources and an imperative need to reduce energy requirements challenge the material research to develop more powerful yet more material and energy-efficient materials and manufacturing processes. Modern high-temperature composite materials undertake a pacemaker function for the industry and are thus key for future technologies and products. The Research Unit FOR 3010 "Refrabund" has set itself the goal to develop an entirely new generation of high-temperature composite materials, which should replace the previously used refractory ceramics and refractory metals. The fundamental idea evolves the merging of both material classes as well as the expertise of both research institutions, the TU Bergakademie Freiberg and the Karlsruhe Institute of Technology KIT.

## RESEARCH TRAINING GROUP GRK 2802 - "REFRACTORY RECYCLING: A CONTRIBUTION FOR RAW MATERIALS, ENERGY AND CLIMATE EFFICIENCY IN HIGH TEMPERATURE PROCESSES"
### Motivation

Every year, approximately 28 million tons of used refractories are generated worldwide. The majority of the consumed refractories are primarily used for foreign applications, such as aggregates for road construction (downcycling) or deposited in landfills. The recycling of such materials played a rather subordinate role until now. For ecological reasons and due to the risen landfill costs, an increased research potential to deal with the application of refractory recyclates was identified in the last few years. The objective of the Research Training Group GRK 2802 is to research and develop new sophisticated recycling options for used refractories. Within the scope of the Research Training Group, fundamental knowledge should be developed, allowing both the recycling (re-utilisation in similar high-temperature materials) and the upcycling (material upgrading) of refractories in metallurgical processes.
## Objectives

*Fig. 2: Scheme of the interconnectivity of the projects.*

The main objectives of the GRK 2802 are an interdisciplinary and structured training of PhD students in the fields of recycling and upcycling of refractories as well as the research and development of a new generation of coarse-grained high-temperature materials based on refractory recyclates with particular functional properties for high-temperature processes in the metallurgy (figure 2).

This will be applied in 2 core ideas:
1.  Core idea I: Recycling - Novel refractories based on refractory recyclates and environmentally friendly binders (resin-free, pitch-free) with an application as lining material for steel ladles
2.  Core idea II: Upcycling - Novel composites based on refractory recyclates with an application as electrode material for aluminium fused-salt electrolysis

The interdisciplinary team of the Research Training Group GRK 2802 comprises 12 PhD students, 1 Mercator Fellow, 12 Principal Investigators and several Associated Members. The training and qualification programme of the Research Training Group GRK 2802 is being developed and organised by a scientific coordinator. The administrative coordinator is responsible for the fund management and accounting.

## CONCLUSIONS

All refractory research activities at the TU Freiberg are supported and supervised by industrial advisory boards ensuring a direct linking to the topics of the real-world industry. Moreover, the developed materials and technologies can be directly tested and approved under real conditions in the end users industry. Therefore, the whole chain, from the raw materials up to the development of particular component as well as the understanding of the properties, needs to be explores in a multiscale approach. Besides the research skills, the main emphasis is on fostering of hard and soft skills in order to develop analytical, organisation and communication competences of the involved PhD-students. The qualification concept is based on lectures, soft skill workshops, networking, industrial internships as well as stays abroad. Consequently, the PhD-students are equipped with knowhow and capabilities to face the challenges of the professional work and to contribute to finding of appropriate scientific solutions. Inspiring environment, passion for innovation and continuous exchange of experiences allow for generations of new ideas, networks and perspectives in the engineering disciplines.

# BACHELOR OF CERAMIC SCIENCE (DUAL) AT KOBLENZ UNIVERSITY OF APPLIED SCIENCE – AN OPPORTUNITY FOR THE INDUSTRY TO OVERCOME SKILLS SHORTAGE

Olaf Krause

Koblenz University of applied Science, Höhr-Grenzhausen, Germany

## ABSTRACT

The challenges facing the ceramics industry today are many and varied. In addition to the supply of raw materials, environmental issues and the energy crisis, the lack of well-trained employees will lead to stagnation in the ceramics industry. The situation will become even worse in the near future if demographic factors are taken into account: Even today, old, experienced engineers cannot be replaced by young, well-educated engineers when they retire. One of the main reasons for this situation is that young people are not interested in materials science because it is not taught in schools. Young people are unaware of the importance of materials and their ongoing development for our ecological and sustainable community. In order to alleviate the still worsening situation, Koblenz University of Applied Sciences with its location in Höhr-Grenzhausen has opened a practice-integrated course in close cooperation with industry in 2018. This course is aimed at industrial partners and offers the opportunity to further qualify employees and also to attract school leavers from the region, with the latter receiving intensive practical insights at the industrial sites while the theoretical basics are taught at the university. This presentation summarises the educational system in general in Höhr-Grenzhausen and with special regards towards the first experiences with the novel and cooperative form of praxis integrated education.

## HÖHR-GRENZHAUSEN A HOTSPOT FOR CERAMICS

Based on excellent clay deposits in the Westerwald region Höhr-Grenzhausen looks back on a long tradition in ceramics. Beside the ceramic industry education and research in ceramics build a hotspot that is unique in Germany and Europe. All levels of education, vocational school for ceramics, state college for ceramics and Koblenz University of Applied Science are situated in Höhr-Grenzhausen. Apprentices and students from all over Germany join in the educational system for Ceramics.

Education in ceramics is closely connected to the Educational and Research Centre for Ceramics (BFZK), which brackets education, research and economy in the broad field of ceramic materials in Höhr-Grenzhausen. It guarantees the close and steady interchange with the ceramic industry that guarantees up-to-date contents and developments in teaching and research.

BFZK makes the educational system permeable for every young people committing themselves for a carrier in the ceramic Industry (figure 1).

Since its foundation in 1991, the Education and Research Centre in Höhr-Grenzhausen has developed very efficient in view of common and successful work of various research and educational institutions. The thereby achieved penetration in teaching and research in the field of ceramics is unique worldwide. Through continuous close contacts with the industry, research and teaching facilities the ceramic materials should even stay what it had always been - a material of the future.

Here, the competence centre provides even more than just research and teaching. So, at Höhr-Grenzhausen one can go through all facets of professional training, from the initial training in the ceramic field (an apprenticeship) to the doctor's degree in materials engineering. Similarly, the aforementioned institutes are closely working together with the industry, the trade, the art scene and with all other representatives of the ceramics sector. Thus, numerous national and international co-operations of manifold types have emerged in recent decades. Content references are available in silicate and high-tech ceramics and refractories, as well as in the technical and artistic applications with design and art issues.

Members of the Education and Research Centre are today eight institutions: the University of Applied Sciences at Koblenz with the Department of Materials Engineering, specializing in ceramics and glass, the Institute of Ceramic and Glass Arts, the State College of Ceramic Engineering and Ceramic Design, the Vocational School of Montabaur with the Department of Ceramics at Hoehr-Grenzhausen, the Research Institute Glass and Ceramics, the Westerwald Ceramics Museum, the centre for business start-up CeraTechCenter and the European Centre for Refractories ECREF. This integrated system enables the institutions to respond quickly to the needs of the industry with respect to the quality of education for the graduates.

The uniqueness of this network is the close connection of practical research (FGK, ECREF and University of Applied Sciences Koblenz), foundation activities (CTC), teaching at University (Bachelor and Master of Engineering "Ceramic Science" degree), the State college (State-certified ceramics engineer, State-certified ceramic Designer) and at the vocational school as well as the steady interchange amongst all of them.

In doing so BFZK aims for two main goals. One particular interest is to make the various fields of applications of this fascinating material group Ceramics available to the public and to unveil its (already existing but hardly seen) tremendous influence on the quality of all our lives.

In addition, the close and steady interchange with the industry guarantees up-to-date contents and developments in teaching and research.

The industry, ranging from primary materials to finished end production, utilizes the affiliate network of the BFZK for its own further development. To benefit from research and teaching experience and to access innovative research achievements clearly is a win-win-situation.

At the same time, the BFZK is an important point of contact for globally working graduates in terms of professional cooperation and exchange of knowledge. Joint projects, conferences, symposia, seminars and advanced trainings are conducted regularly.

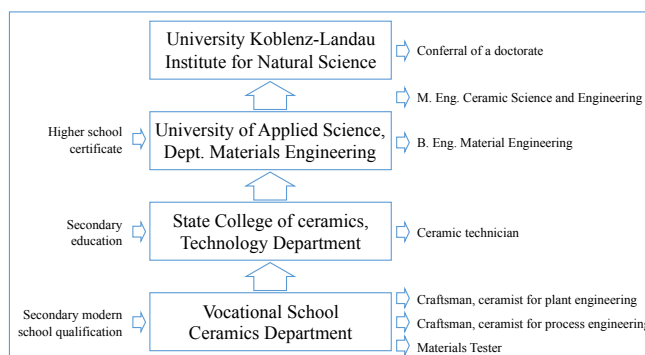

*Fig. 1: With the help of BFZK the educational system is permeable for every young people committing themselves for a carrier in the ceramic Industry.*

## KOBLENZ UNIVERSITY OF APPLIED SCIENCE, WWC CAMPUS IN HÖHR-GRENZHAUSEN

Founded in 1879 as a technical school for ceramics design, with a primarily arts and crafts orientation - Ernst Barlach, for example, was a teacher at the institution in 1904. As early as 1901, with the founding of the state technical school for ceramics, it was seen as necessary to place significantly more emphasis on engineering

ceramics in the training, in order to provide adequately trained specialists for the continuing industrialisation of the ceramics industry. In 1946, the school was recognised as an engineering school, which in 1971 was transformed into the ceramics department of the University of Applied Sciences Rhineland-Palatinate and organisationally affiliated to the regional department, Koblenz as the ceramics department. With around 300 students enrolled, one can speak of a heyday of education in Höhr-Grenzhausen in the 1980s, which, however, collapsed to around half in the 1990s and is still decreasing until today. The institution is designed for 350 students, divided among four degree programmes: A basic 7-semester Bachelor's degree with a consecutive Master's degree (3 semesters), a dual Bachelor's degree (10 semesters) and an industrial engineering and business degree in cooperation with the Department of Business and Economics at Koblenz University of Applied Sciences (7 semesters). For the Master's programme, the University of Applied Sciences and the University of Koblenz cooperate so that graduates have both a university and a college degree, which makes them eligible for doctoral studies without restrictions. Since 2018, the two institutions have maintained a research college, Max-von-Laue Institute of Advanced Ceramic Material Properties Studies (CerMaProS), which supports 11 doctoral students in their pursuit of a PhD. Funding was provided by the Rhineland-Palatinate Ministry of Research, and both institutions are among the first three in the state to receive this funding.

The focus of the training is traditionally in the field of ceramic raw materials and materials and deals with all industrially manufactured ceramic products. Höhr-Grenzhausen thus has a unique selling point, as professorships are specifically occupied in the fields of building ceramics, silicate fine ceramics, structural ceramics, functional ceramics, and refractory ceramics and pursue application-oriented training concepts. It is a living tradition that the course content is closely aligned with the needs of industry, so that graduates are typically put in a position to start adding value in companies immediately upon entering the profession. Entry is also facilitated by the fact that 99.5 % of all final theses are written in industrial companies, which gives students an important first insight into production processes and applied research.

In general, all study programmes in materials science suffer from a lack of demand from young people willing to study, which is generally the subject of much discussion by the study day MatWerk, of which we are a member, as this phenomenon is independent of the materials system. The lack of students in Höhr-Grenzhausen has repeatedly caused discussions in the past and even led to consideration of closure. In the end, it was the companies in the ceramics industry that were able to prevent the worst through intervention. What could not be prevented, however, was that personnel cuts thinned out the number of permanent staff. For example, the number of professors was reduced from 9 to 6, and the number of research assistants was halved from 4 to 2. In principle, the closure of the site is now off the table, as it has been recognised that the Höhr-Grenzhausen site is unique in Germany in the breadth of its orientation. Since mid-2021, the site has been officially recognised as a small subject by the Centre for Quality Assurance and Development (ZQ) in Mainz.

The Höhr-Grenzhausen location of Koblenz University of Applied Sciences is extremely well networked regionally through the Bildungs- und Forschungszentrum Keramik e. V. (BFZK). This institution brackets all training areas in ceramics (vocational school, technical school and university), which are in constant dialogue about this. This makes the training system vertically very permeable. In cooperation with the University of Koblenz, even doctorates are possible for those who have worked their way up through training. Also represented are the European Centre for Refractories as a professional training centre and the Forschungsinstitut für Glas | Keramik GmbH.

The environment and the good contacts in industry also prove to be extremely fruitful in the application and execution of industrial joint projects, which enable research and transfer of research results

in an outstanding directness. Both sides benefit equally from this. Since 2010, third-party funding amounting to 10 million euros has been successfully acquired, making the Höhr-Grenzhausen campus by far the strongest research campus at Koblenz University of Applied Sciences.

**DEGREE PROGRAMME AT KOBLENZ UNIVERSITY OF APPLIED SCIENCE, DEPARTMENT OF MATERIALS ENGINEERING, GLASS AND CERAMICS**

In principle, the dual study programme can be derived from the basic Bachelor's degree, whereby the scope of the specialisation subjects in the ceramic disciplines was greatly reduced in order to increase the studyability, as around 70 % of the time is spent in the industrial companies. On the one hand, the study programme is aimed at high school graduates, but on the other hand, it is particularly aimed at industrial ceramists with work experience who have been identified by the companies as future managers (figure 2).

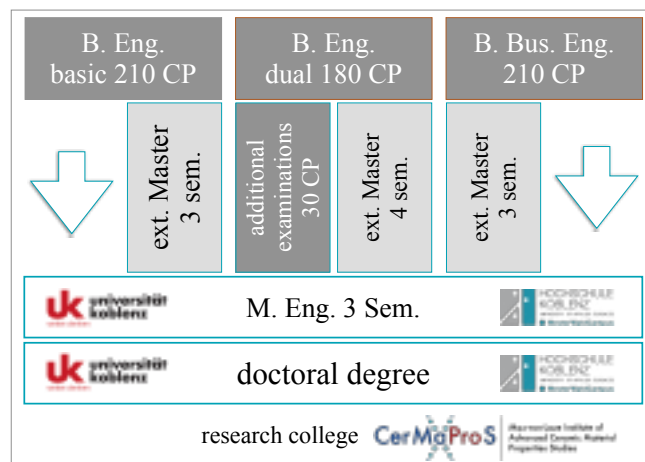

*Fig. 2: The education system is based on three Bachelor's degree programmes, one of which is dual or practice-oriented and requires cooperating companies. In cooperation with the University of Koblenz, a Master's degree can be added. Further qualification with the completion of a doctorate is also possible, whereby support can be provided by a research college.*

**Entrance requirements**

German students registering for the Bachelor of Engineering degree course need to reach "Fachhochschulreife" or equivalent. In terms of British qualifications, this level of attainment would normally be obtained after one year of 'A' level study in England and Wales or at Scottish Higher level. Applicants from England and Wales would therefore need to have 'A' level qualifications with the recommendation that Mathematics and German have been studied at this level.

Current admission requirements of the University require that prospective students provide evidence of their language skills in German (either DSH-2; or TestDaF with TDN 4 in all parts; or Goethe-Institute Certificate C2 (ZOP)).

**Bachelor of Material Engineering**

Within 3.5 years the students gain 210 ECTS (European Credit Transfer System) credit points and finish their degree program as bachelor of material science that enables to take up a master course of studies at any university in Europe that offers a similar apprenticeship. The curriculum as shown in figure 3 can be divided in five sections starting with the basic knowledge in natural science and ceramics that is followed by a deep-in study that provides special lectures in silicate ceramics, ceramics for civil engineering, functional and structural ceramics, refractories, and glazes. The students gain further expertise in general process technology and business and administration. In the 7th semester they complete their

studies with the bachelor thesis that is typically executed in cooperation with industrial partners.

| Basic natural science | | | | | | Bachelor thesis |
| Basics in ceramics | | | Ceramic in-depth study | | | |
| | | Process technology | | | | |
| | | | Business and administration | | | |

*Fig. 3: The curriculum of the Bachelor of Material Engineering*

**Master of ceramic Science and Engineering**

The bachelor-degree programme is followed by a consecutive Master that is executed in cooperation with the University Koblenz-Landau. The students gain further expertise in material physics, materials chemistry, thermochemistry. The courses are provided by the University of Koblenz-Landau. Further in-depth studies in ceramics as listed in figure 4 are given at Koblenz University of Applied Science. After the 2nd semester the students elaborate their master thesis that is again executed in cooperation with the I industry. In total the graduation as Master of Engineering – Ceramic Science and Engineering takes five years as it is common practice beyond the Bologna Process within the European Union. Students who join in the Master after three year's bachelor education must account for supplementary modules in order to gain further 30 credit points that are necessary to finish the master.

|---|---|---|
| Sem 1 | Sem 2 | Sem 3 |
| Materials physics | Materials for Aeronautics | Master thesis |
| Materials chemistry / Korrosion | Thermochemistry | |
| Glass materials | Energy process engineering | |
| Structural and functional ceramics | Further elective modules | |
| Silicate ceramics | | |
| Bio ceramics | | |

*Fig. 4: The curriculum of the Master of Ceramic Science and Engineering*

**Bachelor of Materials Engineering (dual / praxis integrated)**

A praxis integrated curriculum was launched in 2018. It combines on the job training with the curriculum. Instead of seven semesters the curriculum is extended to eight semesters. That is necessary to provide a co-operative education concept that enables students to accomplish a course of studies that is equal to the bachelor as described above (figure 5).

The target group for this co-operative education concept is identified beyond materials testers, craftsman (ceramist for process engineering and ceramist for plant engineering) as well as beyond ceramic technician who work in the ceramic industry and fulfil the entrance requirements reported above. A second target group are pupils that already passed their higher school degree who transact training contracts with industrial enterprises.

Both target groups persist or get recruited as employees in the enterprises and accomplish their course of studies in terms of apprenticeship training. In the 3rd and 5th semester the education is performed in co-operating enterprise, where defined scientific projects are elaborated. From the sight of the industrial partners this educational concept is very beneficial for at least four reasons:

- It is capable of being integrated in the internal qualification structure,
- Offers the opportunity to promote talented workers in a period of life in which they cannot resign their positions,
- the co-operation can obligate talented workers to the company and
- the concept has a high potential to attenuate the oppressive

skills shortage that is especially a problem for enterprises that are in out-of-way regions.

**Bachelor of Materials Engineering (dual) – first experiences**

Currently, 12 students have taken up their practice-integrated studies and some have already completed them. We would like to see a much greater response here in the future and hope to at least triple the number of students. So far, the cooperating companies have only sent employees from their own ranks. An acquisition at local schools seems to fail due to similar problems, which also have to be mentioned with regard to the currently low student numbers in the undergraduate Bachelor's programme. Lack of interest in materials engineering due to a lack of awareness of the subject in schools.

The experiences of the past 5 years have been consistently positive, although some students who have already been working in companies for a longer period first have to relearn goal-oriented learning and easily feel overwhelmed by the high theoretical part of the training. Here we provide individual support if needed and by holding tutorials in which the students' wishes can be specifically addressed. From the beginning of the training, the students are assigned to professors who supervise the respective specialist discipline of the companies in-house and who also maintain communication with the supervising companies. They also accompany the practical semesters and the associated project phases.

**CONCLUSIONS**

In Höhr-Grenzhausen, we have a tradition of offering high-quality training in all ceramic professions, from industrial ceramists to doctoral graduates. We attach great importance to a good mix of theoretical and practical training focal points, which enables graduates to contribute profitably to the company from day one. Ceramists from Höhr-Grenzhausen are successfully pursuing their professions all over the world and are always welcome at their former training centres.

# 8 TESTING AND STANDARDIZATION

# IN SITU HIGH–TEMPERATURE RAMAN SPECTROSCOPY: A POWERFUL TOOL FOR STUDYING REFRACTORY MATERIALS

Sinje Zimmer, Johannes Kehren, Olaf Krause

Koblenz University of Applied Sciences, Höhr-Grenzhausen, Germany

## ABSTRACT

In the last decades, Raman spectroscopy has become an important analytical tool in various research areas such as physics, chemistry, biology, medicine, and geosciences. Initially, the technique was very complex and time-consuming and, therefore, limited to scientific applications. The development of new technologies has opened up Raman spectroscopy to a broader audience. Some companies are already using it to monitor and control quality. Raman spectroscopy enables non-destructive analysis to identify crystalline and amorphous phases and to distinguish polymorphs with a spatial resolution of the order of 1 μm.

Raman spectroscopy in combination with a furnace opens entirely new insights into the thermal evolution of mineral phases in terms of phase reactions and their reaction kinetics, whereat all measurements can be performed space-resolved and *in situ* up to 1500 °C. It speaks for itself that this method allows completely new insights into the sintering behavior of refractory materials and also opens the possibility to observe reactions temperature-, time-, and space-resolved in contact with corrosive media.

This paper gives an overview of *in situ* Raman spectroscopy at high temperatures in general, as well as the information that can be obtained with this method and the challenges that have to be overcome. Furthermore, initial results on the high temperature behavior in the CaO-Al₂O₃ system are presented. These experiments show that high temperature Raman spectroscopy is a promising method for refractory materials.

## INTRODUCTION

Raman spectroscopy is a powerful non-destructive tool for the mineralogical and chemical investigation of various materials. By performing *in situ* Raman measurements at high temperatures, a better understanding of the structure and behavior of refractory materials under these extreme conditions can be gained. This can help optimize their performance and extend their service lifespan.

Using commercially available heating stages, Raman spectra can be measured at temperatures up to 1500 °C. In addition, pressure and different environments can be applied depending on the desired objective [1]. To gain spatially resolved information of mineral reactions and interactions, Raman images have to be recorded instead of point measurements. The first time this was done *in situ* at high temperatures, was by Stange et al. [2] and the method itself was published in Hauke et al. [3]. Since then, several other studies have used it to investigate the high temperature behavior of ternisite [4], Rhenish lignite ashes [5], and silica/calcium phosphate ceramics [6].

This work reports on the application of *in situ* Raman spectroscopy at high temperatures to study refractory materials. Furthermore, it was investigated if the method can provide information to better understand mineral interactions and reactions through spatially resolved measurements. The $CaO-Al_2O_3$ system was chosen as the basis for these investigations because it has already been examined by other methods, and, therefore, the reactions and mineral phases ($CA$, $CA_2$, $C_{12}A_7$, and $C_3A$) during heating are well known [7, 8]. Furthermore, this system is very important in refractory materials as it is the basis for calcium aluminate cement, which is a major component in refractory castables.

## MATERIALS & METHODS

### Sample preparation

Calcite from Merck KGaA (Germany) with at least 99% $CaCO_3$ and corundum from Almatis (The Netherlands) with 99.8% $Al_2O_3$ were used as starting materials for the experiment. The powders were mixed in a weight ratio of 1:1 and pressed into a tablet with a diameter of 3 mm and a height of 3.44 mm. It was then placed in a heating stage (TS1500V, Linkam Scientific Instruments Ltd., United Kingdom) which was mounted onto the x-y-stage of the Raman spectrometer. A schematic drawing of the heating stage is shown in figure 1. The stage can be heated up to 1500 °C with a temperature stability of < 1 °C and a heating and cooling rate of 0.1 to 200 °C/min. Due to the placement of the thermocouple at the bottom of the heating cup and a temperature gradient within the sample, the temperature at the surface (were the measurement takes place) deviates from the temperature recorded. To adjust for this gradient, the temperatures are corrected according to Stange et al. (2018) [2].

*Fig. 1: Schematic drawing of the Linkam TS1500V heating stage. The sample cup size is 7 mm in diameter and 6 mm in height.*

### Raman spectroscopy

The experiments were carried out with a confocal Raman spectrometer (Apyron, WITec GmbH, Germany) equipped with a deep-depletion detector and a 532.06 nm laser at 460 mW under a microscope. A 600 l/mm grating was used for all measurements, resulting in a spectral resolution of up to 2 cm⁻¹ and covering a spectral range from -80 to 4140 cm⁻¹. Furthermore, a 50x LD objective with a working distance of 9.1 mm and a numerical aperture of 0.55 was chosen. With these parameters, the theoretical lateral resolution ($d_1$) was about 1.2 μm and the axial resolution ($d_a$) was about 7.0 μm. The resolutions are given by $d_1 \approx 1.22 \lambda/NA$ and $d_a \approx 4\lambda/NA^2$, where $\lambda$ is the wavelength of the incident laser [9].

### Experimental detail

In the experiment, a total of six Raman images were recorded, two of which were measured at room temperature before (RTs) and after heating (RTe). The remaining images were measured at 1000, 1100, and 1200 °C. The surface temperatures corrected after Stange et al. [2] are 907, 992, and 1078 °C and are used to refer to the images in the following text. At each of these temperature steps, a Raman image was taken, and only at 1078 °C a second one was taken to see if there were any isothermal reactions taking place. The sample was fired to the different temperature steps with 10 K/min and cooled with 100 K/min. The full heating curve is depicted in figure 2.

The Raman images RTs and RTe cover an area of 200 x 200 μm² with 1 μm steps. At elevated temperatures, the images were smaller with 60 x 60 μm² and 1 μm steps, so a Raman image takes less time to measure (about 1 h). A larger area was chosen for the room temperature images because the mineral phases move during heating and can therefore be followed. All images were recorded with an acquisition time of 1 s per spectrum, instead of RTs, which was acquired with 0.1 s.

The Raman spectra of the images were measured in a grid from top left to bottom right, which must be considered when interpreting the data, as time passes during the measurement and mineral reactions proceed.

Before each Raman image, a manual focus was performed at the center position of the Raman image. However, the volume of the sample expanded during the high temperature measurements, resulting in defocusing. Therefore, only the first 20 to 30 min of each high temperature Raman image can be used for interpretation.

*Fig. 2: Heating ramp of the experiment. A Raman image was taken before and after the heating process at room temperature. One Raman image was measured at each temperature step, except at 1200 °C at which two Raman images were taken.*

## Data processing & analysis

The Raman images were first corrected for spikes caused by cosmic rays hitting the detector. Not all spikes could be removed automatically, therefore the remaining ones had to be fixed manually. The spectra were then cropped to a range of about 90 to 1200 cm$^{-1}$ to reduce computational time and improve further processing and analysis. Furthermore, the Raman data was smoothed using the Savitzky-Golay filtering algorithm to correct for noise and 2$^{nd}$ order polynomial was fitted and subtracted from the data to correct the background.

After data processing, the images were analyzed using the True Component Analysis of the WITec Project SIX software. This procedure extracts reference spectra of each phase from within the image to create intensity distribution images, which can then be combined to create a false-color image that includes all phases. The extracted reference spectra were obtained by averaging 9 individual spectra. For some phases no single phase spectrum could be extracted, therefore, interfering Raman bands of other phases were removed with the demixing tool in the project SIX software.

It is important to note that Raman spectra change at high temperatures due to crystal lattice changes, phase transformations, and blackbody radiation. These influences lead to increasing backgrounds, position shifts and broadening of the Raman bands, and an overall weaker signal. Although the Raman spectra of calcite, corundum and the expected CA phases are known at room temperature, the high temperature spectra have to be reassigned due to the shift of the Raman bands. However, it is still possible to correlate the high temperature spectra with the room temperature spectra.

## RESULTS & DISCUSSION

The Raman images of the experiment are shown in figure 3. Initially, calcite can be observed in RTs as well as weak signals from corundum, although both phases are present in the sample in equal amounts. This is due to the higher total Raman band intensities of calcite compared to corundum.

## Decarbonation of calcite

After heating to 907 °C, calcite is still present in the first 3 min of the and then decomposes to CaO. This is the result of the decarbonation of calcite according to the following reaction:

$$CaCO_3 \rightarrow CaO + CO_2$$

CaO can also be detected at 992 °C, but in smaller amounts than at 907 °C. At 1078 °C and in RTe, CaO cannot be clearly identified in the Raman spectra. However, the Raman spectrum of CaO is only a secondary Raman spectrum, which means that the spectrum has a weak signal and only broad Raman bands. Therefore, it is possiblethat CaO is not seen at higher temperatures because the blackbody response increases with temperature and superimposes the CaO signal. After cooling to RT, calcite and portlandite can be observed, which must have formed from unreacted CaO. The recrystallization of calcite follows the reverse reaction of decarbonation:

$$CaO + CO_2 \rightarrow CaCO_3$$
In this process, CaO reacts with the remaining CO$_2$ trapped in the heating stage. The decarbonation and recrystallization of calcite during *in situ* Raman measurements was also observed by Hauke et al. [3]. However, it appears that not all CaO reacts with CO$_2$ to form calcite, but instead reacts with atmospheric moisture to form portlandite:

$$CaO + H_2O \rightarrow Ca(OH)_2$$
Portlandite is only present in the lower part of the Raman image, which is either because the remaining CaO was only present in the lower part of the Raman image, or the CaO took at least 7 h to react to portlandite, although the reaction should be quite rapid.

Corundum can be observed in all Raman images, but its amount seems to decrease with time to form other mineral phases.

## Formation of CA phases

During heating, the formation of three phases can be observed: Phase A, B and C. Phase A forms at 907 °C and appears to crystallize in large amounts at the expense of CaO. Phase B and C appear only at 1078 °C. At RT after heating the calcium aluminates CA, CA$_2$, C$_3$A and C$_{12}$A$_7$ and an unknown phase (Phase D) can be detected. Due to the temperature dependent band shift and broadening, the assignment of the unknown phases at high temperatures cannot be done with certainty. However, first assumptions can be made. According to the CaO-Al$_2$O$_3$ phase diagram, mainly CA and C$_{12}$A$_7$ are formed in the temperature range between 900 and 1100 °C [7]. In figure 4, the unknown phases A, B, and C are compared with reference spectra of CA, CA$_2$, C$_3$A, and C$_{12}$A$_7$ synthesized by the author. Phase A and B both have an intense band at about 500 cm$^{-1}$ and a smaller band between 700 and 800 cm$^{-1}$, whereas the Raman band of Phase A is less intense compared to that of Phase B. However, for Phase A this band is at about 758 cm$^{-1}$ and for Phase B at about 730 cm$^{-1}$. The main band of the reference CA is at 519 cm$^{-1}$. In addition, the spectrum has two sets of Raman band groups, between 100 and 160 cm$^{-1}$, and 770 and 810 cm$^{-1}$. In particular, the second group of bands is much smaller than the main band. The Raman bands of C$_{12}$A$_7$ are located at about 309, 521 and 774 cm$^{-1}$. The second one has the highest intensity. It can be assumed that Phase A is the high temperature Raman spectrum of CA and Phase B is that of C$_{12}$A$_7$. because although the two main bands of the Phase A and B have similar positions, the second band of Phase B at about 734 cm$^{-1}$ has a higher intensity compared to the corresponding main band and correlates with the reference spectrum of C$_{12}$A$_7$. Comparing Phase C with the calcium aluminate spectra, no correlation can be observed. However, the Raman bands at about 500 and between 705 and 790 cm$^{-1}$ are similar to those of Phase B and mainly only one additional band appears at about 585 cm$^{-1}$. In RTe another spectrum (Phase D) was detected, which could not be identified yet. The main band of this phase is at about 601 cm$^{-1}$ (figure 5). Considering the band shift caused by high temperatures, it is possible that Phase C is a mixed spectrum of Phase B and D.

Although CA$_2$ and C$_3$A are present at room temperature after the experiment, there is no evidence of these phases are present in the high temperature images. It could be that the phases were formed during heating but are not within the measured area.

## CONCLUSIONS

In this study, we have shown that Raman spectroscopy performed *in situ* at high temperatures can be a powerful tool for studying refractory materials.

The decarbonation and recrystallization of calcite could be observed, as well as the reaction of CaO to a calcium aluminate during firing at 907 °C and to portlandite at RT. Although we cannot yet identify the unknown phases with certainty, we were able to show that first approaches can be made.

In future experiments, high temperature measurements of pure calcium aluminates will be performed to study the Raman band changes of each phase. This will help to identify the unknown phases in this study. In addition, experiments with other materials such as nitride bonded silicon carbide are planned to further investigate the mineral reactions during heating and to show that this method can also be applied to other refractory materials.

# MATERIAL CHARACTERIZATION & PRODUCT ANALYSIS OF REFRACTORIES VIA X–RAY COMPUTED TOMOGRAPHY

D. Lüftner, P. Seitz, R. P. Rana
RHI Magnesita, Leoben, Austria

**ABSTRACT**

X-ray analysis is a standard approach to investigate all kinds of materials and is well established for refractories (e.g., X-ray diffraction, X-ray fluorescence, and X-ray adsorption). X-ray computed tomography is used to get a sample's three-dimensional (3D) density distribution by capturing X-ray absorption images while the sample is rotating (CT). This provides the opportunity to view the sample's inside in three dimensions with a resolution that ranges from around 100µm down to the submicron range. The capabilities of the CT system at RHI Magnesita's Technology Center Leoben (TCL), which makes it possible to collect precise information about a sample's internal structure, will be illustrated in this article utilizing a few chosen investigations in the field of flow control products.

**INTRODUCTION**

X-ray radioscopy is an indispensable tool for many industrial applications, especially in the field of quality control and has been in use at RHI Magnesita for many years. However, because it yields a two-dimensional (2D) representation of a 3D object, it is often difficult to interpret [1]. In the last two decades the field of industrial CT has been steadily increasing [2]. During an industrial CT scan more than thousand X-ray transmission measurements of a rotating object are performed and then this data is converted into a 3D representation of the object using various reconstruction algorithms. As such, the drawbacks of pure X-ray radioscopy can be overcome because firstly, CT provides a map of the radiation absorption coefficient (i.e., density) for each point in space. Secondly, the dimensions are absolute values, and the 3D tomogram represents the real shape of the object [1]. Therefore, defects or flaws can be detected with high accuracy and their dimensions can be extracted.

In the area of flow control, products such as refractory slide gate plates, ladle shrouds, monoblock stoppers, and SENs are used in the continuous casting process to transfer molten steel from the ladle to the tundish and then into the mould [3,4]. These products are used to regulate the steel flow and protect the molten metal stream from reoxidation. Due to their direct contact with the high-velocity liquid steel stream, they need to resist elevated temperatures, corrosive and abrasive attack by steel and slags, as well as high-temperature gradients during application. To fulfil the rising customer demands (e.g., clean steel and anti-clogging), these refractories are becoming more and more complex. Consequently, improving the product performance is challenging and time consuming. Hence, there is an increasing demand for innovative technologies to support product development in the flow control area. CT, which gives the opportunity to have a detailed look inside the full volume of an uncut product, enables fast optimisation of the manufacturing process, product design, as well as excellent quality control.

In this paper, the capability of CT in the world of refractories is demonstrated using various examples of flow control product ranging from post-mortem investigations of a SEN and slide gate plate, over the development and of 1500 mm long TS-SENs to the characterization of the material used for these products.
.

**X-RAY COMPUTED TOMOGRAPHY DEVICE**

The new tailor-made CT device at RHI Magnesita's TCL (Austria) is depicted in Figure 1a. It is a dual X-ray source device, equipped with a 225 kV direct beam and a 190 kV transmission beam source. While the former has a higher penetration depth and may be used for larger samples, the latter is limited in power but with a focus spot size in the sub-micron range, which enables high-resolution measurements of small samples. As an example, the result of scanning a single MgO grain is shown in Figure 2b, where the light colour corresponds to higher density material and the dark regions are low density areas. A voxel size resolution of approximately 2 µm offers a precise determination of a crack's thickness (i.e., 40 µm in this case) and length. Furthermore, the system is comprised of a 3000 x 3000-pixel flat panel detector with a pixel pitch size of 150 µm, a manipulator with seven independent axes of movement, a maximum focus detector distance of more than 1400 mm (necessary to achieve the geometrical magnification for high resolutions), and a vertical travel distance of the X-ray source and detector of about 800 mm.

*Fig. 1 (a) TS-SEN standing upright on the system's turning table and (b) vertical cut through the 3D CT data set of a single MgO grain with a detailed dimensional measurement of the crack (i.e., 40 µm)*

**APPLICATION OF X_RAY SCANNING TECHNOLOGY**

**Postmortem analysis**
The first postmortem example described in this section is the analysis of a used SEN that showed rather high wear after use.

A full 3D CT measurement of the piece was accomplished, and an image of the sample surface is shown in Figure 2a. A slice through the 3D data is depicted in Figure 2b. The slag band area, which has a high amount of ZrO2 and therefore a higher density, was easily identified at the bottom of the sample and the following conspicuous regions can be observed in the data.

Inside the bore remaining droplets of steel could be detected (whitish because of their high density). The following changes to the body material above the slag band during operation of the product were also identified. Firstly, local densification of the product due to steel and/or slag infiltrating pores was observed in the CT measurements, with the infiltrations leading to a brighter colour that can be seen in the regions indicated with a green arrow (see Figure 2b). Secondly, at the elevated temperatures during casting, oxidation (i.e., decarburisation) of the body material can occur that locally lowers the density and therefore appears darker in the CT data. In this case, it was evident that a large part of the sample above the infiltrations had undergone oxidation. Thirdly, and most importantly, the nozzle was affected by chemical attack from the mould powder above the meniscus, which caused material wear. The wear is clearly visible in Figure 2c, where the red-purple horizontal lines show deviation of the surface of the used SEN from the CAD drawing of an unused product. It can be concluded from the CT images that the root cause of the high product wear was a too deep immersion of the product during casting and/or an insufficiently long slag band.

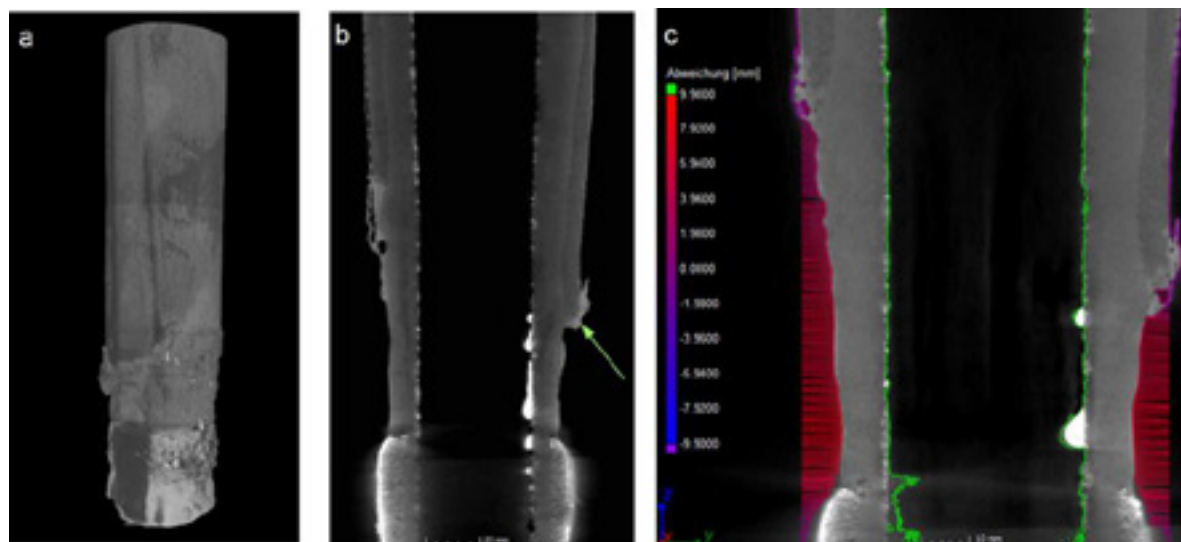

*Fig. 2. (a) 3D view of the SEN surface obtained by CT, (b) vertical cut through the SEN CT data, and (c) difference between the used SEN's surface and the CAD drawing of the product. The inner bore profile of the used SEN is indicated in green.*

For certain flow control products, a 3D CT measurement may not be applicable, for example in the case of slide gate plates. This is primarily due to the aspect ratio of the piece as well as the metal can covering a proportion of the refractory surface. However, the CT device at TCL can also be used to perform 2D radioscopy measurements and this was the approach used in the following post-mortem investigation. In this example, a slide gate plate showed cracks on its surface after application (Figure 3a). The question in this case was whether the cracks occurred during cool down or if they had formed at an earlier stage during application. The 2D radioscopy image of the used slide gate plate is shown in Figure 3b. It should be noted that the radioscopy images directly show the information from the detector, meaning that light grey values correspond to a high radiation intensity and hence a low linear absorption, while dark values indicate a higher density/thickness. Thus, the black area surrounding the grey circle is the steel jacket around the slide plate and the bore hole appears white. The cracks can be seen as white lines radiating from the bore hole. Because there are no visible steel infiltrations, which would have appeared dark, it can be concluded that the cracks formed during cool down of the product due to thermal shrinkage of the material. The darker areas indicated by the red arrow are due to the remaining mortar located on the backside of the plate.

*Fig. 3. (a) image of the used slide plate and (b) 2D radioscopy measurement of the corresponding slide gate plate.*

In addition to these examples, the CT equipment has been pivotal for the post-mortem analysis of many other flow control products such as monoblock stoppers and ladle shrouds. Furthermore, if the root cause of a sample failure cannot be determined directly from the CT scan, the images can be used to identify the ideal location for sampling so that further analyses can be performed, such as microscopic investigations.

**Product development and process improvement**

Another important application for the CT technology is supporting new product developments or improving existing ones. This is particularly important for flow control products with an elaborate design, consisting of multiple different materials, and/or a complex shape and therefore requiring an expensive production process. One example for which these criteria hold true are TS-SENs, which are used for thin slab casting where a well-controlled flow of the steel from the tundish to the mould is essential. Here, the potential of CT lies in a fast analysis of any change in the production process and/or material recipe for the whole volume of a piece in a non-destructive way. This enables a direct link to be established between implemented changes and their effect on the product in terms of defects or imperfections. As such the CT can significantly reduce the development time for this kind of product in the prototype stage.

The following is an example of how the CT equipment was used to expedite the development of a TS-SEN design. Due to the large size of the TS-SEN, a full 3D CT scan of the whole volume would have been more time consuming and expensive compared to a 2D scan. Therefore, only the most critical parts, namely the slag band and port area are 3D-scanned. Because of the TS-SEN's rotational symmetry along a high proportion of the shape, it was sufficient to measure these sections three times in 2D with a 60° rotation selected between each image. Thereby any defect could be detected in the entire sample volume. The remaining TS-SEN volume, namely a proportion of the slag band region and the nozzle outlet, was investigated using 3D CT measurements and several anomalies were identified that occurred while trying new production routes or alternative recipes. For example, Figure 4a shows the outcome of a new production approach that led to scratches and zirconia contamination at the outlet and Figure 4b depicts the results of a trial where significant intermixing of the slag band and body material occurred. Only with the fast and direct feedback from the CT measurements, could such trials be done efficiently and economically. The images in Figure 4c, which show vertical cuts in three orientations (i.e., top, front, and side view) demonstrate two more imperfections. Firstly, there are white lines which are, as already discussed above for the 2D measurements, due to the zirconia material migrating down from the slag band area. This indicates an improper filling of both the alumina graphite and zirconia graphite materials. Secondly, a crack is visible in all three Figure 4c images, which can be identified from the typical nonlinear shape and the sharp contrast to the surrounding material. Based on these results the necessary improvements were made.
*Fig. 4. Compilation of anomalies found in TS-SENs. The images show vertical and horizontal cuts through the 3D CT data. (a) scratch on the inner surface and zirconia contamination at the outlet, (b) intermixing of slag band and body material, and (c) crack close to the slag band material in three orientations (top, front, and side view) and zirconia material migration (white).*

**Material characterization**

The last example of an application of X-ray CT is the characterization of the refractory material. Because the resolution which can be obtained in the CT measurement depends on the size of the investigated sample, it is necessary to take samples from the products. Figure 5 shows an example of such an investigation for the body material of an isostatically pressed product. In this case a cylindric sample with a diameter of 8 mm has been utilized allowing for a voxel size and, due to the low power, a resolution of about 3 μm. Clearly, different components can be recognized, however, for a further analysis of such kind of data, it needs to be segmented into the different components of interest. Different algorithms can be applied to perform the segmentation, from very simple ones like global threshold, which is often sufficient if only the pore space is needed for further investigations, to more complex ones like convolutional neural networks, which have been used in this work [5] and can be seen in Fig. 5c. Here, the red colour corresponds to the coarse grains, the green to graphite, yellow to the remaining matrix (e.g., fine grains) and grey to the porosity. To have a reference for the annotation of the different components the sample has been cut after the CT measurement and has been investigated using an optical microscope, Fig. 5b shows the corresponding image. Clearly, apart from a small misalignment and the different contrast, the slice corresponding to the cut plane has been found in the 3D CT data, which can be seen best when considering the coarse grain fraction.
*Fig.5 (a) Slice through the 3D CT data of a high resolution (<5µm) µ-CT scan. (b) Microscopy image of the same sample at the plane indicated in panel a. (c) Slice through the segmented CT data, at which red corresponds to the coarse grains, green to graphite, grey to the porosity and yellow to the remaining matrix of the refractory.*

Once the computed tomography data is correctly segmented (Fig. 5c), various further analyses can be done on such kind of data. From the three-dimensional characterization of the microstructure, i.e., the size- and geometric distribution of pores and grains and the orientation of different components, over the calculation of integral properties of the investigated material like the permeability or the thermal- or the electrical conductivity, to the prediction of e.g., elastic properties by using the segmented data as input for thermomechanical simulations.

## CONCLUSIONS
In conclusion, with the possibility to get a rapid and complete picture of a sample's inner structure, ranging from a single grain to the full dimensions of a complex product in a non-destructive way, CT is an indispensable tool for refractory investigations. In this article the following uses of an industrial CT system were discussed:

- Raw material characterisation.
- Post-mortem analysis.
- Dimensional measurement/wear measurement.
- Quality control.
- Process optimisation.
- Product development.
- 3D Microstructure characterization.

Besides these applications, there are several other possibilities for the CT system within the world of refractories. Among them are 3D microstructure characterisation, for example the geometric and size distribution of pores or inclusions (material characterisation), use as a reference method for other non-destructive testing methods, and generating input data for subsequent mechanical or thermomechanical simulations such as finite element method and discrete element method. In the future, it is planned to perform in-situ measurements at elevated temperatures or with applied stresses. Finally, it can be concluded that the new X-ray equipment significantly supports refractory developments, especially in the area of flow control. It has become a key technology for detecting all kinds of anomalies and leads to a better understanding of their origin, thereby increasing the product and process quality and hence refractory performance.

# FRACTURE ENERGY DETERMINATION OF CARBON–CONTAINING REFRACTORIES WITH CONSIDERATION OF THE CREEP BEHAVIOUR

Dietmar Gruber, Martin Stückelschweiger, Shengli Jin, Harald Harmuth

Montanuniversität Leoben, Leoben, Austria

## ABSTRACT

A carbon-containing magnesia refractory product (MgO–C) as it is applied in steel ladles of the secondary steel metallurgy was investigated for the Mode I fracture behaviour. Usually, it is determined with the wedge splitting test to quantify the thermal shock behaviour, the materials' brittleness or to gain input parameters for thermomechanical Finite Element (FE) simulations. For high-temperature testing of carbon-containing refractories, gas purging, for example, with argon, is required to avoid carbon oxidation in the sample. Laser speckle extensometers measure the displacement in a contactless manner. Based on the results obtained from the tests, fracture mechanical parameters such as the specific fracture energy and the nominal notch tensile strength were calculated. An inverse FE simulation yielded tensile strength, the total specific fracture energy, and the strain-softening behaviour. As refractories often show significant creep rates at application temperatures, the creep behaviour was also considered in the inverse evaluations. Finally, the contribution of creep to the determined area under the load-displacement curve was quantified and a corrected specific fracture energy was determined.

## INTRODUCTION

The wedge splitting test is commonly used to characterise the fracture mechanical behaviour of refractory materials [1,2]. The advantages are the relatively stable crack propagation and the possibility of developing a large fracture process zone [3]. When testing carbon-containing materials at high temperatures, protection against carbon burnout is essential. This may be achieved by gas purging. At elevated temperatures, the results of wedge-splitting tests could be influenced by creep; this means the results will depend on the loading velocity. A decrease in the loading speed will increase the effect of creep [4]. An approach to quantify the contribution of creep is to determine the creep behaviour in advance and conduct a Finite Element inverse evaluation considering creep and fracture. The procedure and results for a Magnesia carbon material are explained in this paper.

## MATERIAL AND SAMPLE PREPARATION

A resin-bonded magnesia carbon brick consisting of fused magnesia, magnesia clinker and graphite was tested. After coking at 1000°C for 5h under a reducing atmosphere, the residual carbon content was 10%. The C/S weight ratio was 3.8.

## EXPERIMENTAL

The wedge splitting test according to Tschegg was applied for the fracture mechanical investigations [1]. The samples are prismatic, with a starter notch and additional crack-guiding notches at the lateral surfaces. The specimen dimensions and a schematic of the wedge-splitting test setup are shown in Fig. 1. The relatively high ratio of the fracture surface area to the specimen volume and the decrease in the elastically stored strain energy in the testing machine by the action of the wedge favour stable . A vertical load is applied to the wedge during the test, resulting in a horizontal reaction force and crack propagation in the vertical direction. The test is performed with a 0.5 mm/min vertical loading rate. A laser extensometer detects the horizontal displacement at the measuring points during the test. The displacement is measured at the height where the rolls contact the load transmission elements.

*Fig. 1: (a) Wedge splitting test shape and dimension in mm and (b) testing setup*

The sample is supported by a corundum piece (prismatic, $3\cdot3\cdot90mm^3$) to allow sample deformation (Fig. 1 (b)). The vertical force $F_V$ is measured, and the horizontal force is calculated according to eq 1.

$$F_H = \frac{F_V}{2tan\frac{\alpha}{2}} \tag{1}$$

$\alpha$ is the angle of the wedge (10°). The specific fracture energy $G_f'$ and the nominal notch tensile strength $\sigma_{NT}$ were calculated according to eq. 2 and 3.

$$\sigma_{NT} = \frac{F_{H,max}}{bh}\left(1 + \frac{6y}{h}\right) \tag{2}$$

$$G_f' = \frac{1}{A}\int_0^\delta F_H d\delta_H \tag{3}$$

$b$ and $h$ are the width and height of the ligament area, respectively, and $y$ is the vertical distance of the horizontal force from the centre of gravity of the ligament area. The measured horizontal displacement is defined with $\delta_H$, and the horizontal displacement at 15% of the maximum load is $\delta$.

Usually, the material brittleness is characterised by the characteristic length $l_{ch}$ (eq. 4) [5]:

$$l_{ch} = \frac{G_f E}{f_t^2} \tag{4}$$

Here, $E$ is the Young's modulus and $f_t$ the tensile strength. To avoid oxidation of carbon in the sample at elevated temperatures, the tests were carried out in an argon-purged furnace (10-70 l/h). The horizontal displacement was measured on the front and rear sides with laser speckle extensometers (LSE) through quartz glass windows [6]. The resolution of the displacement measurement is 0.11μm.

## SIMULATION MODEL

It is impossible to directly determine tensile strength, the complete specific fracture energy, and the contribution of creep to the testing result. For this reason, an inverse evaluation method was applied to a two-dimensional finite element model of the wedge-splitting test [7]. The commercial software package ABAQUS was applied for the simulations. Fracture was assumed to happen in the ligament area (Fig. 2).
*Fig. 2. Finite element model and ligament area*

According to eq. 5, an exponential softening was applied to simulate the Mode I fracture.

$$\sigma = f_t \left\{ 1 - \left( \frac{1 - e^{-\varphi \frac{x}{x_{ult}}}}{1 - e^{-\varphi}} \right) \right\} \qquad (5)$$

$f_t$ is the tensile strength of the material, the parameter $x_{ult}$ is the ultimate crack opening and $\varphi$ is a non-dimensional parameter that defines the strain softening behaviour [8]. An adaptive nonlinear least-squares algorithm was applied to inversely determine the fracture parameters by fitting the finite element simulation results to those of laboratory wedge splitting tests. To evaluate the influence of creep on the results, inverse evaluations were carried out with and without consideration of creep. The Norton-Bailey creep was applied (eq. 6):

$$\dot{\varepsilon}_{cr} = K(T)\sigma^n \varepsilon_{cr}^a \qquad (6)$$

$\sigma$ is the von Mises stress, $\dot{\varepsilon}_{cr}$ is the creep strain rate, $\varepsilon_{cr}$ is the creep strain, $K(T)$ is a temperature-dependent function, and the parameters $n$ and $a$ are the stress and strain exponents, respectively. Creep was considered in the whole sample volume.

**RESULTS AND DISCUSSION**
Fig. 3. Shows the load-displacement curves from experiments carried out at 20°C, 1100°C, 1370°C and 1470°C.

*Fig. 3. Load/displacement curves of the magnesia carbon material measured at different temperatures.*

Tab. 1 shows the maximum horizontal force $F_{Hmax}$, the specific fracture energy $G_f'$ and the nominal notch tensile strength $\sigma_{NT}$

according to equations 1, 2 and 3.

Tab. 1: Fracture mechanical parameters determined from tests performed at 20°C, 1100°C, 1370°C and 1470°C

|  | 20°C | 1100°C | 1370°C | 1470°C |
|---|---|---|---|---|
| $F_{Hmax}$ [N] | 1720 | 1646 | 2508 | 2510 |
| $G_f'$ [N/m] | 240 | 125 | 362 | 513 |
| $\sigma_{NT}$ [MPa] | 2.71 | 3.13 | 4.02 | 4.35 |
| $G_f'/\sigma_{NT}$ [mm] | 0.09 | 0.04 | 0.09 | 0.12 |

For the tests above 1000°C the specific fracture energy $G_f'$ and the nominal notch tensile strength $\sigma_{NT}$ show an increase with temperature. The test at room temperature shows the smallest nominal notch tensile strength $\sigma_{NT}$, but the specific fracture energy $G_f'$ was higher than that at 1100°C and lower than that at 1370°C. The ratio between the specific fracture energy $G_f'$ and the notch tensile strength $\sigma_{NT}$ was applied to indicate the brittleness, showing the highest brittleness at 1100°C. After the test at 1470°C, the weight loss was below 1% for a purging rate of 70 l/h. The weight loss after the test at 1370°C was 0.8%. For the test at 1100°C the weight loss decreased to 0.5%.

**Results from the inverse evaluation**
A comparison of measured and in the inverse evaluation determined load-displacement curves for the high-temperature tests are given in Fig. 4-6. The black curves show the laboratory experiments. The red curves were simulated without the consideration of creep and the blue ones were simulated considering creep.

*Fig. 4: Load-displacement curves at 1470°C.*

The curves show in general good fits, especially in the pre-peak and post-peak regions. Slight deviations appear around the maximum loads.
745
Fig. 5: Load-displacement curves at 1370°C.

Fig. 6: Load-displacement curves at 1100°C.

Fig. 7-9 show the inverse evaluation results for the strain softening behaviour. In the cases where creep was considered (blue curves), the area under the curves (representing total specific fracture energy $G_f$), is smaller and the strength is higher. The ultimate displacement increases with the temperature.

Fig. 7: Strain softening behaviour at 1470°C.

Fig. 8: Strain softening behaviour at 1370°C.

Fracture mechanical parameters and brittleness indicators from the inverse evaluation without consideration of creep are summarised in Tab. 2. Here creep contributes to fracture characteristics. $G_f$ is in all cases higher than $G_f'$ (Tab.1), because for $G_f'$ the integration was stopped at 15% of the maximum force on the post-peak side. $G_f'/\sigma_{NT}$ and $G_{ff}/f_t$ show the same trend but higher values for $G_{ff}/f_t$, the minimum of $l_{ch}$ was detected for 1370°C and the maximum at 1470°C.

Fig. 9: Strain softening behaviour at 1100°C.

Tab. 2: Fracture mechanical parameters and brittleness indicators at different temperatures calculated from ABAQUS simulations without consideration of creep.

|  | 1100°C | 1370°C | 1470°C |
|---|---|---|---|
| $G_f$ [N/m] | 162 | 453 | 563 |
| $f_t$ [MPa] | 1.42 | 2.26 | 2.40 |
| $\sigma_{NT}/f_t$ | 2.2 | 1.77 | 1.83 |
| $G_{f}/f_t$ [mm] | 0.11 | 0.20 | 0.23 |
| $l_{ch}$ [m] | 2.00 | 1.91 | 2.93 |

Fracture mechanical parameters and brittleness indicators from the inverse evaluation with consideration of creep are summarised in Tab. 3. Here creep does not contribute to fracture chartacteristics. Further this table shows the differences caused by the action of creep. The influence on $G_f$ is significant and has a maximum at 1370°C with ann increase of 47% by creep. $f_t$ is higher with a maximum increase of 0.73 MPa for 1370°C by creep. The higher strength and the lower $G_f$ result in a higher brittleness (shown by the lowest $l_{ch} = 0.57$ m) for pure fracture without creep.

Tab. 3: Fracture mechanical parameters at different temperatures calculated considering creep and the influence on fracture mechanical parameters.

| | 1100°C | 1370°C | 1470°C |
|---|---|---|---|
| $G_f$, creep considered [N/m] | 137 | 238 | 417 |
| $\Delta G_f$ [N/m] | 25 (15%) | 215 (47%) | 146 (26%) |
| $f_t$, creep considered [MPa] | 1.71 | 2.99 | 2.47 |
| $\Delta f_t$ [N/mm²] | 0.29 | 0.73 | 0.07 |
| $G_f/f_t$, creep considered [mm] | 0.08 | 0.08 | 0.17 |
| $l_{ch}$ [m] | 1.17 | 0.57 | 2.05 |

## CONCLUSIONS

With the applied procedure it was possible to:
- determine the fracture mechanical parameters $G_f'$, $\sigma_{NT}$ for a carbon-containing refractory at elevated temperatures with minimised carbon burnout,
- determine the parameters for an exponential strain softening behaviour as well as the tensile strength $f_t$ and $G_f$ with finite element simulations coupled with the inverse evaluation procedure,
- assess the influence of creep during the high-temperature tests on the determined parameters.

As expected, $G_f$ is raised by creep because it contributes to energy consumption (even without crack propagation, a displacement could be recorded after load application). Creep further leads to lower inverse evaluated $f_t$, because creep decreases the loads in the sample in general and around the maximum force in the load-displacement diagram. Lower $l_{ch}$ indicates higher brittleness due to the action of creep originating mainly from the higher $f_t$, especially for 1370°C the lower $G_f$ has a further significant influence.

## ABSTRACT

Whenever a refractory product is used in a lining of an industrial vessel at high temperatures, it simultaneously experiences a thermal gradient and mechanical loading. In operation, each part of the lining expands, as do all the neighbouring parts, resulting in substantial compressive stresses parallel and near to the hot face of the lining. As a result, specific microstructural changes that condition the behaviour of the refractory material in service take place. Such changes could, until now, not be reproduced at laboratory scale. The closest commonly used method to experimentally simulate the impact of temperature and load is the determination of refractoriness under load, which only applies stresses of 0,2 MPa in a single direction.

With a new testing system, refractory materials can be restrained or subjected to loads at the hot face of a prismatic test piece (54 x 54 230 mm), which is heated up to 1700 °C though one of its small end faces (54 x 54 mm) and accordingly experiences a thermal gradient. Stress levels of up to 30 MPa were assessed or applied to the test piece in either one or two directions perpendicular to the thermal gradient near to the hot face. High load and high temperatures trigger typical microstructural changes, especially a coarsening of the matrix near the hot face.

With the new testing device, the evolution of refractory materials used as linings can be understood better, which opens new perspectives for material development.

## INTRODUCTION

The common denominator for most refractory product applications is that they must withstand high temperatures and substantial loads [1]. In case of refractory linings, only one side of the structure is typically exposed to the process heat, resulting in a steep thermal gradient within the lining. With regards to the mechanical loadings of the refractory linings, these have two main origins. Firstly, individual parts of typical refractory structures support the weight of the parts which are above them. For example, in a brickwork lining, the bricks in the lower part support the weight of all the other bricks above them. Secondly, as temperatures rise in the lining, the hot part of the structure expands and, when at last the expansion joints are closed and/or the cold part of lining cannot follow anymore the thermal expansion of the hot part, the free thermal expansion of the hot part is retrained and significant compressive stresses arise near to the hot face of the lining. The combined effect of the thermal gradient and compressive stresses near to the hot face leads to an inhomogeneous evolution of the microstructure and properties of the refractory materials. This is expected to play a critical role and significantly impact the high temperature and long-time performance of refractory linings.

## BACKGROUND

Currently, unless considering the thermal shock resistance, the characterization of refractory materials in the laboratory is mostly limited to test procedures in quasi-isothermal conditions. Some information on the behaviour of refractories experiencing thermal gradient might be obtained from thermal shock tests. However, standardized tests imply a dwell time at elevated temperature, which homogenises the temperature in the test piece and accordingly does not allow for a practice-relevant temperature gradient. The main focus of these tests is, of course, to trigger damage in order to appraise the resistance of the test pieces against thermomechanical stresses, not simulating the behaviour of the test piece as part of refractory lining. In fact, a testing procedure where test pieces are simply heated from one side and experience a thermal gradient comparable to those occurring in service for refractory lining is not challenging to implement, but fails to consider the impact of the compressive stresses at the hot face of a refractory lining. Neither the obtained microstructures, nor the observed deformations, would reflect accurately the evolution of the material as part of a refractory lining. On the other hand, test procedures that apply a compressive load on test pieces, especially the testing standards EN ISO 1893: Determination of refractoriness under load, and EN 993-9: Determination of creep in compression, rely on quasi-isothermal conditions. Both testing standards are carried out with the same testing equipment and similar testing procedure. A cylindrical refractory test piece (50 x 50 mm) is subjected to a constant load (0,2 MPa) while increasing the temperature (5 °C.min$^{-1}$). The deformation (height) of the test piece is recorded continuously. For the determination of refractoriness under load (RuL), the test is stopped once a prescribe deformation is attained, typically 5 % of its initial length [2]. In contrast, for the determination of creep in compression (CiC), once a specified temperature is reached, the heating is maintained constant for a given time. While both methods are prominently used to investigate the behaviour of refractory materials at high temperature, namely their refractoriness and the creep rate, the exerted load is actually very low and applied in one direction only. In service, much higher levels of stresses are expected and a biaxial loading state in the plane parallel to the hot face of refractory linings prevails [3].

## NEW TESTING SYSTEM

### Experimental setup

In order to simulate the behaviour of refractory products as part of a lining in service, a new testing system has been developed (Fig. 1). The testing system triggers a realistic thermal gradient in a prismatic test piece (54 x 54 x 230 mm). This has been achieved by heating the test piece through one of its small end faces (54 x 54 mm), later called hot face, thanks to a laboratory furnace with a fitting opening (Fig. 3 and 4).

Fig. 1: Schematic representation of the new testing system and the testing procedure to investigate the combined effect of mechanical loading and thermal gradient.

The maximum operating temperature of the laboratory furnace, and accordingly the maximum temperature at the hot face of the test piece, is 1750 °C. During heating, temperature differences of several hundred Kelvin arise between the two small end faces of the test piece (x-direction). Simultaneously, the testing system mimics the thermomechanically induced compressive stresses at the hot face of refractory linings (in the y-z-plane). This was accomplished by applying a load F onto the test piece or constraining the free thermal expansion of the test piece perpendicular to the thermal gradient near to the hot face (Fig. 1). These loads or constraints are applied to the test piece through four refractory "plungers" (54 x 54 x250 mm), two of those fixed and the other two mobile. Each of the two mobile plungers is connected to a servomotor that is fixed to a robust frame made of high-strength aluminium and can build up compressive forces up to 4 kN (Fig. 4). The displacements of the mobile plungers are monitored by Linear Variable Differential Transformer (LVDT).

Fig. 2: Design model of the furnace to heat a test piece through one of its smaller end faces (hot face) and apply load or constraint near to the hot face.

Fig. 3: Inside of the furnace during heating.

**Testing strategy**
Test pieces made of hydratable alumina (HA) bonded high alumina castable were heated from one end face with a rate of 5 K.min⁻¹. Two different loading conditions were considered:
– applying a constant load/force near to the hot face of the test piece and following the displacement of the mobile refractory plungers,
– restricting the free thermal expansion of the test piece by blocking the displacement of the mobile refractory plungers and following the evolution of the resulting force.
These two loading configurations can be applied separately on each of the two directions perpendicular to the hot face. Hence, it is

possible to just exert a uniaxial loading or perform a biaxial loading. In the case of a biaxial loading, the same configuration can be used in both direction (i.e. constant load or restriction of the free thermal expansion) or a combination of the two different loading combinations (i.e. constant load in one direction and restriction of the free thermal expansion in the other direction) can be applied.

Fig. 4: New testing system to investigate the combined effect of mechanical loading and thermal gradient.

**RESULTS AND DISCUSSION**

**Development of stresses in test pieces with restrained free thermal expansion**
To examine the development of stresses in a test piece, the laboratory furnace was heated up to 1200 °C while the free thermal expansions in both directions y and z (see Fig. 1) are being restrained. As the temperature increases at the hot face, the heated part of the test piece strives to expand under the fixed refractory plungers and as a result stresses built up. Since the refractory castable is mostly anisotropic, very similar levels of stresses are assessed in the two perpendicular y and z directions, reaching almost 20 MPa (Fig. 5). The increase of the stresses is not directly proportional to the temperature inside of the furnace, nor linear. The two main reasons for this behaviour are: 1) the part of the test piece in contact with the plungers is not homogenously heated (thermal gradient) and accordingly does not expand linearly, and 2) the refractory plungers themselves heat up as heat from test piece is transferred to the plungers at the contact surfaces. Accordingly, the plungers do also expand, but again not linearly. The second effect also means that the plungers do not only restrain the thermal expansion of the test piece but also compress it further, in a comparable way as neighbouring bricks or parts of a refractory lining would do in service.
*Fig. 5: Evolution of the furnace temperature and induced stresses for a test piece made of HA bonded high alumina castable with restrained free thermal expansion in the directions y and z near to the hot face.*

Following that, the laboratory furnace was heated to 1700 °C with the displacement of the mobile plunger again blocked in one direction (z), i.e. restraining the free thermal expansion, but the free thermal expansion in the other direction (y) allowed. Actually, a comparably small load of 0,15 MPa is always applied in the y-direction to guarantee the contact between the plunger and the test piece, as well as maintaining the test piece in position, while still allowing the free thermal expansion of the test piece. A stress level of about 23 MPa was assessed in the z-direction and the non-linearity of the expansion of the test piece and plungers confirmed (Fig. 6). It is also worth noticing that, as the test piece was allowed to expand in the y-direction and because of the Poisson effect, the deformation in the y-direction (perpendicular to the applied load) is slightly higher than the free thermal expansion. This also means that, in case of the restriction of the free thermal expansion in both directions perpendicular to the thermal gradient (y and z-directions), the level of achieved stresses after heating the laboratory furnace to 1700 °C should be significantly higher. By extrapolating the combined results from two experiments (Figures 5 and 6), stresses larger than 30 MPa could be expected in the case of the complete restriction of the free thermal expansion in both directions perpendicular to the thermal gradient and accordingly near to the hot face of refractory linings in services.

*Fig. 6: Evolution of induced stresses for a test piece made of HA bonded high alumina castable with restrained free thermal expansion in the z-direction and displacement of the refractory plunger in the y-direction near to the hot face.*

### Displacement and creep of test pieces under load

Another important aspect of interest is the creep of refractory materials at high temperature. To investigated this, a series of measures was performed in which the laboratory furnace was heated to 1700 °C and the load kept constant in both the y and z-directions. Again, a load of only 0,15 MPa was applied in the y-direction to guarantee a contact between the plungers and the test piece. In the z-direction, the load was first set to 0,15 MPa, but then increased to 10 MPa, 20 MPa or 30 MPa.

Under a load of 0,15 MPa applied in both directions, the displacement of the mobile refractory plungers was found to be almost identical in both directions, which is further evidence of the anisotropic behaviour of the castable under examination. The obtained

displacement curve for a load of 0,15 MPa was considered to represent the almost free thermal expansion of the test piece and partially heated refractory plungers. By increasing the load in the z-direction, the corresponding displacement of the plunger in the z-direction followed closely the thermal expansion previously observed for a load of 0,15 MPa, at least up to a furnace temperature of 1200-1300 °C. Above these temperatures, the displacements stay significantly below the displacement previously observed for a load of 0,15 MPa, namely was partially restrained (Fig. 7). More than just the consequence of a mechanical compression that impedes the free thermal expansion, it is likely that creep occurred near the hot face. Indeed, creep is a function of the temperature and applied load. In the present case, it seems to begin at a furnace temperature of 1200-1300 °C and its contribution increase with increasing temperature and higher applied load, namely the higher the temperature and applied load were, the more limited the displacement in the z-direction was. It is also worth noting that the displacement in the y-direction, in contrast, tended to increase with increasing load in the z-direction (not shown in the figure 7 to avoid overloading the graph with too much information). This is also likely the result of the creep process. As the test piece is compressed and irreversibly deformed (due to creep) in the z-direction, this deformation is at least partially accommodated by an expansion in the y-direction.

*Fig. 7: Evolution of the furnace temperature and displacement of the mobile refractory plungers applying different load on a test piece made of HA bonded high alumina castable near to the hot face (the displacement in the y-direction corresponds to the measurement where a load of 0,15 MPa was applied in both directions).*

*Fig. 8: Difference between the displacement ($\Delta\delta$) of the mobile refractory plungers in the z-direction and y-direction as a function of the furnace temperature and time after having reached 1700 °C.*

Although not perfectly depicting creep (because of the above-mentioned phenomenon), the difference between the displacement of the mobile refractory plungers in the y-direction and z-direction ($\Delta\delta_{(z-y)}$) provides a valuable information on the creep process (Fig. 8). Under a load of 0,15 MPa applied in both directions, the displacement of the mobile plungers is almost the same in both directions, and $\Delta\delta_{(z-y)}$ is accordingly almost constant (near to zero). Increasing the load (in the z-direction) resulted in $\Delta\delta_{(z-y)}$ that increases (in terms of absolute value) with increasing furnace temperature. Higher temperatures as well as higher loads in one direction promote the creep process that results in an increased difference between the displacement of the mobile refractory plungers in the y-direction and z-direction. This is also reflected in a higher apparent creep rate ($\Delta\delta(z-y)/\Delta t$) with increasing load in the z-direction at a furnace temperature of 1700 °C (Tab. 1).

Tab. 1: Difference between the displacement of the mobile refractory plungers in the y-direction and z-direction over time ($\Delta\delta(z\text{-}y)/\Delta t$ – apparent creep rate) at a furnace temperature of 1700 °C for test pieces made of HA bonded high alumina castable.

| Load / MPa | apparent Creep rate / $\mu m.min^{-1}$ |
|---|---|
| 0,15 | -0,38 |
| 10 | 3,32 |
| 20 | 8,00 |
| 30 | 9,97 |

SEM micrographs revealed the manifest influence of the compressive stresses near to the hot face on the microstructure of the test pieces (Fig. 9). The higher the applied load, the more advanced the coarsening of the matrix is. In light of these results, it is unlikely that simple pre-firing of test pieces or the load imposed by the standards EN ISO 1893: Determination of refractoriness under load, and EN 993-9: Determination of creep in compression, namely 0,15 MPa, are sufficient to promote the formation of the microstructure that can be found near the hot face of refractory linings in service. Furthermore, the observed microstructural changes are expected to impact the properties, behaviour, and performance of the refractory materials at high temperature, such as their strength and resistance to corrosion, erosion and thermal shocks. This aspect can be studied in subsequent investigations on test pieces after being exposed to high temperatures and load in the new testing system.

## CONCLUSIONS

A new testing system was developed to simulate the thermal gradient and compressive loading that refractory materials experience as a part of linings in industry furnaces and vessels in service. The thermal gradient resulted from the heating of a prismatic test piece from one side (hot face). The loading was applied through refractory plungers connected with servomotors, either by restricting the free thermal expansion or applying a constant load. Stress levels of up to 30 MPa were assessed or applied near to the hot face, in either one or the two directions perpendicular to the thermal gradient. Such level of stress should definitely be expected near to the hot face of refractory linings.

High load and high temperatures promoted specific microstructural changes in the test piece near to the hot face, especially a coarsening of the matrix that cannot be achieved by a simple pre-firing or moderate load as prescribed in the standards EN ISO 1893: Determination of refractoriness under load, and EN 993-9: Determination of creep in compression.

A better insight into the behaviour of refractory materials exposed to thermal gradient and high compressive stresses as occurring in refractory linings was gained and should open up new perspectives for material development.

## ABSTRACT

Our group is developing a new test system called "Ultra-high speed heating test system". This apparatus is a hot observation system with the advanced features of ultra-high-speed and ultra-high-temperature heating. Currently, we are examining various applications of this system as a multi-purpose evaluation system. In this paper, we will report about the thermal property evaluation methods used to investigate refractories materials used with this system. One of the structural features of this system is that the specimen is placed on the heater directly. This heating method can be applied for estimation of thermal conductivity, and examining the evaluation method.

We prepared pellet specimens of various raw material powders for refractories. As a simple comparing test, we placed these specimens on the heater of the system and measured the top and bottom temperatures while heating. The temperature gaps between top and bottom showed different temperature dependency according to the sample. This result suggest that this test method can be used to evaluate the relative thermal conductivity and its temperature dependence at high temperature. In addition, we will report on the investigation of measurement of the thermal conductivity as a physical property evaluation. Numerical analysis suggested that the effect of heat transfer from heater to specimen should be excluded, and we are considering improvements in the specimens setting and temperature measurement methods.

## INTRODUCTION

The newly developed testing system called "Ultra-high speed heating test system" [1-3] is shown in fig. 1. This system was developed primarily to focus on the observations at high temperature and to be operational at ultra–high temperatures and ultra–high speeds of heating. For this purpose, the system employed a distinctive heating method in which the specimens are placed on the heater directly. This method reduces the volume to be heated and enables extreme heating. The maximum achievable temperature is 2,800 °C, and the temperature rate reaches 100,000 °C/min [1]. Moreover, this method can reduce the heat quantity, thus this facility requires no insulation for the enclosure and can be installed with observation windows.

We are now examining the utilization of this facility for various applications. For example, taking advantage of the ability to observe heating in this facility, we measured the contact angles between oxides and melts [2], and we also tried experiments of rapid rate sintering by ultra–high speed heating [3]. As a part of this examining, we tried to measure thermal conductivity. Thermal conductivity is one of the most important parameters in the design of refractories

*Fig. 1: Schematic view of ultra–high speed heating test system.*

and kiln furnace linings with effects on energy conservation and durability of products.

Thermal conductivity is difficult to measure under the conditions in which refractories are actually used. Specifically, the hot wire method, the most commonly used method for refractory bricks, is insufficient for measuring temperatures, on the other hand, the flash method used for fine ceramics assumes a uniform texture and is limited in its application to refractories specimens. The new system has fewer sample limitations and can be raised to high temperature, so if it can be used to measure thermal conductivity, it will provide more useful data. In this paper, we will report about the consideration of measurement methods and discussion of results.

## EXPERIMENTS

### Simple relative evaluation test

First, we attempted a simple experimental method of relative evaluation of thermal conductive behaviour by continuous temperature measurements of pellet samples of refractories raw material powders. We prepared the specimens by pressing the powder materials into ⌀20 mm samples, sintering them at 1600 °C, and grinding them to a thickness of 3 mm. The sample properties are shown in table 1. A schematic image of measurement system is shown in Fig. 2. The temperatures were measured by two-color radiation thermometer (Chino, IR-CZH8N3, 900-3000 °C, spot size 1.7 mm) at the top center of the specimens and the bottom center of the heater. The test temperature was set to 1500 °C, and the

*Table 1: Properties of samples used for simple relative evaluation test.*

| Sample | | A | AS1 | AS2 | AS3 | M |
|---|---|---|---|---|---|---|
| Chemical composition / % | Al₂O₃ | 99 | 87 | 61 | 47 | |
| | SiO₂ | | 7 | 36 | 50 | 2 |
| | MgO | | | | | 95 |
| Apparent porosity / % | | 26 | 0.96 | 11 | 0.75 | 16 |
| Material type | | Fused alumina | Chinese bauxite | Mullite | Chamotte | Magnesia crinker |

*Fig. 2: Schematic view of measurement system for simple relative evaluation test.*

temperature was increased by 1 °C/s. The internal atmosphere was substituted with Ar.

**Evaluation of thermal conductivity**

We attempted to estimate thermal conductivity as a physical property with the alumina sample. Specimens, $\varnothing20$ mm cylindrical alumina ceramic (Nikkato, SSA-S) were prepared with various thicknesses. We set the specimens on the heater, substituted the atmosphere with Ar, and held them at each test temperature until steady. The test temperatures were set in 100 °C increments to 1600 °C. From the temperature measurement results and sample thickness $t$, the temperature gradient in the sample $\nabla T$ was calculated under the assumption that the temperature of the sample bottom and the heater were the same. The thermal conductivity was calculated by Fourier's law;

$$q = -\lambda \cdot \nabla T \tag{1}$$

where, $q$ is the heat flux density and $\lambda$ is the thermal conductivity. The heat flux $q$ was calculated from the current $I$, the resistance of the heater $R$ and heating area of the heater $A$.

*Fig. 3: Temperature gap $\Delta T$ in specimens in simple test.*

$$q = I^2 R / A \tag{2}$$

In additon, we considered improvements for the measurement methods from the obtained results. We examined the results by simulation with a one-dimensional steady heat transfar model to evaluate the influence of the factors. And based on the results, we considered the improvements in the sample setting and the temperature measuring methods.

**RESULTS AND DISCUSSION**
**Simple relative evaluation test**

Figure 2 shows the measurement results of temperature gap $\Delta T$ between the top and the bottom of the specimens in the simple tests. $\Delta T$ can be used as a rough indicator of thermal conductivity with larger values of $\Delta T$ corresponding to less thermal conductivity. The measured $\Delta T$ showed different behaviour depending on the sample, with the sample M sowing the smallest value over the whole test temperature rage, followed by sample A, AS1, and AS3 in the order of decreasing value. The temperature dependence of $\Delta T$ for sample AS2 differed significantly from the other samples, with $\Delta T$ for S being as small as sample A at low temperature, but as large as sample AS3 at high temperature.

From these results, it was found that this testing method can evaluate the relative magnitude and temperature dependence of the thermal conductivity of the specimens. This method allows measurement at high temperatures where refractories are actually used, and is considered to be an effective technique that complements the existing measurement methods.

*Fig. 4: Measured temperature with alumina ceramics sample.*

*Fig. 5: Measured temperature with alumina ceramics sample.*

*Fig. 6: Model for simplified investigation.*

## Evaluation of thermal conductivity

Figure 4 shows the temperature measurement results for the alumina ceramics specimen. The apparent thermal conductivities calculated from the measured temperatures of the specimens at each thickness are shown in fig. 5. This evaluation method resulted in the apparent thermal conductivity being dependent on the thickness of the specimen. As a physical property, thermal conductivty is essentially independent of specimen geometry. So it is considered that factors other than thermal conductivity had some effects.

## Simplified model investigation

We examined the factors that seemed to influence the thermal conductivity results with a simplified model. The calculation model is shown in fig. 6. The model is an infinite flat plate steady-state heat transfer model with the assumption that the temperatures are measured on the central axis of the sample. The heat transfers in the model are expressed eq. 3.

$$q_1 = \sigma \cdot (T_0^4 - T_1^4) / (\varepsilon_H^{-1} - (\varepsilon_S^{-1} - 1)) + H \cdot (T_0 - T_1) \quad (3a)$$
$$q_2 = -\lambda \cdot (T_2 - T_1) / t \quad (3b)$$
$$q_3 = \sigma \cdot \varepsilon_S \cdot (T_2^4 - T_A^4) \quad (3c)$$
$$q = q_1 = q_2 = q_3 \quad (3d)$$

Where, $q$ is the heat flux density, $q_1$ is due to heat transfer from heater to sample, $q_2$ is due to heat conduction within the sample, and $q_3$ is due to heat radiation from the top of the sample. Moreover, $\sigma$ is the Stefan–Boltzmann constant, $\varepsilon$ is the emissivity, $t$ is the sample thickness, $H$ is the coefficient of heat transfer between heater and sample, and $\lambda$ is the thermal conductivity. In the investigation, $\lambda_0 = 5.0$ W·m$^{-1}$·K$^{-1}$ was assumed as the true value for thermal conductivity. We solved the simultaneous equations by Newton's method to obtain $q$, $T_1$, and $T_2$, and calculated the apparent thermal conductivity. And we evaluated the effect on the sample thickness dependence of the apparent thermal conductivity for varying $\varepsilon_S$, $H$ and $T_A$.

The results of apparent thermal conductivity calculation with the simplified model are shown in fig. 7. Fig. 7(a) shows the effect of the ambient temperature $T_A$, and (b) shows the effect of the sample emissivity $\varepsilon_S$. Tentative values were set for parameters other than those of interest. We could find no significant effect of $T_A$ and $\varepsilon_S$ on the results of apparent thermal conductivity. On the other hand, $H$, shown in fig. 7(c) exhibited significant influence on the apparent thermal conductivity and its sample thickness dependence. When the $H$ value was sufficiently large, the apparent thermal conductivity $\lambda_A$ was close to the set true value $\lambda_0$; when the $H$ value was small, the value of $\lambda_A$ became smaller than the true value $\lambda_0$, and the sample thickness dependence increased, with smaller sample thickness $t$ showed a tendency for the value of $\lambda_A$ to be smaller. The small $H$ value correspond to high thermal resistance and heat loss between the heater and the sample. The calculation of apparent thermal conductivity approximated that the temperatures of the heater $T_0$ and the bottom of the sample $T_1$ were the same, however it was suggested that there was actually a significant temperature difference. Furthermore, when the sample thickness $t$ was small, the deviation of the apparent value $\lambda_A$ from the true value $\lambda_0$ was considered to be lager because the ratio of contact thermal resistance in the total thermal resistance was larger. In summary, the approximation of $T_0 = T_1$ was inappropriate.

## Reduction of heat transfer influence

The heat transfer coefficient depends on various conditions such as the materials and surface properties of samples and the heater, the

*Fig. 7: Calculation results of apparent thermal conductivity in simplified model with varying parameters; (a) ambient temperature $T_A$, (b) sample emissivity $\varepsilon_S$, (c) coefficient of thermal transfer H between heater and sample.*

atmosphere composition, and the temperature of each part, making it difficult to accurately determine. Therefore, the contact thermal resistance is considered to be a cause of systematic errors and inhibit reliable measurements. Therefore, we have investigated reducing the influence of contact thermal resistance. The coefficient of contact thermal heat transfer between two solid phases in no load contact is expressed by eq. (4).

$$H = \lambda_g / \delta \quad (4)$$

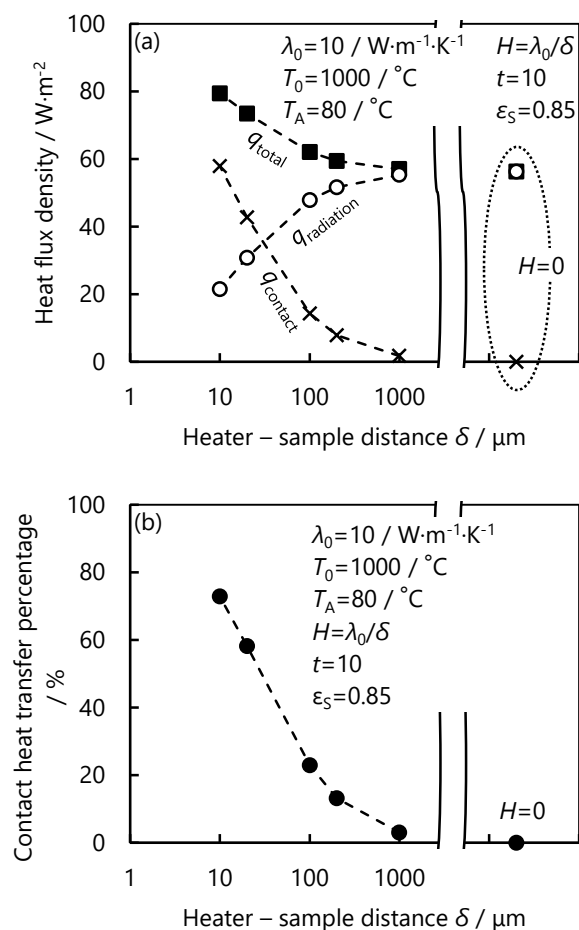
Where, H is the coefficient of contact thermal heat transfer, $\lambda_g$ is the thermal conductivity of the atmosphere, $\delta$ is the distance between the phases. Assuming that $\delta$ is 10 μm when the sample is in direct contact with the heater, and $\lambda_g$ is 0.01 W·m$^1$·K$^{-1}$ when the atmosphere is Ar, H is 1000 W·m$^{-2}$·K$^{-1}$. In reference to fig. 7, this value of H


*Fig. 8: Culculation results of heat flux in simplified model with varying distance between heater and sample δ; (a) heat flux density (b) fraction of contact heat transfer to total heat flux density.*

*Fig. 9: Schematic image of improved measuring system.*

*Fig. 10: Estimated apparent thermal conductivity with measured temperatures by improved measurement method..*

corresponds to a condition where the sample thickness dependence of apparent thermal conductivity is large. The calculated heat flux density with varying values of $\delta$ is shown in fig. 8(a). As $\delta$ increased, the value of heat flux density due to radiation $q_{radiation}$ increased, and $q_{contact}$ due to contact decreased. The variation of the percentage of contact heat transfer to the total as $\delta$ was varied as shown in fig. 8(b). As $\delta$ reduced, the percentage became smaller, and the percentage fell below 3 % at $\delta$ = 1 mm. From this result, it was considered that heating with a distance of 1 mm between the heater and the sample would make it possible to supress the influence of the heat transfer coefficient.

**Improvement of heating method**

A schematic image of the improved measurement method based on the investigation is shown in fig. 9. To create a gap between the heater and the specimen, we placed spacers under the specimen. Moreover, for more accurate measurements, we made a hole in the centre of the heater to directly measure the temperature of the bottom of the specimen $T_1$. The apparent thermal conductivities estimated from the temperatures measured by the improved measurement method are shown in fig. 10. The dependence on sample thickness of the data was drastically supressed. By this improvement, the accuracy of thermal conductivity estimation has been increased and it enabled the thermal conductivity measurement of alumina ceramics samples by the ultra–high speed heating test system.

**CONCLUSIONS**

We tried to estimate thermal conductivity with the newly developed "Ultra–high speed heating test system". By simple tests, it was able to carry out relative evaluation of thermal conductivity. This test can be done rapidly, easily, and under high temperature. It should be utilize to approximate estimations which complements existing standard tests.

To estimate thermal conductivity as a material property, it was necessary to consider the heat loss in heat transfer from heater to sample. To reduce the influence of the loss, it was effective to make a gap between the heater and the sample. Simplified model calculation revealed that the heat loss should be suppressed by separating the heater and the sample by 1 mm. We confirmed experimentally, the improved accuracy of the thermal conductivity estimation. This improvement made measuring thermal conductivity in alumina ceramics samples by Ultra–high speed heating test system possible.

# EUROPEAN AND INTERNATIONAL STANDARDIZATION WORK IN REFRACTORIES

Franziska Baensch of DIN, Berlin, Germany

## ABSTRACT
The topics and contents of standardization in the refractory industry are mainly influenced at international and European level. For success, the personal commitment of the experts and delegates is indispensable. Afterall, for those who do not standardize, they will be standardized and must ultimately use rules that others shaped according to their own interests. A prerequisite for participation in European and international standardization bodies is the involvement in the corresponding national mirror committees of the national standards institutes, which mirror the European and international activities and authorize the technical experts to participate at ISO and/or CEN.
The relevant committee structure at international level (ISO/TC 33 Refractories) and at European level (CEN/TC 187 Refractory products and materials) and the function of the national mirror committees, the interaction of these committees, and the possibilities for exerting influence are shown.

## ISO/TC 33 REFRACTORIES
The technical committee (TC) of international standardization on *Refractories*, ISO/TC 33, was established in 1947 and is currently held by the British Standards Institution (BSI). Current chairperson is the German expert Prof. Olaf Krause. The scope of ISO/TC 33 is the standardization of raw materials and products of the refractories industry and their properties [1].
The 15 voting participants are Austrailia (SA), Austria (ASI), Belgium (NBN), China (SAC), Egypt (EOS), France (AFNOR), Germany (DIN), India (BIS), Japan (JISC), Republic of Korea (KATS), Poland (PKN), Russian Federation (GOST R), Spain (UNE), Ukraine (SE UkrNDNC) and United Kingdom (BSI). Moreover, 22 members observe the activity of ISO/TC 33. National and multinational raw material suppliers and producer companies provide technical experts to advance the work. ISO/TC 33 is substructured with 5 working groups (Fig. 1), whose experts create the standard documents:

- WG 17, Chemical analysis
- WG 25, Refractory test piece preparation – Gunning techniques
- WG 27, Refractory mortars – Determination of permanent change in dimension on heating
- WG 31, Phase quantitative analysis of residual quartz in silica bricks
- WG 32, Dense shaped refractory

However, WG 26 (Thermal shock resistance), WG 28 (Determination of Young's modulus at elevated temperatures), WG 29 (Determination of compressive strength at elevated temperatures) and WG 30 (Determination of bulk density of granular materials, grain density) are currently disbanded.
About 93 standards are published and in the responsibilty of ISO/TC 33. Currently under development are 9 standards.

This committee contributes with 20 standards to the Sustainable Development Goals SDG9, "Industry, innovation and infrastructure" and SDG 12, "Responsible consumption and production", which are defined by the united nations (UN). Improvements have included a reduction in energy consumption and the use of cleaner energy resources. While there has been a reduction in the consumption of raw materials, there has also been an increased emphasis on reducing the amount of material finally going to land fill as a result of the activities of the refractories and related user industries.

## CEN/TC 187 REFRACTORY PRODUCTS AND MATERIALS
The technical committee (TC) of European standardization on *Refractory products and materials,* CEN/TC 187, was established in 1989 and is currently held by the British Standards Institution (BSI). Current chairperson is the German expert Prof. Olaf Krause. The scope of CEN/TC 187 includes classification, methods of test and sampling for refractory products and materials, including shaped and unshaped products and ceramic fibres [2].
CEN includes the 34 voting participants Austria (ASI), Belgium (NBN), Bulgaria (BDS), Croatia (HZN), Cyprus (CYS), Czech Republic (UNMZ), Denmark (DS), Estonia (EVS), Finland (SFS), France (AFNOR), Germany (DIN), Greece (NQIS/ELOT), Hungary (MSZT), Iceland (IST), Ireland (NSAI), Italy (UNI), Latvia (LVS), Lithuania (LST), Luxembourg (ILNAS), Malta (MCCAA), Netherlands (NEN), Norway (SN), Poland (PKN), Portugal (IPQ), Republic of North Macedonia (ISRSM), Romania (ASRO), Serbia (ISS), Slovakia (UNMS SR), Slovenia (SIST), Spain (UNE), Sweden (SIS), Switzerland (SNV), Türkiye (TSE) and United Kingdom (BSI).
CEN/TC 187 aims to contribute to the elimination of technical barriers to trade and to facilitate the European Union's internal market for refractory materials. To this end, standards are developed for characterizing refractory materials by classifying and determining their chemical and physical properties. Additional work items are related to product requirements, dimensions and quality assurance of items delivered in bulk. National and multinational raw material suppliers and producer companies provide technical experts to advance the work. The technical work is managed in two active working groups (Fig. 2):

- WG 1, Dense shaped refractory materials
- WG 4, Chemical analysis.

However, WG 2 (Unshaped refractory materials), WG 3 (Insulating materials and high temperature insulation wools) and WG 5 (Chemical attack on refractory products) are currently disbanded.
About 70 standards are published and in the responsibilty of CEN/TC 187. Currently under development are 8 standards. All CEN member countries participate in the development of refractories standards.

*Fig. 1: Structure of ISO/TC 33, year 2023*

*Fig. 2: Structure of CEN/TC 187, year 2023*

CEN systematically addresses environmental issues in standardization to reduce the environmental impacts of products and services. CEN/TC 187 is aware that some of its methods have an impact on the environment. Thus, wherever feasible, the use of

toxic chemicals is avoided. Also methods for the determination of hazardous compounds such as hexavalent chromium (chromium V!) are standardized. There is a gradual move to instrumental methods such as X-ray fluorescence analysis XRF not requiring corrosive acids and potentially toxic spectrophotometric colouring agents. Furthermore, the reduction in energy consumption and the use of cleaner energy resources are focussed by CEN/TC 187.

The objectives of CEN/TC 187 are to contribute to the elimination of technical barriers to trade and to facilitate the internal European Union market for refractory materials. Through the liaison with ISO/TC 33 the aim is to give standards an international diffusion and thus develop further the global market.

## NATIONAL STANDARDIZATION ORGANIZATION

All members of ISO and/or CEN are entitled to nominate delegates to Technical Committees and experts to Working Groups, ensuring a balance of all interested parties (Fig. 3). Participation as observers of recognized European or international organizations is also possible under certain conditions. To participate in the activities of ISO and/or CEN, please contact the national standards organization in your country.

*Fig. 3: Secondment of delegates and experts to European and international committees*

## CHALLENGES FOR ISO/TC 33 AND CEN/TC 187

The large work programme in ISO/TC 33 and in CEN/TC 187, besides the development of new standards, includes regular review and appropriate action, i.e. confirmation, amendment, revision or withdrawal of each standard. Additionally, work programmes and the development of standards in the area of refractories are frontated with further challenges, f.e. the limited number of experts, which often results in an imbalance of relevant stakeholders. A lack of expertise would result in standards not up-to-date and state-of-the art, and consequently, in withdrawing standards. In addition, international as well as European committees have no budget for hosting meetings. This and the fact, that attending any meeting are becoming more prohibitive, may result in difficulties finding a member to host a TC or WG meeting and in reduced levels of participation.

Moreover, lack of funding obviously affects the number of laboratories able to participate in interlaboratory trials. Thus, some standards already lack on precision data from an interlaboratory test, which actually are required for validating any test methods.

All issues together have the effect of keeping responsible personnel at full capacity and create a number of several competing priorities.

## ADVANTAGES OF STANDARDIZATION

International standards are the common denominator and shared language of suppliers and customers. By international standardization the transfer of technologies and trade are facilitated and the technical compatibility is ensured. Regulation in health, safety, security and environmental matters are supported by being at the cutting edge of science and technology, and trade agreements are successfully implemented by international standardization.

European standardization is fundamental in ensuring free trade and an effective European Single Market. For business, harmonized standards are a reliable indicator of conformity with relevant EU legislation and legal certainty is increased through a technical interpretation of unspecific legal terms.

# YOUNG'S MODULUS OF REFRACTORIES AT HIGH TEMPERATURES: COMPARISON OF DIFFERENT TESTING METHODS AS BASE FOR MASONRY MODELLING

Thorsten Tonnesen, Jesus Gonzalez-Julian
RWTH Aachen University, Institute of Mineral Engineering (GHI), Aachen, Germany

Michel Henze, Gerhard Hirt

## ABSTRACT

Comprehensive knowledge about thermomechanical behavior is mandatory for an accurate prediction of occurring stresses to design load-optimized linings. Refractory linings are, in addition to loads due to corrosion and creep processes, particularly affected by thermo-mechanical stresses caused by the restricted thermal expansion of the lining. These stresses can occur within individual components as well as in bricks and can lead to plastic deformation, cracks, and material failure.

This study compares methods for determination of Young's Modulus at different temperatures for the use in refractory modelling of lining systems. In three point bending tests the deflections of different refractory materials was examined during loading by means of digital image correlation (DIC) up to high temperatures. The achieved data allows to evaluate static Young's Modulus values respectively. In parallel refractoriness under load (RUL) tests with higher loads up to 1.5 MPa have been carried. The measured data of change in temperature and length are then corrected by the thermal expansion and used to construct elastic lines for several temperatures, where the elastic slope is determined using the change in length and the respective load. Thus, Young's modulus for several temperatures can be determined.

These obtained values for static Young's modulus are then compared to values which have been determined by the dynamic resonant frequency damping analysis (RFDA) measurements without load apply. Finally a validation for refractory linings using a Finite Element (FE) model by means of these data is discussed.

## INTRODUCTION

Nowadays numerical modelling of refractory lining concepts are in favourable use for the prediction of thermo-mechanical stresses. Thus better description of material behaviour leads to better calculation of relevant technical parameters by means of Finite Element Modelling (FEM). E.g. the non-homogenous material properties due to brick-mortar linings with joints increase the modelling efforts. This leads to the concept of the homogenization of material properties and the characterization of the behaviour of complete systems. The simulations will support the plant design since the determination of static load cases can be realized. For this accurate material data such as thermal properties, creep behaviour and elastic-plastic behaviour are essential. To determine the dynamic elastic behaviour Resonance Frequency Damping Analysis (RFDA) is state of the art and allows a standardized calculation [1]. Nevertheless static values representing the elastic behaviour under load are desirable for the modelling of refractory lining concepts. Therefore an approach using the standardized method for determination of the Refractoriness under Load (RUL) is in focus of these studies [2].

## EXPERIMENTAL

Analogous to the bending tests, Young's moduli were determined by means of 3-point bending tests according to DIN EN 993-6 using DIC (Digital Image Correlation). According to this method, the modulus of elasticity is determined from the ratio of stress and strain or the deformation. In addition to the test forces that occur, the deflection of the specimen must also be measured during the test. Experience has shown that the crosshead travel of the testing machine is usually subject to significant measurement inaccuracies, since setting effects and system stiffness are included in the measurement data. Therefore, the measurement record of the testing machine does not represent the elastic behavior of the test specimen. To determine the Young's modulus as accurately as possible, the change in displacement or deflection was therefore measured directly on the specimen. For this purpose, an optical strain measurement was used. This was also used to determine the system stiffness, i.e. the difference in displacement measurement between specimen and system. The optical measurement system requires high contrast, approximately 50% black and 50% white areas, and sample dots with a size of 3-5 pixels. This was ensured by the refractory materials used. The principle of stochastic pattern detection is shown in Figure 1. First, individual facets are defined in the reference image (Fig. 1 left). Within a facet, a gray value distribution is then performed. Thus, even with perspective distortion (Fig. 1 right) and a stretching, the gray value distribution is almost the same.

*Fig. 1: Individual facet in the reference image (left) and distortion (right).*

Refractoriness under load (RUL) tests without load were performed on specimens according to DIN 993-19 for the refractory materials investigated in the project to determine the thermal expansion of the materials. At least three test repetitions were carried out for each material. The thermal expansion as a function of temperature was then determined on the basis of the determined temperature-displacement records.

Subsequently, RUL tests were carried out on cylinder specimens with load according to DIN EN ISO 1893, initially with the standard load of 0.2 MPa, then also with loads of 0.3, 0.4 and 0.45 MPa, and on average-reduced cylinders with loads of 0.7 and 1.3 MPa. Using the averaged curves for constant stresses at increasing temperature, elastic straight lines at constant temperature for increasing stresses were created from corresponding measurement points. The slope of these straight lines can be used to determine the E-Modulus of the material. In parallel, resonant frequency measurements were carried out to determine the dynamic modulus of elasticity according to DIN EN ISO 12680-1 and ASTM C1548-02 for the first materials in order to obtain a comparative value for the moduli of elasticity determined.

Based on the measurement data provided, the coefficients of thermal expansion as well as Young's moduli could be calculated or validated for the tests performed. For the validation, the material data used were stored in corresponding FE models of 3-point bending and RUL, and the deflection or change in length calculated

758

by the solver was compared with the experimental measurement data. In addition, values for the Young's modulus could be determined by means of inverse modeling; for this purpose, the Young's modulus values stored in the simulations were adjusted until the deviation of the change in length or deflection between simulation and experiment reached a minimum.

**RESULTS AND DISCUSSION**

*Determination of different E-moduli by means of 3-point bending test and DIC*

To visualize the crack propagation and deformation of the specimen during the three-point bending test, the strain of the specimen is displayed in the horizontal x-direction (Figure 2). About 100 frames in 2 seconds are recorded by the measuring system. The evaluation of the bending tests is then carried out using the bending line method according to the following formula:

$$w = \frac{F \cdot L_s^3}{16E \cdot I} \cdot \frac{x}{l} \cdot \left[ 1 - \frac{4}{3}\left(\frac{x}{L_s}\right)^2 \right], x \leq \frac{l}{2}$$

(1)

F: Maximum force; $L_s$ : span; E: E-modulus; l: specimen length
I: Area moment of inertia

Two different materials were used to determine the elastic modulus by means of a bending line model. On one hand, the deflection was recorded on a metallic aluminum prism and the Young's modulus was calculated according to the bending line. On the other hand, bauxite material also used for the RUL determinations was tested. Figure 2 shows the time-displacement measurements and the deflections of the refractory bauxite specimen. The values determined for the deflections are very different, so that the deflection of the aluminum sample is four times as large as that of the refractory bauxite sample. However, the different deformation behavior and the resulting crack formations in the refractory specimens must also be taken into account here. The values determined for bending force, deflection and modulus of elasticity are summarized in Table 1:

Tab. 1: Bending force, deflection and modulus of elasticity determined by three-point bending and DIC

| Material | Deflection [mm] | Bending Force [MPa] | E-Modulus [GPa] |
|---|---|---|---|
| Aluminium | 0.172 | 9879 | 70.7 |
| Bauxite Brick | 0.042 | 1623 | 47.5 |

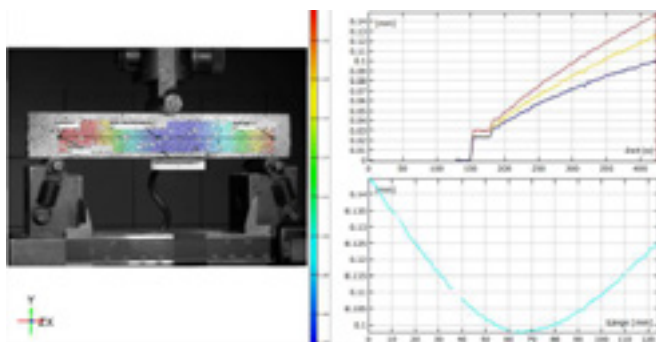

Fig. 2: Time dependant deformation of a refractory bauxite brick specimen in the three-point bending test and determined deflection

FE model of the 3-point bending test was set up as a 2D model; in order to represent the machine stiffness of the system mentioned above, additional springs were modeled at the two lower supports (Fig. 3). With the modulus of elasticity values previously determined by means of various evaluation methods in the 3-point bending test, simulations were carried out in each case and then the force-displacement diagram of the laboratory experiment was compared with the simulation results. It was found that the

evaluation by means of bending line theory provided the best agreement between simulation and experiment.
A Young's modulus determined inversely on the basis of the force-displacement relationship deviates only slightly from the Young's modulus of bending theory, as can be seen in Figure 4.

Fig. 3: FE model of the 3-point bending test

Fig. 4: Comparison of the force-displacement curves calculated by the 3-point bending model with experimental measurement results for different Young's modulus values

*Determination of thermal expansion and Young's modulus*

Temperature-strain data from RUL tests of refractory lightweight bricks with 99% $Al_2O_3$ (ASTM Group 34) have been measured and documented. For validation of the determined temperature-dependent Young's modulus, the corresponding Young's modulus data from the RUL tests and RFDA measurements were each deposited in a model of RUL (1.3 MPa load). The comparison of the temperature-strain data from simulation and experiment show very good agreement between simulation and experiment for the Young's modulus data determined by RUL for the refractory lightweight bricks. In contrast, the simulation using the Young's modulus data from the RFDA measurement significantly overestimates the strains that occur, so that the simulation results are closer to experimental data from RUL test at 0.01 MPa than to the 1.3 MPa actually simulated. These results suggest that the static modulus of elasticity determined by means of RUL tests represents the static load case occurring the practical conditions significantly better than the dynamic modulus of elasticity of the RFDA measurements [3].

Industrial shaped refractory material based on bauxite represents another reference refractory material for the evaluation of the modulus of elasticity from measurement data of the RUL tests. Compared with the lightweight refractory, it has a significantly higher density and strength and is used for refractory structures subjected to higher thermal and, above all, mechanical loads.

Initially, cylindrical bauxite brick specimens were used for the determinations during this project period. The entire RUL tests have been measured at loads between 0.7 MPa and 1.3 MPa. It should be noted that such refractory materials have been engineered and microstructured in terms of mechanical loading capacity. High load rates are thus necessary to achieve the corresponding elastic behavior. Figure 5 and 6 show all measurements and following determinations of stress strain curves of the bauxite material with the increasing load rates. It should be noted that a Y-offset at the beginning of the measurements is already considered in this plot. The general trend line is clearly visible. Nevertheless, there are small deviations between 0.7 MPa and 1 MPa resp. 1 MPa and 1.3 MPa. It should be noted that these are not repeat measurements but always new measurements. Figure 10 shows the elastic curves

required to determine the static modulus of elasticity of the bauxite brick for different temperatures. Significantly higher and also more realsitic Young's modulus determinations are now recorded than before the Y-offset. Turning points as in the determinations before are only recognizable at 1200°C in these measurements. The determined values before and after the Y-correction are listed in Table 2. With regard to the static Young's modulus values, the value for 600°C shows the highest deviations with 1.8 GPa.

The determined measurement results for thermal expansion of the bauxite brick specimens (0.01 MPa) and the measurement results for higher loads up to 1.3 MPa showed slight differences among them, but the tendency was observed. The series of measurements at 0.01 MPa showed the largest relative change in length, and the series up to 1.3 MPa the smallest. In contrast to earlier measurements, straight lines can now be constructed from the available measurement results to determine the Young's modulus. As described above, the material group of lightweight refractory bricks and the bauxite bricks show that the measurement principle is suitable for determining the Young's modulus. The assumption that higher superimposed loads are required for this purpose was thus also confirmed independently of previously conducted compression tests.

Tab. 2: Young's modulus determinations from the straight lines constructed for different temperatures from fig. 4 (RUL), initial measurement as well as correction after Y-offset adjustment

| Temperature [°C] | E-Modulus (RUL test) [GPa] | E-Modulus after Y-Offset [GPa] |
|---|---|---|
| 200 | 4.0 | 20.1 |
| 400 | 3.5 | 7.6 |
| 600 | 2.7 | 1.8 |
| 800 | 2.6 | 3.8 |
| 1000 | 2.3 | 4.4 |
| 1200 | 0.8 | 0.9 |

Inverse modeling of the individual measurements was then recognized as a solution for this, since the Young's modulus of the refractory bauxite material is known from previous measurements. A variation of the Young's modulus values of the mortar was performed until the applied simulation and the applied experiment were in good correlation. This was done by three tests per material to check the reproducibility of the method.

Fig. 5: RUL tests with different loads between 0.01 and 1.3 MPa for bauxite bricks (multiple measurements)

Fig. 7: RUL tests with different loads between 0.01 and 0.5 MPa of bauxite-mortar samples (multiple measurements)

**CONCLUSIONS**

In these studies a new approach for the determination of $E_{static}$ (T) values using RUL tests was examined. Therefore different RUL tests on refractory lightweight bricks as well as bauxite bricks have been performed leading to $E_{static}$ values using isothermal lines. The comparison with $E_{dynamic}$ data achieved by means of RFDA shows reasonable deviations. Finally FEM validation using model of RUL test lead to a good agreement for determined $E_{static}$ values.

For comparison with the results of the RUL tests, 3-point bending tests at elevated temperature are planned in the future in order to be able to determine a temperature-dependent static modulus of elasticity here as well.

For both refractory materials the measurement principles using RUL and DIC are suitable for the determination of mechanical behavior.

For future works a modification of the RUL test setup to achieve higher stresses would be favourable. Higher loads are then essential. In regard of the examination of brick-mortar lining systems at higher temperatures these studies support the utilized method to test multi-layer specimen of refractory and mortar as an experimental homogenization technique.

Fig. 6: Elastic straight lines for different temperatures generated from RUL tests of bauxite material (from Fig. 5)

Measurement results of RUL determinations for multipart bauxite specimens with mortar joints are shown in Figure 7. The load here was initially increased from 0.01 MPa to 0.5 MPa. However, it is not possible to determine the static modulus of elasticity by isotherm from these measurements because the thickness of the applied mortar layer was highly influencing.

# STATISTICAL EVALUATION OF INFLUENCING FACTORS ON VARIOUS COLD CRUSHING STRENGTH DETERMINATION METHODS

Gerhard Urbanek*, Hans-Jürgen Klischat, Manuel Miranda-Martinez,
World Refractories Association, Brussels, Belgium

## 1  ABSTRACT

Measurement of cold crushing strength (ASTM C133) strength resp. cold compressive strength (ISO 10052-1) (CCS) has been used over 100 years as a test method for characterizing refractory products. Although CCS describes in a limited way the performance of a refractory, it is widely used as a key parameter in data sheets and product definitions. Moreover, there are several different CCS standards, each with different influences, a circumstance leading to different and sometimes hardly comparable results which may cause complex trade issues.
For these reasons, a Task Force on Testing Methods and Standards of the World Refractory Association (WRA) has investigated precision data and the comparability of the different CCS standards. More than 1000 individual tests were performed by seven renowned laboratories on six different refractory grades.  This work presents the statistically assured results.
The standards ASTM C133 and ISO 10059-1 differ mainly in the load rate applied and the usage of an interlayer (packing) between the plunger and the test specimen. The results have shown that ASTM C133 gives on average around 24% lower values, this is attributed to the use of the packing.  The influence of the geometry of the test specimens (be it cylindrical or cubic) was also investigated and showed only a minor effect on the values.
The precision data collected in this study have shown for both ASTM C133 and ISO 10059-1 a relative repeatability interval of around 20%. Regarding reproducibility, ASTM C133 performed slightly worse than ISO 10059-1 (40% compared to 30%).
In a further step, the integration of the precision data and the comparative results into ISO/TC 33 for ISO 10059-1 will be proposed.

## 2  OBJECTIVE: THE COMPARISON AND ESTABLISHMENT OF CORRELATIONS BETWEEN STANDARDS ISO, EN (I.E.: DIN, ETC), ASTM, AND GB/T

CCS measurements have always been the subject of controversy. Unfortunately, there is not a single standard but several national and international ones.  They produce a significant scattering of results, generally known up to 20 % standard deviation.

This is a foregone result of the heterogeneous structure of refractories, whose microstructure consist of grains and pores, each of different size and distribution. As a matter of fact, even small deviations in their production process - like the pressure applied during forming, the temperature distribution in the kiln during firing, etc. - may contribute to the unevenness of the resulting material, and thus to the scattering of measured CCS values.

Several CCS testing methods have been standardized, applying various possible influencing factors (section 6).

Tab. 1: Roundup of various international CCSstandards

| Standard | Country | Sample Shape | Sample Size | Packing | Load Rate |
|---|---|---|---|---|---|
| ISO 10059-1 | International | cylinder | 50 mm or 36 mm | No | 1,0 MPa/s |
| ISO 10059-2 | International | cylinder or cube | cylinder 50 or 36 mm<br>cube 75 mm or half standard brick | Yes<br>3-7 mm | 1,0 MPa/s |
| EN 993-5 | Europe | cylinder or cube | 50 mm or 36 mm | No | 1,0 MPa/s |
| ASTM C133-97 | USA | cylinder or cube | 51 mm | Yes<br>6,4 mm | 0,2 MPa/s |
| GOST 4071.1-94 | Russia | cylinder or cube | 20 - 100 mm | No | 1,0 - 2,0 MPa/s |
| JIS R2206 based on ISO 10059-1 | Japan | cylinder | 50 mm or 36 mm | No | 1,0 MPa/s |
| JIS R2206-2 based on ISO 10059-2 | Japan | cylinder or cube or half of a standard brick | cylinder 50 or 36 mm<br>cube 75 mm or half standard brick | Yes<br>3-7 mm | 1,0 MPa/s |
| IS 1528;4 | India | cubes, cylinder or standard brick or half of a standard brick | 50 mm or standard brick or half of a standard brick | No and Yes<br>3-7 mm | 1,0 MPa/s |
| GB/T 5072-2008 | China | cylinder | 50 mm or 36 mm | No | 1,0 MPa/s |

## 3  FOCUS OF THE INVESTIGATION

The focus of our investigation has been the evaluation of the most important influencing parameters on CCS testing.

Various types of refractory brick grades, both basic and non-basic, covering a wide range of CCS values, from very high to low ones, were studied (MgO-C, magnesia spinel, bauxite, andalusite, fireclay, lightweight fireclay).

For each grade the evaluation has included several testing scenarios, those a priori considered having an influence on the dispersion of the CCS values measured, namely:

– Testing the influence of the testing standard employed: ASTM C133-97 (2021) and ISO 10059-1.  The latter chosen as it is matchable with several other standards (Table 1).
– Testing within each brick and each laboratory separately (repeatability).
– Testing in different laboratories (reproducibility).
– Testing the influence of specimen shape (cylinder or cube) for each grade and each laboratory, as sample preparation for both standardized shapes is different.
– Testing the influence of load rate (0.2 and 1.0 MPa/s).
– Testing the influence of using packing or not.

The aim has been the determination of reproducibility and repeatability of standards, and to find systematic deviations that may be harmonized by a distinct factor to convert values from one standard into another.

## 4 LABORATORIES AND MATERIALS

### 4.1 Laboratories
Seven internationally well-respected laboratories were selected for the investigations:
– Laboratories in Germany, Poland and Spain all specialized in measurements on refractory and ceramic materials.
– Refractory manufacturer's laboratories: In the United States of America, Great Britain, Austria (which also created the design, performed data preparation and statistical analysis) and in Germany (which also acted as coordinating laboratory).

### 4.2 Refractory brick grades
Six industrially, on hydraulic high-performance presses formed brick grades were selected to cover the whole range of dense refractory materials and expected material strengths.

### 4.3 Design of tests and sample description

#### 4.3.1 General
To achieve significant and meaningful results, a sophisticated procedure was elaborated to determine possible correlations among the influencing parameters.

The population constituted by all samples was used to carry out:
– An interlaboratory tests for each standard method and brick grade (round robin test),
– A comparison of the tests carried out following ASTM C133-97 (onwards ASTM) and ISO 10059-1 (onwards ISO), where the results obtained testing by each method were compared to those obtained for 50 mm cylinders tested according to ISO.

The Spanish laboratory and the two refractory manufacturers laboratories in Austria and Germany also carried out some additional tests intended for determining the influence of load speed on ISO cylinders (1 MPa/s vs. 0.2 MPa/s) and the effect of packing on ISO cylinders separately, and not only both together in the combinations defined by ASTM and ISO.

#### 4.3.2 Sample preparation
All samples for the comparative tests were wet drilled and/or cut in a single laboratory, using the same equipment that was operated by one person. The final sample preparation (cutting/grinding) was completed in each laboratory separately, so that the influence of sample preparation is as it is in real business.
For each refractory grade three bricks were selected from a higher initial population. In order to avoid deviations in CCS results that are caused by inhomogeneities typical for the brick production, bricks were selected according to fit in a 0.01 g/cm$^3$ interval.
From these three bricks, cylinders as well as cubes were prepared. The samples were dried immediately after cutting to prevent hydration (most important for basic bricks) or influence from the filling of pores with water.
The sampling was designed to compare each type of test specimen and condition with that of the ISO cylinders taken as reference, Fig. 1.
– On brick #1: ISO cylinders (A,D,E,H) as reference for ISO cubes (B,C,F,G)
– On brick #2: ISO cylinders (A,D,E,H) as reference for ASTM cubes (B,C,F,G)
– On brick #3: ISO cylinders (A,D,E,H) as reference for ASTM cylinders (B,C,F,G)

Fig. 1: Design pattern of specimens' extraction for comparison test for both: i) ASTM cylinders and cubes and ii) ISO cylinders and cubes.

## 5 DETERMINATION OF PRECISION (ISO 5725-2)
Based on the results of the interlaboratory study, the precision of the different tests methods was calculated according to ISO 5725-2.

Precision was evaluated under the following conditions:

1. Repeatability: one equipment, tests carried out by one operator, with the same material in one laboratory.
2. Reproducibility: different equipment, tests done by different operators with the same material in different laboratories).
3. According to ISO 5725-1 the repeatability (r) reflects the closeness of agreement, that is, the maximum permissible difference due to the test error between two test results under repeatable conditions (ASTM C133). As such, two test results that do not differ by more than the repeatability interval will be from the same population. The reproducibility (R) has the same definition under reproducibility conditions.

Tab. 2: Precision data for the different methods and grades. The color marking indicates very good precision values in green and lowest precision values in red, and intermediate precision values in yellow.

| method | interval | A Andalusite | B Bauxite | C Magnesia Carbon | F Fireclay | R Low density Fireclay | S Magnesia Spinel | all grades |
|---|---|---|---|---|---|---|---|---|
| ILS 1 repeatability interval | | | | | | | | |
| ISO 10059-1 | r [%] | 25.2 | | 15.0 | | | | |
| ILS 2 repeatability interval | | | | | | | | |
| ISO 10059-1 | r [%] | 18.4 | 18.1 | 14.7 | 14.4 | 13.9 | 27.6 | 17.9 |

| ASTM_cyl | R [%] | 46.9 | 48.9 | 25.3 | 32.3 | 30.5 | 37.9 | 36.9 |
| ASTM_cub | R [%] | 48.1 | 42.9 | 28.3 | 36.9 | 34.5 | 51.1 | 40.3 |
| ASTM C133 reproducibility interval | | | | | | | | |
| ASTM C133 | R [%] | | 45.0 | | | 18.1 | | |

## 6 COMPARISON OF THE MAIN DIFFERENT FACTORS OF THE STANDARDS

The main differences of the standards are:
- shape (cube, cylinder)
- packing (with/without)
- load rate (0.2 or 1.0 MPa/s, see Table 1)

A statistical evaluation on so called "twin" samples (as close as possible sample positions at the bricks – see fig.1 like A-B or C-D) shows table 3.

Tab. 3: ANOVA for all variated parameter based on all differences of pairs
Horizontal data (red): Parameter has significant influence on CCS (p-value < 0.05)

| effect | step of effect | parameter | standard error | t | p | -95% confidence | +95% confidence |
|---|---|---|---|---|---|---|---|
| Constant | | -8,70 | 0,52 | -16,82 | 0,00 | -9,72 | -7,69 |
| Laboratory (reference 6) | 3 | 1,84 | 1,11 | 1,65 | 0,10 | -0,35 | 4,02 |
| | 1 | 0,54 | 1,13 | 0,48 | 0,63 | -1,67 | 2,75 |
| | 7 | -0,07 | 1,02 | -0,07 | 0,94 | -2,07 | 1,92 |
| | 2 | -0,95 | 1,02 | -0,92 | 0,36 | -2,95 | 1,06 |
| | 4 | -0,24 | 1,11 | -0,21 | 0,83 | -2,42 | 1,95 |
| | 5 | -0,78 | 1,13 | -0,70 | 0,49 | -2,99 | 1,43 |
| Grade (reference R) | S | 0,17 | 0,90 | 0,18 | 0,85 | -1,60 | 1,93 |
| | C | 1,25 | 0,84 | 1,48 | 0,14 | -0,40 | 2,90 |
| | A | -1,15 | 1,12 | -1,03 | 0,30 | -3,34 | 1,04 |
| | B | -1,23 | 1,12 | -1,10 | 0,27 | -3,42 | 0,96 |
| | F | 0,07 | 1,12 | 0,07 | 0,95 | -2,12 | 2,26 |
| Sample shape | cylinder | 2,33 | 0,50 | 4,69 | 0,00 | 1,36 | 3,31 |
| packing | no | 11,41 | 0,75 | 15,20 | 0,00 | 9,94 | 12,88 |
| load rate | 1.0 MPa/s | 3,86 | 0,75 | 5,13 | 0,00 | 2,39 | 5,33 |

This ANOVA is calculated based on twin samples. All three parameters are significant: cylinder, without (no) packing, and load rate 1.0 MPa/s give higher results, with the main effect by packing, as also may have been proposed by theoretical considerations.

A calculated linear regression of absolute values and differences of twin specimen shows that a conversion between the test methods according to Fig. 2 is possible and reasonable. More tests would increase the accuracy due to statistical reasons

764
Fig. 2: Linear regression for the different methods compared on twin specimens for ISO cylinder specimens. One point is the mean value of all results of all laboratories for one grade.

## 7   CONCLUSION

In conclusion, more than 1000 single CCS tests have been performed from seven leading refractory laboratories (producer and independent laboratories) on six different refractory grades according to different standards to provide a closer look on this very common test method for refractories. The goal was to statistically compare the results of the different standards (ASTM and ISO) to establish a basis and allow a conversion between the methods and to obtain precision data for all considered test methods. A special drilling schema, which ensures a direct comparison of the different methods with samples from one brick (twin or pair specimen), has been applied to avoid possible differences in the CCS of different bricks and to avoid unknown influencing parameters. Both standards differ mainly in the load rate applied and the usage of an interlayer (packing) between the plunger and the test specimen. ASTM C133 gives around 24 % lower values, attributed to the use of the packing. The influence of the geometry of the test specimens (be it cylindrical or cubic) was also investigated and showed only a minor effect on the values. The precision data collected in this study have shown for both standards a relative repeatability interval of 20 %. Regarding reproducibility ASTM C133 performed slightly worse than ISO 10059-1 (40 % compared to 30 %). In a further step, the integration of the precision data and the comparative results into ISO/TC 33 for ISO 10059-1 are proposed

# EVALUATION OF COLD CRUSHING STRENGTH METHODS ON STATISTICAL VALUES OF VARIOUS REFRACTORY BRICK GRADES

Hans-Jürgen Klischat*, Gerhard Urbanek, Manuel Miranda-Martinez,
World Refractories Association, Brussels, Belgium

## ABSTRACT
The cold crushing strength (CCS) test is a standard test method for refractory products, which is indicated in nearly all data sheets of refractory materials. The measurement, although theoretically quite simple, often produces a wide variety of results, which sometimes raise unnecessary discussions between refractory producers and refractory users. A statistical evaluation of precision data and the comparability of different standards, encompassing seven laboratories and the application of Mandel's statistics for all laboratories and materials tested, was carried out by the Task Force "Testing Methods and Standards" of the World Refractory Association. The results gathered show the influence of application of the standards ASTM C133 and ISO 10059-1 not only regarding the influence of testing parameters, but also some material dependencies. So, a higher scatter of values with increasing strength values was observed. Specific features were also observed mainly for magnesia spinel bricks which may be explained by the presence of microcracks, which certainly influence the strain field within the specimen. Furthermore, the values of all brick grades are also affected by the laboratory measurements conditions themselves, as various influences are considered to result in lower values. Therefore, it would be desirable that more statistical data on CCS are reflected into standards (ISO/TC 33 for ISO 10059 and ASTM C133), as should also be the results for different refractory grades.

## INTRODUCTION
Although the measurement of cold crushing strength seems rather simple at first sight, the results can differ to a great extent due to several influencing factors, mostly speed of load increment, shape and size of specimen, and use of an interlayer between sample and plungers of the testing machine. Although the latter is used mainly to compensate unevenness of plates and sample, the stress distribution changes dramatically from compressive stresses to tensile stresses. Ceramic materials are more sensitive to tensile than compressive stresses, so this interlayer or packing leads to lower values of the cold crushing strength, (1), (2), Fig. 1.

Fig. 1 Types of strain induction on a specimen during measurement of cold crushing strength without (left) and with packing (right)

Unfortunately, the most well-known standards use variations in test methods, which will inevitably result in differing values. From a statistical approach, an attempt was made to determine the precision and reproducibility of data, which gave mostly satisfying results for the overall data, and concluded that a conversion between the test methods according is possible and reasonable. The precision data have shown for both ASTM C133 and ISO 10059-1 a relative repeatability interval of around 20%. Regarding reproducibility, ASTM C133 performed slightly worse than ISO 10059-1 (40% compared to 30%). Still, more tests would increase the accuracy. To complete the statistical evaluations, material behaviour under the differing conditions of the two main standards

is discussed. Repeatability standard deviations and relative repeatability standard deviations are given in Figs. 5 and 6. They reflect the dependency of scatter under repeatability conditions and reproducibility, being ordered by the grades with increasing strength values.

## MATERIALS AND TEST PROCEDURE
Basic and non-basic refractory bricks grades, covering a wide range of CCS values, were studied. The properties of magnesia carbon (C), magnesia spinel (S), bauxite (B), andalusite (A), fireclay (F), and lightweight fireclay (R) bricks are shown in Figure 2.

| Brick grade | Brick C | Brick S | Brick B | Brick A | Brick F | Brick R |
|---|---|---|---|---|---|---|
| Raw materials | magnesia carbon | magnesia spinel | bauxite | andalusite | fireclay | fireclay |
| Density [g/cm³] | 2.96 | 3.01 | 2.88 | 2.67 | 2.24 | 1.78 |
| Porosity [%] | 2.45 | 14.1 | 17.50 | 13.40 | 56.00 | 26.70 |

Fig. 2: Properties of the investigated brick grades

For each grade several testing scenarios with an influence on the dispersion of the CCS values were measured. These were (i) influence of the testing standard employed: ASTM C133-97 (2021) and ISO 10059-1, (ii) testing within each brick and each laboratory separately (repeatability), (iii) testing in different laboratories (reproducibility), (iv) influence of specimen shape (cylinder or cube), (v) influence of load rate (0.2 and 1.0 MPa/s), (vi) influence of using packing (or not).

Due to the expected high scatter of results, Mandel's statistics for interlaboratory testing were used to retrieve a correlation with material properties as well as material's response. The specific values are the h-statistics for comparison of mean values of all laboratories and grades (and to determine the consistency of interlaboratory tests, and to confirm if a laboratory is an outlier) and the k-statistics for the repeatability performance of each laboratory (comparing the standard deviation of a laboratory with the average of the standard deviation of all laboratories). The Mandel's statistics are recommended by ISO 5725-2, (3) as well as ASTM E691, (4).

## RESULTS OF INTERLABORATORY TESTS
### Tests according to ISO 10059-1 with cylinders
Reference tests containing all precision data were carried out with cylinders for all laboratories and brick grades, Fig. 3.

Fig. 3: Results of the interlaboratory study based on ISO cylinders with separate precision data for grades (outliers eliminated) as an example for all performed tests

All collected laboratory data were evaluated. As an example, the data for magnesia carbon bricks are given in Fig. 4, showing the single CCS values as well as their scatter, the median value, and the tolerance limits.

Laboratory 3 is characterized by a significantly too wide range of values as single results (red dots). These results were eliminated for further precision calculation.

*Fig. 4: Detailed graph for the magnesia carbon brick C with all single results of each laboratory, grouped with increasing strength values by laboratory*

*Fig. 5: Increase of repeatability standard deviation with increase of absolute CCS values and reproducibility standard deviation*

*Fig. 6: Relative repeatability standard deviation (MPa) with increase of absolute CCS values*

Figs. 5 and 6 reflect the dependency of scatter regarding repeatability conditions and reproducibility, respectively, with ordering points of grades. The peaks in both diagrams are related to grade S (magnesia spinel brick).

For magnesia carbon bricks C, an amount of 188 samples were tested. The mean value was calculated for all tested samples excluding outliers. For this grade, 7 laboratories conducted the test, but one laboratory was an outlier. The absolute and relative reproducibility intervals are similarly descriptive than other precision parameters like repeatability standard deviation. Two single results under repeatability or reproducibility conditions should not differ more than these intervals. Otherwise, it is not the same sample, or the methods are different. A graphically overview for comparison of mean values of all laboratories and grades are given by the two figures of Mandel's h- and k-statistics for the repeatability performance of each laboratory, Figs. 7, 8.

The bars are grouped by the laboratories, each bar represents the standardized results of each grade. The "h" statistics displays positive values for higher results than the mean of all laboratories vice versa. The "k" statistics displays the repeatability: bars, yellow or red, mark "significant" to "high" variations. Fig. 7 shows that laboratories 6 and 7 measure predominantly higher values, while laboratories 1, 2, and 3 measure values which are generally lower than the overall mean value. Laboratories 4 and 5 measure values

which correspond to the mean value but show a wide scattering of values for the different brick grades. All laboratories are within the critical value. A systematic dependence on special brick grades cannot be derived.

*Fig. 7: Mandel's h statistics for ISO cylinder method*

*Fig. 8: Mandel's k statistics for ISO cylinder method*

For Mandel's statistics, a red or yellow bar (a result is significantly different to the other grades/samples and laboratories) is defined as outlier and erased for further calculations of the precision data. In this case, laboratories 2 and 3 show outliers (above the critical value), but only for some brick grades (Lab 2: C, R; Lab 3: A, C), Fig. 8.

**Tests according to ISO 10059-1 with cubes**

The test procedure was similar to the one with cylinders, but the results varied between the two geometrical shapes.

Several values for laboratory 2 regarding cubes are outside of the critical value (andalusite, bauxite, and fire clay), while all other values show a similar trend as for cylinders. Remarkably labs 6 and 7 continue the trend of high Mandel's h values, which means they measure higher values than the mean of all laboratories, Fig. 9.

Laboratory 2 had once again a significantly too high scatter in its results.

For the geometrical parameter "cube" the similar results as for "cylinder" are found also for Mandel's k, Fig. 10. Laboratory 2 shows statistically differing results compared to the other ones, mainly for magnesia carbon, fireclay, and magnesia spinel bricks. Still, the other values are also higher. It has to be noted that the outliers for Mandel's h and Mandel's k statistics affect different brick grades, still belonging to laboratories 2 and 3.
*Fig. 9: Mandel's h statistics for ISO cube method*

*Fig. 10: Mandel's k statistics for ISO cube method*

**Tests according to ASTM C133 with cylinders**

As a comparison to ISO 10059-1, tests according to ASTM C133 were performed to investigate the influence of the lower load rate and, more significantly, the influence of the packing layers between plungers and specimen on the results, Figs. 11, 12.

*Fig. 11: Mandel's h statistics for ASTM cylinder method*

For ASTM cylinders the trend for Mandel's h-statistics is similar as for ISO data, Laboratories 6 and 7 always show values above the average, but contrarily to previous results, laboratory 3 also shows high values. Remarkable is the very high effect of andalusite bricks in this laboratory, indicating the effect of tensile stresses on the result especially for this brick grade, which, on the other hand, is not observed by the other laboratories.

Here, also laboratory 2 shows significant effects on repeatability. It is worth noting that lab 2 exceeds the critical value for three brick grades, magnesia carbon, insulating fireclay and magnesia spinel bricks.

*Fig. 12: Mandel's k statistics for ASTM cylinder method*

## VIEW ON BRICK GRADES

**Magnesia carbon bricks C**

Generally, the measurements on ISO cylinders show that Laboratories 2, 6, and 7 show the highest values, while laboratory 4 measures the lowest values, Fig. 7. Laboratory 3 is characterized by a high standard deviation, which exceeds the lower tolerance limit, which is ± 2 standard deviations from the mean value of all laboratory results.

The measurements on ISO cubes show a different picture, Fig. 9, while laboratories 6 and 7 still homogeneously show the highest values, Laboratory 2 shows an unacceptable high variation, while the other laboratories show intermediate values with a low scatter of results.

The measurements on ASTM cylinders result in a very high scatter of values from Laboratories 2 and 4, while laboratories 6 and 7 again measured the highest values with a low standard deviation, Figs. 9, 10.

All in all, there is no systematic dependence on the measurements of the MgO-C bricks. Laboratories 6 and 7 measure the highest values, while all other laboratories sometimes measure values with a very high standard deviation exceeding or undercutting the tolerance limits, but this cannot be assigned to a special laboratory. An assignment to material properties, e. g. the orientation of plate-like graphite grains which can align themselves during the pressing process of brick production, is not obvious.

**Magnesia spinel bricks S**

For magnesia spinel bricks, there is also no systematic dependence of the values on the measurements. ISO measurements give higher values than ASTM measurements. Cylinders give tighter tolerance limits only for ISO cylinders, for ASTM there is no significant difference. Laboratories 6 and 7 measure the highest values. An assignment to material properties by Mandel's statistics is not obvious. With regard to Fig 5 and 6, the influence of the microcrack system (caused by the thermal expansion mismatch between magnesia and spinel to reduce Young's modulus and increase brick elasticity) has to be considered as an influence on the brick behaviour.

**Bauxite bricks B**

The results for ISO cylinders show for all laboratories values within the tolerance limit, Figs. 7, 8. Taken the high strength values into account (one reason why bauxite bricks were chosen), the scattering is not increased but remains stable below 10%. Again, Laboratories 6 and 7 measure the highest values.

This is confirmed for ISO cubes, except for Laboratory 2, where significantly lower values are measured, Fig. 9. A reason from material's point of view is not obvious.

ASTM measurements give lower values compared to ISO measurements. For ASTM cylinders, Laboratory 5 is characterized by low values of CCS, accompanied by a high scattering of the

standard deviation, Figs. 11, 12. Laboratory 2 also gives low values, Fig. 11.

Although bauxite bricks, in this case with an additional phosphate bond, are characterized by a very high strength (median value 134 MPa), there are no material characteristics obvious which influence their statistical behaviour.

### Andalusite bricks A

The results for ISO cylinders show for all laboratories values within the tolerance limit, although strength levels are very different for all the laboratories, they increase from 78 MPa to 99 MPa, but very consistently and with typical standard deviations. For this brick grade this could be a hint for a systematic influence of the testing conditions. It is obvious that Laboratory 2 measures again the lowest values, but at a similar level as Laboratory 3, Fig. 7. Again, Laboratories 6 and 7 measure the highest values.

This is confirmed by measurements of cubes, with the exception that Laboratory 2 measures all values significantly below the lower tolerance limit, Fig. 3, confirming the results of bauxite bricks.

The values for cubes are well below the ones of the cylinders.

For measurements on ASTM cylinders, all laboratories measure similar strength values of ca. 68 MPa, Fig. 6, except laboratory 3, where all measured values are located above the upper tolerance limit. Also here, a special material specific correlation cannot be found regarding an influence on CCS.

### Fireclay bricks F

Contrarily to the other products, the tolerance limits and the standard deviations for the different laboratories are less pronounced. All standard deviations are below 6.5 MPa. Laboratories 6 and 7 show again the highest values but are not far apart from the other laboratories, Fig. 7. A clear explanation for this behaviour is not obvious, as also fireclay bricks consist of several mineral phases (mullite, glass phase, cristobalite), which would theoretically result in a behaviour comparable to the other brick grades.

All other values for ISO cube measurements confirm the already known results. Laboratory 2 still measures the highest scattering of results, Fig. 9, which cannot be directly related to material properties.

### Insulating fireclay bricks R

The standard deviation of insulating fireclay bricks is, like fireclay bricks, comparatively small, with a maximum standard deviation of 3.3 MPa. Laboratory 6 does not measure the highest values, while laboratory 7 again measures the second highest values

The results are roughly confirmed by ISO cube measurements, but a higher scatter of values (standard deviation maximum 4.75 MPa of Laboratory 2), Figs. 9. 10. This high value contributes also to the comparatively high limits of tolerance.

Regarding material properties of this unburnt brick grade, there is also no direct influence on the cold crushing strength values obvious.

### CONCLUSIONS

Various refractory brick grades covering a wide variety of cold crushing strength values were investigated to get information on their influence on CCS testing reproducibility and repeatability in seven laboratories with the aim of possibly finding a correlation to brick composition.

As a helpful tool, Mandel's statistics were applied to detect differences between samples measured by different laboratories to examine if a material contains outliers in comparison to others. The h statistic is relevant for differences between mean values, the k statistic is relevant for differences between variances.

Most of the evaluated influencing factors had a high dependency on the grades. Still, a direct influence of the material's structure to the scattering of values was not obvious, neither to the h-value nor the k-value. The pure ceramically bonded magnesia spinel brick behaves different to the other brick grades, as can be read from the repeatability standard deviation and the relative repeatability standard deviation, Figs. 5, 6. This is most probable due to the special microstructure intentionally created by the installation of a microcrack system to reduce Young's modulus. These microcracks are created by a thermal expansion mismatch between magnesia and spinel. This may result in a different stress and strain pattern in these bricks during the tests, being responsible for the unique behavior.

For further measurements, to minimize the effect of laboratory influences, the application of knowledge of Mandel's h and k values is advantageous, and its application would also be advisable when updating international standards.

Measurement values being too high can only be explained by a not centric location of the ancillary adaptor. This can result in the pick-up of forces which results in higher values, especially at low forces. On the other hand, there are several possibilities for explaining too low measurement values:

o   Uneven face surfaces of the cylinders and cubes resulting in uncontrollable stress peaks.
o   Not rectangular preparation of the specimen.
o   Not parallel surfaces of specimen.
o   Pop-outs of the sample surfaces.

Some laboratories may also have more experience in preparation of cylinders instead of cubes, and therefore may be more prone to failures when testing cubes.

Furthermore, uneven steel plates, be it worn or scratched, result in uncontrollable stress peaks. Roughness decreases by permanent measurements. Due to the lack of the hardness, a faster wear may occur.

A number of hints may be taken from this work for revision of CCS standards. Generally speaking, it would be advisable to include precision data, consider advancement in the conversion between test methods, establish of the number of specimens for one sample (n=4) and for more precise comparison the special drilling scheme.

# BULK DENSITY DETERMINATION OF REFRACTORY RAW MATERIALS – FASTER AND BETTER WITH A SPIN-DRYER

Andreas Buhr, Almatis GmbH, Frankfurt, Germany

Geert Wams, Almatis BV, Rotterdam, The Netherlands

John Stevenson, Almatis Inc., Benton/AR, USA

## ABSTRACT

In order to determine the bulk density of refractory raw materials, the so-called water method following the Archimedes principle is normally used. This is where the effect of water displacement on the weight of the sample is used to determine the bulk volume of the sample grains. During this test procedure, the surface of water infiltrated sample grains must be dried with a wet towel. Experience shows, that this drying step is the main root cause for variation in reproducibility of results and even repeatability of tests. A new spin dryer (centrifuge) was developed and introduced to automate this surface drying step, and is now included as a new method in ISO 8840:2021. The paper discusses the improvement of measurement with the new approach and industrial experiences from two big industrial players in the raw material business.

## INTRODUCTION

The bulk density is an important property for refractory raw materials and the apparent (open) porosity is also an essential part of the specification. It is measured frequently as in-process control in refractory aggregate production. During tabular production, Almatis performs about 28,000 bulk density measurements per year over its six sites in the USA, The Netherlands, Germany, India, China, and Japan.

The different standard methods for determination of bulk density are briefly and comprehensively described by Lorenzoni [1] and will not be discussed in detail here. Popular methods such as DIN-EN 993-18 [2] and ASTM C357-07 [3] include sample volume determination by weighing the immersed sample in water following the Archimedes principle with buoyancy related to the volume of the immersed body. An important part of that procedure is weighing the water - infiltrated sample without excess water on the surface of the sample. This would lead to grain bulk density appearing lower. However, undesired removal of water from open pores at the grain surface would give apparently higher bulk density.

Therefore a wet cotton towel is wrung and then used to manually blot the grains to dry the surface until the wet sheen on the grains has disappeared (figure 1). It is clear that this procedure adds variability to the results because of slight differences between operators and their subjective judgements. This has been proven by multiple round robin tests both internally and externally at Almatis and RHI Magnesita. A bulk density variation of +/- 0.02g/cm³ is commonly accepted for tabular alumina or other refractory aggregate grain density measurements.

RHI Magnesita has developed a new method for this critical step in grain bulk density measurement, This replaces the manual and subjective method by the use of a centrifuge (spin dryer), to give an automated and more reproducible process [1]. It has been included in ISO 8840:2021 [4]. Almatis, at first, tested the centrifuge and then purchased six machines from RHI Magnesita for use in all worldwide tabular alumina sinter plants. The current status of experiences and results is described as follows.

*Fig. 1: Surface drying of immersed tabular alumina grains by blotting with wet towel (cotton cloth).*

## CENTRIFUGE METHOD

### Centrifuge for surface drying

Fig. 2 shows the centrifuge with five baskets for carrying the immersed, water-infiltrated grain samples. If less than five samples are to be tested, dummies should be used in the other baskets to ensure balance during the spinning process. The rotation speed and time can be adjusted based on calibration experiments depending on the requirements of specific materials. However, Almatis found the setting of 680 RPM for 90 secs as recommended by RHI Magnesita was also suitable for tabular alumina. This figure was defined by RHI Magnesita after an extended series of tests over a broad range of raw materials but with a particular focus on magnesia.

For each bulk density measurement Almatis uses three 90 g tabular alumina samples, crushed and sized to 5 - 8 mm. This is coarser than the figure in ISO 8840:2021 where 2 – 5.6 mm or 3 – 4 mm is recommended for the centrifuge method. Tabular alumina is a very hard material and lab-crushing of the 19 mm diameter sintered balls down to 3 – 4 mm for bulk density testing would be inappropriately cumbersome for the high number of samples in daily processing in the plants. The high homogeneity of tabular alumina as a granulated and sintered product allows that deviation from the norm.

Fig. 3 shows the bulk density of tabular alumina samples comparing surface drying with the towel with the centrifuge method. The correlation found in this and multiple other tests was very good and triggered the decision to equip all tabular alumina sintering plants within Almatis with centrifuges for bulk density measurement. With regard to nomenclature some clarification is

needed here. Historically, bulk density of tabular alumina was always referred to as bulk specific gravity (BSG) which strictly speaking is a unitless figure relating the gravity to that of water with 1 g/cm³. Nevertheless, BSG was and is used with g/cm³ as unit in data sheets and all technical communication.

The process of establishing the centrifuge method and qualifying it as a replacement of the towel method for drying is ongoing in Almatis sinter plants..The plants that started first have already implemented this change.

*Fig. 2: Centrifuge (spin dryer) built at the RHI Magnesita Technology Center Leoben, Austria.*

*Fig. 3: Bulk Specific Gravity (BSG) of tabular alumina - centrifuge vs. towel drying.*

## Centrifuge for grain infiltration

The centrifuge provides another interesting opportunity for improving the bulk density measurement of raw material aggregates. RHI Magnesita has successfully tested grain infiltration with the centrifuge. In the standard methods, the sample is infiltrated with water either by the vacuum method [2] or by boiling in water [3]. Both procedures require a minimum of 45 minutes to achieve the required infiltration of the grains. At Almatis, boiling the sample in water is the common way for infiltration. When the dry sample is put into a plastic container with water and then into the centrifuge basket (figure 4), the spinning can be used to infiltrate the sample grains. Here, rotation speed and time have to be increased when compared to the surface drying step later in the procedure. For Almatis tabular alumina samples, 880 RPM for 220 seconds was established as the standard setting for achieving stable infiltration results. This is significantly faster than the boiling method.

With this new approach, using the centrifuge for infiltration and drying the surface, results from bulk density measurement are already available after about 15 minutes. This compares to about 90 minutes using the old approach. It also means that the lab analysts can perform the testing in one operation instead of having interruptions, waiting for the infiltration to be finished.

*Fig. 4: Basket with plastic container for infiltration of tabular grains by centrifuge.*

## Results from new method with tabular alumina

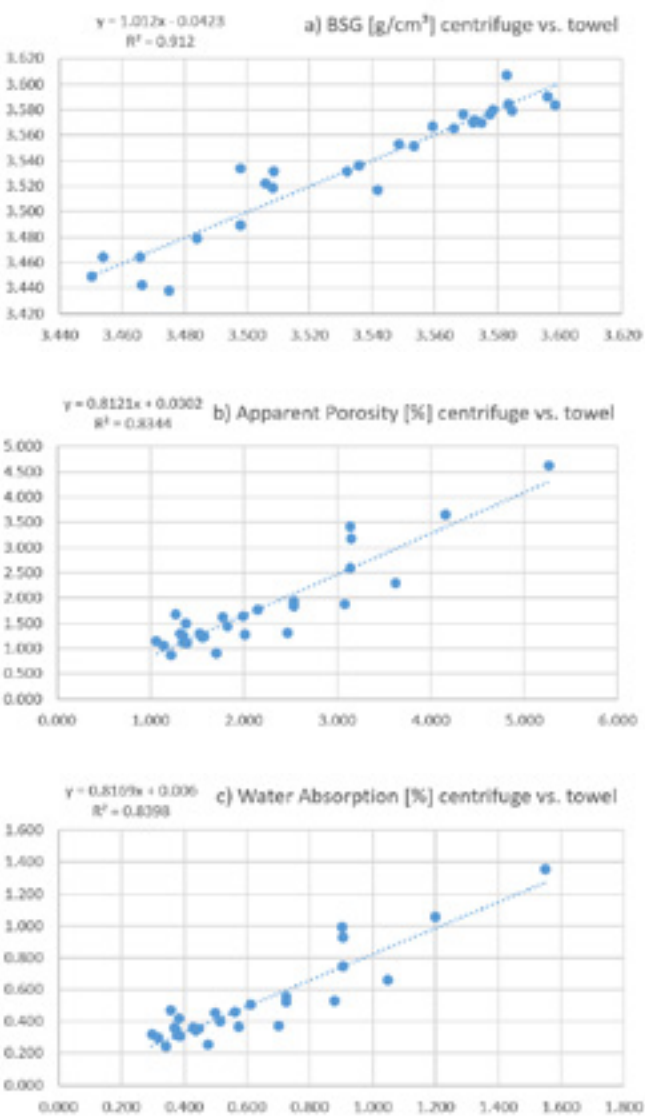
Test series were started in different locations to compare results using the new method (centrifuge for infiltration and surface drying) with the old method (boiling in water and surface drying with wet towel). Fig. 5 shows good correlation of BSG between both methods from a test series of 48 samples and six different analysts at Almatis Rotterdam. There were only slight differences in apparent porosity (AP), and water absorption (WA). Fig. 6 shows box plots from the same comparison at Almatis Benton, AR with 30 samples and 4 different analysts. In addition, correlation for BSG is good here, and differences in AP and WA are small. More test series are ongoing in all Almatis tabular alumina sinter plant locations including a global Gage R&R test for establishing the new method as the future standard within Almatis.


*Fig. 5: Correlation of BSG, AP, and WA - centrifuge vs. towel method at Almatis Rotterdam, The Netherlands.*

*Fig. 6: Box plot of BSG, AP, and WA results Almatis Benton, USA.*

## CONCLUSION AND OUTLOOK

The centrifuge enables automation of the surface drying step in bulk density measurement based on the water method. It can help to reduce human element variation in lab work. This will improve repeatability and reproducibility in bulk density measurement in the laboratory and between different laboratories. The extension of centrifuge usage for the infiltration of the grains replacing the vacuum or boiling method leads to significantly reduced times for the entire measurement. Intensive work is ongoing to qualify this new approach as the future standard within Almatis.

## ABSTRACT

There are many direct and indirect ways to measure thermal conductivity, a property that is becoming increasingly essential for energy-efficient projects. While some indirect methods can speed up measurement times, only real direct methods, such as the one defined by ASTM C201, are adequate to measure the real heat transfer in refractory linings. A new test method has been developed by SSV in collaboration with DTS: said method allows to significantly reduce analysis time and costs compared to ASTM panel ones, while still relying on direct method. Earlier results with the first version of this new method were found to be extremely comparable with results from ASTM C201 standard, within laboratory deviation. Such findings have been topic for scientific publications in 2022. A new version of SSV thermal conductivity has been developed, with capability of reaching higher temperatures. In this article, findings of these results on dense, insulating and castable materials, together with a deeper study on earlier results, will be discussed and compared with results obtained from standard ASTM C201 Thermal conductivity instrument.

## INTRODUCTION

Thermal conductivity is an essential property in refractory materials. Their ability to insulate or to conduct heat is, in many cases, their primary function. Thermal conductivity coefficient ($k$) determines the heat flow for a given temperature gradient, or inversely, determines the temperature gradient when a specific heat flow is given.

If heat can be defined as the energy required to raise the temperature of a standard substance, heat transfer is described as the flow of heat due to temperature differences and its subsequent distribution. The heat transfer occurs in three different modes – conduction, radiation and convection- and generally two or all three of these modes are simultaneously involved in every actual case[1].

For all high temperature heat enclosures, an accurate calculation for the refractory lining is essential to reach a high reliability, thermally efficient refractory lining. Although there are mathematic models that can predict $k$ by correlating it with some physical properties of the refractory, these fit poorly when combining more parameters simultaneously, giving as a consequence less accurate results[2].

Insulating refractories have a pore structure as a major component of its microstructure. The main mechanisms that govern the phenomena are radiation and solid conduction, as well as pore convection if the pores' diameter is considerable. As radiation increases as the fourth power of the absolute temperature, the higher the overall temperature is, the more significant the heat transfer by radiation becomes. This is particularly important over 800°C with highly porous insulation [3]. Additionally, the more heterogeneous the refractory is, the more complex the interaction between true conductivity (by conduction) and apparent conductivity (by radiation) within the internal pores and the grains[4] [5] will be.

**Most diffused test methods for refractories**

Thermal conductivity measurements based on Fourier's law are determined by temperature gradients and heat flow. These methods can be based in steady or dynamic-state measurements, as we will briefly describe and compare in this study.

Suitable for isotropic homogeneous ceramics, the Laser Flash Method [6] is a quick and practical measurement for the characterization of technical ceramics, with good repeatability and accuracy. The method consists of rapidly heating the front side of a sample surface with a short laser pulse and to measure the time evolution of the back surface temperature variation using an infrared detector. The major downside of this technique is that it is not suitable to test most common refractory types, as typical heterogeneities of refractories brings discrepancies in the results: the small dimension of the test specimen (a few cubed millimeters) are not in-line with the refractories internal structure, and highly porous materials such as ultra-lightweight or ceramic-fiber refractories renders the measure impossible due to major laser's scattering [7]. Lastly, the measuring equipment can be very expensive.

Hot-wire method, defined in the ASTM Standard C1113 [8] is considered adequate for most isotropic refractory materials, but is not suitable for anisotropic materials or materials with large pores, since the underlying assumptions behind the method does not take into account heat transfer by radiation[9] [10]. The hot-wire method uses a furnace to heat the sample to a specified temperature; embedded in the sample, an additional heating source (the hot-wire) is used to introduce a local controlled heat, and the temperature rise is recorded by a thermocouple embedded at a defined distance. This technique can be used to determine thermal conductivity in a broad range of temperatures and materials, though with the above stated limitations.

A steady-state method developed for the fiberglass Industry that can be applied to determine thermal conductivity is the ASTM C177's Guarded-Hot-Plate [11]. The apparatus is adequate to measure fiber mats and boards to up to 650°C [9], but is not suitable for thicknesses higher than 2". Besides, it requires certain level of expertise to operate, maintain or repair the apparatus [11] compared to other methodologies.

ASTM C201 water-calorimeter method [12] is based on the hot wall principle, simulating the exposure of insulating bricks to a hot environment and measuring thermal conductivity coefficient (k) using Fourier's equation (1) [13] that establishes that thermal conductivity coefficient (k) is equal to the heat flow (Q) by a given thickness (x) per unit of area (A) and temperature gradient (ΔT).

773

$$k = \frac{Q \cdot x}{A \cdot \Delta T} \quad (1)$$

It is an accurate method to determine thermal conductivity of dense, insulating and castables materials, of ceramic fiber boards and mats[7], but it has the disadvantage of the long duration of the test itself: not only for being a steady-state method, but also because of the practical difficulty to stabilize the water calorimeter. The apparatus consists in a furnace that heats one face of the sample, distributing the heat uniformly with a SiC plate diffusor, and a calorimeter on the opposite side of the test specimen. The temperature on the hot face and the cold face is measured, the thickness of the specimen is registered, and the heat flux is determined by measuring the temperature rise in the water and its flow.

The main disadvantage of the ASTM 201's apparatus is operational: to obtain a trustable value of thermal conductivity is necessary to perfectly balance the main and secondary fluxes of water passing through the calorimeter circuit to assure temperature homogeneity all over the plane. A minor fluctuation leads to changes in the measurement of the heat flux and the analysis loses accuracy. For this reason, a new model was developed eliminating the necessity of a water calorimeter altogether.

**Modification to ASTM C201 Method**

To address ASTM C201 limitations and improve the robustness of the thermal conductivity measurements, a variant of this direct method has been developed both for lower and higher temperatures. Similarly to ASTM C201, this method uses an electric furnace and a SiC plate to uniformly heat-up the hot-face of the test specimen. The temperature gradient is obtained and registered by means of a pair of thermocouples at the hot and the cold faces too.

This method relies on determining the heat flux by placing a black plate and calculating its heat transfer coefficient.

*Figure 1: Schematic design of the apparatus*

The heat transference between a horizontal black plate with its upper face exposed and air in a steady environment can be calculated by determining the amount of heat emitted by radiation and the heat by convection [14]–[16]. A back-up layer of insulating material is set between this plate and the test specimen to reach more convenient temperature gradients, allowing to work with reasonably low heat emissions. The test specimen is positioned on a Silicon Carbide refractory plate that transfers the heat of the furnace in a uniform way all over its contact area. Finally, sets of thermocouples are placed on both horizontal faces of the test specimen (the so called hot-face and cold-face), in the interface between the back-up layer and the black plate, and near the latter to register the air temperature.

All the temperatures are to be recorded once the system reaches its steady state at the desired temperature.

The higher temperature model differs from its counterpart of lower temperatures by employing thicker layers of insulating material around the heating chamber, to ensure the heat flux stays vertical. Verifications of the verticality of the heat flux have been performed by placing 2 thermocouples at a defined distance between 2 layers of refractory and checking the difference in temperature is not greater than 0,5°C.

**MEASURES**

For the purposes of this study and the validation of the developed method, a series of refractory materials with different bulk densities (*BD*) were prepared: two different monolithic refractories with BD from 2150 kg/m³ to 2300 kg/m³ after firing and three insulating firebricks (BD 412 kg/m³ to 825 kg/m³). The same samples had previously been sent to an accredited European laboratory for an inter-laboratory comparison. An additional test for castables was conducted in-house to evaluate the extended repeatability of the developed method: a sample composed by three test specimens of a monolithic refractory with a bulk density of 1100 kg/m³ was cast in the manufacturer's facilities, at Seven Refractories d.o.o. After curing and firing to 815°C, the specimens were tested for thermal conductivity and the variation between triplicates was analyzed.

**RESULTS AND DISCUSSIONS**

Firstly, the results of the set of three specimens with a BD equal to 1100kg/m³ was analyzed (fig. 2) to check for repeatability of the method. The tests have been conducted with the same isothermal conditions, same operator and same accessory instrumentation. The variance between tests was calculated giving as result a mean coefficient of variation of 2,10% with the maximum discrepancy at the lower isotherm of 225°C equal to 2,57%. This value enters within the range of variability given for the ASTM C201 apparatus in the international standard, validating the method.

*Figure 2: In-lab thermal conductivity analyses of a castable monolithic refractory (BD = 1100 kg/m³) with the developed apparatus. Three test specimens of the same sample tested separately to determine the repeatability of the method with this kind of matrix. Reported temperatures are mean of sample.*

Secondly, the method was checked to be comparable to the results obtained from the third-party laboratory using ASTM C201 testing methods. In absence of an experimental calculation of variance for the reference laboratory's data, a coefficient of variation within laboratories of 3.4% reported in the standard method has been used to establish the error bars of the series. For the series of data produced with the apparatuses, a coefficient of variation of 2.4% has been

determined by repeating eight times a measure using an internal standard.

The adherence to the results produced by the 2 apparatuses was thus tested against the ones made according to the material specific ASTM norms based on ASTM C201. Considering the variance reported in the ASTM C201 standard, expressed as coefficients of variations of 9.0% and a precision of 26.6% between laboratories [12], there is an acceptable correlation for all the three different insulating firebricks studied (Figure 3).

*Figure 3: Inter-laboratory thermal conductivity analyses of three insulating firebricks: the developed apparatus (black series) compared to the standard ASTM C201 apparatus of an external laboratory (red series). Reported temperatures are mean of sample.*

For the case of the monolithic castables analyzed between laboratories, bigger discrepancies were generally found regarding the dispersion of the thermal conductivity value as a function of temperature, and the correlation between both methods used. The results obtained for the first of the two test specimens (BD = 2280 kg/m$^3$) are well aligned between both labs and follow a good correlation respect to their tendency line (see fig. 4). Even though the trend is to increase the k proportionally with the increase of temperature, it is expected to start decreasing gradually with the higher temperature ranges as the curve begins to show.

This phenomena is due that for dense refractories heat transportation is attributed to phonon conduction (lattice vibration waves) and since the scattering of this lattice vibrations increases with temperature, the thermal conductivity coefficient lowers [2].

*Figure 4: Inter-laboratory thermal conductivity analyses of a castable monolithic refractory (BD = 2280 kg/m$^3$): the evaluated apparatus (black series) compared to the standard ASTM C201 apparatus of an external laboratory (red series). Reported temperatures are mean of sample.*

An extensive number of tests was finally performed on a range of products with Bulk Densities ranging from 0,71 g/cm$^3$ to 3,02 g/cm$^3$ (fig. 5) at temperatures up to 1200°C. Different behaviors were observed, as different refractory types were tested, but a general increase in conductivity with Bulk Density and a correlation with chemical composition were found as expected.

776

## CONCLUSIONS

The main methods available to measure thermal conductivity of different refractory materials have been compared highlighting their strengths and disadvantages. Based on this, ASTM C201 water-calorimeter method was taken as a reference, analyzing its operative bottlenecks and weaknesses. A variant of the water-calorimeter method has been developed successfully obtaining the heat flux of the system by means of a black plate with known radiation emissivity and thermocouples to determine the temperature gradients. A series of materials with different BDs and chemical compositions were analyzed to compare the obtained thermal conductivity values with reference values from ASTM C201 standard apparatus.

With this new method, thermal conductivity could be measured in a broad range of densities, compositions and thermal conductivities, reaching an accuracy that suits within the repeatability and reproducibility given by the ASTM C201 reference standard [12]. The second apparatus, able to reach temperatures of 1450°C in the hot face, was successfully produced and tested and allowed to measure conductivities at higher mean temperatures.

## ABSTRACT

Since decades the presence of non-metallic inclusions within steel products is of high interest. Because of their detrimental impact on the processing technologies and the properties of fabricated metallic components, their population has to be under complete control. Therefore, suitable characterization methods for non-metallic inclusions are indispensable. One of them, presented in this work, is automated feature analysis, which automatically determines non-metallic inclusions based on grayscale differences. However, to achieve the greatest possible benefit from this method, proper data evaluation and interpretation of the obtained raw data is required. The paper introduces the key principles of evaluating AFA data, emphasizing its capabilities and constraints by utilizing four large datasets obtained from solidified steel blocks, each containing a minimum of 4000 features.

## INTRODUCTION

Current research still aims to improve the steel quality with regard to non-metallic inclusions (NMIs) as they drastically reduce the properties of the final metallic components. Contamination of the steel melt must be avoided, especially in the steel ingot casting process, where the focus is on steel quality rather than production quantity [1]. Therefore, there is in ongoing demand for improving the refractory lining materials used in such applications [2,3]. Recently, a newly developed refractory material based on rice husk ashes functionalized by a flame-sprayed alumina coating was presented potentially used in the steel ingot casting process [4]. However, its influence on the steel quality needs to be evaluated. In the end, it is usually the mechanical properties of the produced metallic components that are of highest interest. However, characterizing such properties is time-consuming and expensive. A simplified approach is therefore the indirect evaluation of the steel quality taking the NMIs into account.

NMIs are commonly analyzed via image analysis on polished samples extracted from the melt or from solidified components [5]. The impact of NMIs on steel properties is closely related to their specific characteristics, including size, chemical composition, hardness, and morphology. Therefore, a comprehensive characterization of the NMI population supported by an appropriate statistical tool is essential.

Automated feature analysis (AFA), a threshold-based method for identifying NMIs in a continuous matrix, is a suitable approach that meets such requirements. The method utilizes an automated scanning electron microscope equipped with energy-dispersive X-ray spectroscopy (EDS) and detects areas of interest, called features, by their contrast to the matrix in BSE micrographs (Fig. 1a). Therefore, the AFA method is applicable to any material system that provides a continuous matrix with a sufficiently high contrast to the features of interest in the BSE contrast. The output of the AFA is a large dataset including positional parameters, elemental composition, size, and shape of each feature. However, in order to draw meaningful conclusions, the following issues must be considered during the analysis.

AFA detected features within a steel matrix inherently contain a certain amount of Fe. For example, pure alumina inclusions detected in a steel matrix appear to contain Fe, see Fig 1c. This issue is based on interactions of the electron beam during EDS analysis with the volume of the surrounding matrix. The Fe content increases with decreasing feature area as the perimeter to volume ratio of the feature increases. Consequently, the fraction of the adjacent matrix volume

of a feature interacting with the electron beam increases. As a result, the alumina inclusions appear with different elemental composition, which not only correspond to reality and must be taken into account when interpreting the data. In addition, AFA unintentionally also detects non-relevant features (artifacts) caused by pores or scratches, resulting in dust accumulation and/or a corroded surface. It is crucial to address such artifacts adequately in order to obtain accurate results. Subsequently, the absolute number of an inclusion total population already gives an indication of the steel cleanliness. However, not all NMIs are equally detrimental to the steel properties, making their species also relevant. Studying different inclusion species in an inclusion total population requires a clustering of the features based on their elemental composition

The paper introduces the fundamental concepts of assessing AFA raw data while emphasizing its potential and limitations. To demonstrate the practical application of AFA, the paper utilizes four extensive datasets acquired from solidified steel blocks resulting from immersion experiments conducted with various refractory materials.

*Figure 1. Detection of non-metallic inclusions (dark areas) in a steel matrix (gray areas) via AFA; search mode (a), feature characterization (b), results (c) [6].*

## EXPERIMENTAL

Automated feature analysis (AFA) was conducted using a scanning electron microscope equipped with energy dispersive X-ray spectroscopy (ASPEX PSEM eXpress, FEI, USA) to analyze four polished steel samples, resulting in four separate datasets. Specifically, two datasets were acquired from immersion tests involving composite materials comprising rice husk ash and a flame-sprayed alumina coating (datasets D1 and D2), while the other two datasets (D3 and D4) originated from immersion tests with different MgO-C refractory materials.

## CONCLUSIONS

Automated feature analysis is a highly effective tool for analyzing inclusions and assessing the cleanliness of metals. This study demonstrated the practical application of automated feature analysis using four extensive datasets, which provided essential principles for data evaluation. The analysis of these datasets focused on identifying characteristic inclusion species and quantifying their presence.

The fundamental approach for data analysis can be summarized as follows:

- Removal of non-relevant features such as scratches, pores, and dirt/dust.
- Composition normalization based on the elements of interest.
- Classification of relevant features using appropriate rulefiles based on their chemistry.

777

To cluster inclusions, scatter plots of the elements of interest can be employed to identify distinct gaps in the data. The process of defining proper conditions is iterative process includes the following steps:

- Defining conditions based on distinct gaps between data points.
- Conducting an inclusion classification.
- Evaluating the proper assignment of features through scatter plotting.

Furthermore, each rulefile must include an "Others" class to account for features that do not meet the criteria of any the defined classes. The proportion of inclusions assigned to the "Others" class relative to the total number of inclusions serves as a measure of the rulefile's suitability for the underlying data, and it should ideally be minimized.

In general, a rulefile can accommodate an unlimited number of classes with varying complexity. Allocating inclusions into more specific classes allows for a more detailed description of the inclusion population in terms of their species. However, for an overview analysis, a simplified rulefile may suffice. The level of detail required in the rulefile depends on the analysis purpose and the variation in the total populations of inclusions being compared. Therefore, the development of the rulefile and the definition of conditions should always be done in conjunction with the responses, including scatter plots of assigned features, the proportion of features assigned to the "Others" class, and the results of the inclusion classification. Consequently, it is crucial to use the same rulefile for inclusion classification when comparing multiple datasets.

The application of automated feature analysis requires a sample with a continuous matrix and a significant contrast between the matrix and the features of interest. Therefore, AFA is not restricted to the analysis of inclusions in solidified metals but can be applied to any other material system that fulfills these requirements.

# IMPROVING THE REFRACTORIES SELECTION REGARDING THEIR THERMAL SHOCK RESISTANCE (TSR) BY USING PRACTICE–ORIENTED INVESTIGATIONS PROMOTING EXPERIMENTAL THERMAL LOADING CLOSE TO THEIR SERVICE CONDITIONS

Erwan Brochen, Tim Waldstädt, Michael Kaminski and Christian Dannert

Forschungsgemeinschaft Feuerfest e. V. at the European Centre for Refractories, Höhr-Grenzhausen, Germany

**ABSTRACT**

In service, refractories undergo thermal shocks, which magnitudes and ranges of temperature depend on the processes in which they are being used. The suitability of refractory products to serve in a given process, and more especially their ability to sustain thermal shocks, is, however, still widely established by using standardised testing methods that hardly represent their actual service conditions. As a result, refractory products may be selected despite not being the best fit for a given application. A refractory product could perform well at medium temperatures, even when faced with thermal shocks of high magnitude, but fail at higher temperatures despite experiencing thermal shocks of smaller magnitude.

A new testing system for thermal shock resistance (TSR) was used to assess the response of different refractory products (high alumina, andalusite and fused silica bricks) to different thermal cycling conditions. Different temperature ranges (moderate or high temperatures), different magnitudes of thermal shocks and different thermal shock modalities (ascending/descending) were investigated. The resulting damaging was assessed using ultrasonic measurements. For the investigated refractory products, the damaging was found to be more severe for thermal cycling applied at high temperature (above 900 °C) than at moderate temperature (below 900°C) despite having the same magnitude ($\Delta T$ of at least 580 K). Additionally, the resistance to thermal shocks was found to be dependent of the applied testing conditions, and even reversed in different temperature ranges.

Practice-oriented investigations, promoting experimental thermal loading close to their service conditions, lead to more relevant claims about the TSR of refractory products and help achieving better predictions of the lifetime of refractory linings.

**INTRODUCTION**

Depending on the processes in which they are being used, refractory products encounter different thermal loading conditions. For instance, in refractory linings of tunnel kilns in the tableware industry temperatures rarely exceed 1350 °C and mild, steady heat flow conditions prevail, whereas in the steel industry, linings in process units must withstand severe temperature changes with temperatures exceeding 1700 °C. Consequently, the response of refractory products to these thermal loading conditions, and the corresponding thermal stresses, vary considerably. A specific material might exhibit satisfactory performance at moderate temperatures when experiencing substantial temperature differences, but the very same material could fail when exposed to higher temperatures, even with smaller temperature differences and comparable heat transfers. Conversely, another material might behave differently, performing better at higher temperatures than at a lower temperature range.

In this regard, assessing the thermal shock resistance of refractory products using the common standardized testing conditions may result in inaccurate conclusions regarding the selection of the most suitable refractory solution for a specific application. Hence, there is a definite requirement for a testing approach that adjusts to the varied thermal shock conditions encountered by refractory products during their service.

**DETERMINATION OF THE THERMAL SHOCK RESISTANCE OF REFRACTORY PRODUCTS**

By the very nature of their function, refractory products, which serve as linings in high-temperature vessels and furnaces, are exposed to more or less severe transient or steady-state thermal gradients. One side of a refractory lining faces high temperatures as it comes into direct contact with the process heat that needs to be contained within the system. The opposite side of the lining remains at much lower temperatures, so that heat losses are minimized and the immediate vicinity of the structure is being protected. However, the presence of such a thermal gradient within a massive solid body is not without consequences, as thermal stresses arise that pose a threat to the material's structural integrity.

While, depending on the application, thermally-induced damage (thermal spalling) may not always be the primary wear mechanism, refractory materials will almost inevitably suffer from the formation of cracks. However, modern well-designed refractory materials and linings exposed to thermal stresses typically do not experience catastrophic failure but instead undergo a gradual wear process, maintaining their structural stability despite significant damage. Even severely cracked refractory linings do not disintegrate into fragments. Yet, the presence of cracks is very likely to increase the susceptibility to other wear mechanisms (corrosion and erosion), and the determination of the resistance to thermal-induced damage is therefore of particular relevance for many refractory applications.

Unfortunately, when it comes to testing the thermal spalling resistance of refractory products, more commonly referred to as their thermal stress/shock resistance (TSR), there is no such thing as a "one-size-fits-all" method [1]. The performance of refractory products exposed to thermal stresses is not an intrinsic material property [2]. Instead, the thermal stress resistance of refractory products is influenced by various factors, most of them varying significantly with the application. In addition to the thermomechanical and thermal properties of the material (thermal expansion coefficient, thermal conductivity, modulus of elasticity, mechanical strength, and specific fracture energy), which are highly dependent on temperature, the geometry of the refractory components (including shape, presence of edges, and dimensions) and the specific thermal conditions (process temperature, heat transfer coefficient, thermal cycling or steady-state) play a significant role.

Typically, a set of narrowly specified testing conditions are applied to test refractory pieces of well-defined geometry to evaluate the TSR of refractory products. The most common standardised test methods are DIN 51068, EN 993-11 and ASTM-C-1171. All these standardised procedures describe quenching cycles between either 950 °C (DIN and EN) or 1200 °C (ASTM) and room temperature with water (DIN) or compressed air (EN and ASTM). Such test conditions are relatively straightforward to perform in the laboratory and efficient in inducing thermal stresses and damage to refractory materials, but they are not particularly consistent with actual service conditions of refractory products and can therefore lead to misleading conclusions. As a result, testing procedures that are more focused on the refractory's service conditions have been developed over the last decades. In particular, the melt immersion test, in which test pieces are at least partially immersed in a melt (e.g. pig iron, steel, aluminium), is particularly proficient to simulating the service conditions encountered in steel and metal manufacturing processes [3]. Open flame burners are sometimes used to reproduce the heating process in tunnel kilns, rotary kilns or glass melting furnaces as well as to mimic the pre-heating process of metallurgical vessels for the steel production, or simply as heat source to provide more efficient heat transfer into a test piece as compared to a cold test piece that is simply placed into a hot laboratory furnace [4-5]. More exotic testing procedures are occasionally reported, such as the use of a laboratory furnace with two chambers at different temperatures to perform hot temperature cycling [6-7], or the direct irradiation of test pieces by focusing artificial light or by an intensively radiating susceptor that is induc-

779

tively heated to incandescence, [8]. However, these procedures are time consuming and labour intensive. In order to advance the testing procedures, Forschungsgemeinschaft Feuerfest e. V. has developed a new, fully automated thermal shock testing system.

## PRACTICE-ORIENTED THERMAL SHOCK TESTING SYSTEM

### Description of the new thermal shock testing device

A crucial aspect of the new system is to enable thermal cycling at different ranges of temperatures for both ascending and descending thermal shocks. To achieve this, the testing system uses three chambers, through which a test piece (50 x 50 mm cylinder) is conveyed (Fig. 1). The middle chamber serves as a standby furnace with the ability to heat or cool the test piece to a predetermined temperature (Fig. 1 (b)). Ascending thermal shocks are achieved in the upper chamber by transporting the test piece into a carbon ring which is inductively heated to incandescence (chamber 2). The intensive radiation emitted by the carbon ring (susceptor) is particularly efficient to raise the surface temperature of the test piece inside the carbon ring quickly up to 1800 °C (Fig. 1 (a)). Descending thermal shock takes place in the lower chamber by gas quenching (Fig. 1 (c)). A lifting device carrying a tube made of alumina assures the transport of the test piece through the three chambers

that are stacked on top of each other. The system is continuously flushed with inert gas to protect the carbon ring in the chamber 2.

### Assessment of the thermally induced damage

During the thermal cycling, stresses of sufficient magnitude to damage the test piece are generated. The impact of the thermal shocks is assessed quantitatively by measuring the decrease of the ultrasonic velocity inside the test piece, which reflects the deterioration of the mechanical properties of the test piece after having undergone a specified number of thermal cycling. Finally, for a better insight, the thermal damage is quantified using the dimensionless damage parameter according to Kachanov [9]:

$$D = 1 - \left( \frac{v}{v_0} \right)^2 \qquad (1)$$

where v is the ultrasonic velocity as it propagates through the test piece after thermal cycling and $v_0$ is the initial ultrasonic velocity as it propagates through the undamaged test piece before thermal cycling. D = 0 means therefore no damage, while the value of D increases with increasing damage.

Fig. 1: Schematic representation of the new thermal shock testing system and the testing procedure. Preheating and tempering in the chamber 1 *(b, middle)*, ascending thermal shock through driving the test piece into an inductively heated carbon ring in the chamber 2 *(a, left)* or descending thermal shock by gas quenching in the chamber 3 *(c, right)*.

## TESTING STRATEGY

### Materials under investigation

Three refractory materials were investigated:

*High-Alumina bricks* with a content of $Al_2O_3$ above 99 % and ceramic bonded. Especially resistant to atmospheres containing CO and hydrogen up to very high temperature, they are typically used in the petrochemical and chemical industry (e.g. soot reactor).

*Fused Silica bricks* with a content of amorphous $SiO_2$ above 99 %. Because of their great resistance to acid environments, they are used in the chemical industry, as well as in the glass industry and as a hot repair material (for glass melters and coke oven plants).

*Andalusite bricks* with an $Al_2O_3$ content of 60 % and ceramic bonded. A versatile product presenting good resistance to creep, slag corrosion as well as to thermal shocks, and accordingly is a fitting solution for many applications in furnace engineering, iron and steel industry, waste incineration and glass melting furnace.

### Thermal shock procedure

Either 5 or 10 ascending or descending thermal shock cycles were applied to test pieces as described above. A dwell time of 30

minutes in the middle chamber (chamber 2) was implemented to ensure the temperature homogeneity of the test pieces. Since thermal stresses tend to quickly reach a maximum during thermal shocking, which roughly corresponds to the maximal temperature difference in the test piece i.e. before its core starts to heat up and the thermal gradient inside of the test pieces gradually flattens out, there is no need to reach temperature homogeneity after applying the thermal shocks. Accordingly, a shorter dwell time (15 minutes) was used in the upper and lower chambers (chambers 1 and 3).

To quantify the resulting damage, the ultrasonic velocity inside the test pieces was measured at room temperature by pulse technique of ultrasonic (C.S.I. Concrete Tester, Type RBT 2-A) before and after the thermal cycling.

## RESULTS AND DISCUSSION

On the whole and as expected, the damage increases with increasing temperature difference applied to the surface of the test pieces, i.e. increasing thermomechanical load. While small temperature differences (e.g. 380 K) cause little or no damage, large temperature differences (e.g. 880 K) almost systematically cause significant damage.

Tab. 1: Results from the TSR investigations with the new testing system on the test pieces made from high-alumina bricks.

| Test | Temperature / °C | | | ΔT / K | Number of thermal shock cycles | D / - |
|------|------------------|--------|-------|--------|--------------------------------|-------|
| | Lower chamber | Middle chamber | Upper chamber | | | |
| **1** | RT (~20 °C) | 900 | - | 880 | 10 | 0,24 |
| **2** | RT | 800 | - | 780 | 10 | 0,21 |
| **3** | RT | 600 | - | 580 | 10 | 0,04 |
| **4** | RT | 400 | - | 380 | 10 | 0,00 |
| **I** | | RT | 900 | 880 | 5 | 0,00 |
| **II** | | RT | 800 | 780 | 5 | 0,00 |
| **III** | | RT | 600 | 580 | 5 | 0,00 |
| **A** | - | 900 | 1280 | 380 | 5 | 0,09 |
| **B** | - | 900 | 1480 | 580 | 5 | 0,27 |

| **C'** | - | 900 | 1680 | 780 | 10 | 0,44 |

*Duplicate to check the repeatability*

Fig. 2: Evolution of the damage for test pieces made from high-alumina bricks in function of the temperature difference applied to the surfaces of the test pieces for different testing conditions (low temperature range = below 900 °C, high temperature range = above 900 °C).

In the case of high-alumina bricks (Tab. 1 and Fig. 2), in the low temperature range (< 900 °C), gas quenching (descending thermal shocks) is more efficient to induce damage in the test pieces than intense heating with radiation (ascending thermal shocks). Quite surprisingly, no damage could even be detected as a result of ascending thermal shocks with intense radiation below 900 °C. Descending thermal shocks (quenching) on homogeneously heated test pieces promote more intense tensile stresses, to which refractory materials are notoriously more susceptible, while ascending thermal shocks promote initially more intense compressive stresses. Additionally, the applied gas quenching may lead to a more effective heat transfer than applying intense radiation.
However, in contrast, even a small applied temperature difference (380 K) resulted in significant damage during thermal cycling above 900 °C by means of intensive radiation. As expected, the extent of the damage increased with increasing applied temperature difference at the surface of the test pieces and with increasing the number of thermal cycles. Finally, significantly higher levels of damages due to thermal cycling were observed in the high temperature range than in the low temperature range, indicating a higher thermal shock sensitivity of the high-alumina bricks at high temperatures.

Tab. 2: Results from the TSR investigations with the new testing system on the test pieces made from andalusite bricks.

| Test | Temperature / °C | | | ΔT / K | D / - |

Fig. 3: Evolution of the damage for test pieces made from high-alumina bricks, fused silica bricks and andalusite bricks in function of the applied temperature difference to the surface of the test pieces for different testing conditions (low temperature range = below 900 °C, high temperature range = above 900 °C).

When comparing the three refractory materials, significant damage occurs as a result of gas quenching (i.e. low temperature range) for temperature differences applied to the test piece surface (ΔT) of 780 K and 880 K in the test pieces made from high-alumina bricks and andalusite bricks respectively. Test pieces made from fused silica bricks remained virtually undamaged by every gas quenching performed. Fused silica bricks are indeed well-known for their excellent thermal shock resistance up to approx. 1000 °C.
For ascending thermal shocks in the high temperature range (intense radiation heating), the previous classification is reversed, i.e. test pieces from fused silica bricks were already severely damaged

for a ΔT of 580 K (inhomogeneous transformation of quartz glass to cristobalite), andalusite bricks displayed slightly less damage and high-alumina suffered the least damage under these test conditions. Besides, these test conditions result in higher damage for all investigated materials compared to gas quenching in the low temperature range. This illustrates the great importance of TSR investigations that reflect the service conditions as much as possible to ensure a fair and application-oriented classification of the performance of refractory materials.

Visual inspection of the cut test pieces makes the extent of the damage even clearer. However, macrocracks could only be unequivocally detected in specimens whose dimensionless damage parameter D exceeded approximately 0,3 (Fig. 4). Furthermore, in materials such as andalusite bricks, which displays a network of cracks from the beginning (i.e. as a part of their microstructure), the increase and growth of the cracks is very difficult to assess visually. While helpful to gain an initial impression of the state of the test piece after thermomechanical loading, optical assessment does not allow an objective and quantitative assessment of the damage. However, the combination of optical inspection with ultrasonic measurements and calculation of the dimensionless damage parameter is particularly suitable for quantifying specific features and patterns resulting from thermomechanical loading.

## CONCLUSIONS

In service and depending of their application, refractory products are subjected to thermal stresses and shocks of different magnitudes, and in different ranges of temperatures. Their suitability to sustain thermal stresses for a specific application is usually assessed using standardized testing conditions regardless of their actual service conditions, thus increasing the likelihood of coming to erroneous conclusions, or at least, to a suboptimal solution. On the contrary, thermal shock experiments tailored to the service conditions applied to refractory products are needed to obtain relevant information about the performance of refractories in their intended applications.

Thanks to a three chambers testing system, descending (gas quenching) as well as ascending (fast irradiation heating) thermal shocks of different intensity can be applied automatically and repeatedly to refractory test pieces previously heated to a defined temperature. Hence the temperature changes triggered at the surface of a test piece are controlled and a tailored automatic investigation of refractory product's resistance to thermal shocks in the application relevant temperature range is being achieved.

For the investigated products (high alumina, andalusite and fused silica bricks), the damaging was found to be more severe for thermal cycling applied at high temperature (above 900 °C) than at moderate temperature (below 900 °C) despite having the same magnitude (ΔT of at least 580 K). Additionally, while test pieces made of fused silica bricks outperformed the two other materials during descending thermal shocks in the lower temperature range, the classification obtained was completely reversed for ascending thermal shocks at high temperature.

As a result, the suitability of a given refractory product and/or the selection of refractory products for a given application can be assessed with enhanced reliability and a better prediction of the lifetime of refractory linings is expected.

## ABSTRACT

Among the many properties of ceramic foams used in metal melt filtration, thermal shock resistance is one of the most critical features. In contrast to dense refractory materials, there is no thermal shock resistance testing standard available for ceramic foam filters at the moment. This work aims to investigate the influence of the different test parameters such as temperature and quench medium when testing ceramic foam samples. Reference alumina ($Al_2O_3$) foams and commercially- available ceramic foam filters ($ZrO_2$, $Al_2O_3$-$ZrO_2$, $Al_2O_3$-P, and SiC) were subjected to thermal shock tests with water and air as quenching medium. The thermal shock performance was evaluated by estimating the mechanical strength and elastic modulus before and after the thermal shock. The experimental results were compared with the calculated values using the Gibson and Ashby equation.

## INTRODUCTION

Thermal shock resistance is an important feature of ceramic foams used in metal melt filtration [1]. Although there are existing standards for testing the thermal shock resistance of refractories, i.e. DIN 51068:2008-11 (Determination of resistance to thermal shock - Water quenching method for refractory bricks) [2] and DIN EN 993-11: 2008-3 (Methods of test for dense shaped refractory products - Part 11 Determination of resistance to thermal shock) [3], there are none specific to ceramic foams for melt filtration applications. The typical porosity of ceramic foams ranges from 70- 90% [4] places it out of the standard´s scope [2]. In the first part of the study, the thermal shock tests were conducted on reference $Al_2O_3$ foam and bulk samples wherein the influences of the thermal shock parameters were investigated.

Aside from experimental thermal shock tests, the thermal shock behavior can also be estimated through the material properties by the calculation of the thermal shock resistance. Gibson and Ashby developed Equation (1) for the thermal shock resistance of ceramic foams [5].

$$R_{foam} = \Delta T = \frac{\sigma_{fs} \cdot (1 - \nu)}{E_S \cdot \alpha_S \cdot \rho_{rel}^{0.5}} \quad (1)$$

Where $R_{foam}$ is the thermal shock resistance of the foams, $\sigma_{fs}$ is the bending strength of the strut, $E_S$ is the elastic modulus of the strut, $\rho_{rel}$ is the relative density given by the ratio of the foam´s geometric density to its strut density, $\alpha_S$ is the thermal expansion coefficient of the struts, and $\nu$ is the Poisson ratio.

The second part of the study compares the calculated thermal shock resistance of the commercially available filters ($ZrO_2$, $Al_2O_3$-$ZrO_2$, $Al_2O_3$-P, and SiC) to the experimental data.

## MATERIALS AND METHODS

The samples used in the study is comprised of $Al_2O_3$, $ZrO_2$, $Al_2O_3$-$ZrO_2$, $Al_2O_3$-P, SiC foam and bulk samples. The $Al_2O_3$ samples served as reference for preliminary testing. $Al_2O_3$ foams (150 x 50 x 22 $mm^3$ and 50 x 50 x 22 $mm^3$) were prepared by means of the Schwartzwalder process [6] whereby polyurethane foams were coated two times with an $Al_2O_3$ slurry through a dip-spin coating procedure and sintered at 1600 °C [7]. The commercially-available foam filters (75 x 75 x 22 $mm^3$) were supplied by the industrial manufacturers.

Additionally, bulk samples (70 x 7 x 7 $mm^3$) were uniaxially pressed from the dried slurries which are used to produce the ceramic foams. The pressed $Al_2O_3$ samples were then sintered at 1600 °C while the pressed industrial filter materials followed a sintering procedure similar to that used for the industrial foams.

The bulk and foam samples were characterized with regard to their bulk density, foam relative density $\rho_{rel}$, and thermal expansion coefficient α. Whereas Equation (1) was used to determine the theoretical thermal shock resistance, the experimental values are taken from the results of the thermal shock tests and are characterized by residual mechanical properties.

For an evaluation of the thermal shock resistance, the elastic modulus, crushing strength, and bending strength were measured before and after the thermal shock. The residual values were calculated from the values measured at the as received ($P_{pre\ thermal\ shock}$) and thermal shocked samples ($P_{post\ thermal\ shock}$) with Equation (2) [3].

$$P_{residual} = \frac{P_{post\ thermal\ shock}}{P_{pre\ thermal\ shock}} \cdot 100\% \quad (2)$$

## RESULTS AND DISCUSSIONS

### Influence of the thermal shock parameter

Figure 1 illustrates the impact of the thermal shock test parameters on the residual elastic modulus and residual strengths of the different reference $Al_2O_3$ samples. The difference between the measured elastic modulus and strength of the pre-heated samples (preheated 950 °C air) and directly heated samples (950 °C air) is within the standard deviation so the difference is marginal. The only exception is the elastic modulus measured for the 50 x 50 x 22 $mm^3$ foams. The reason for this exception is not known at the moment.

The quench medium clearly has a more pronounced impact, with water-quenched samples showing a lower residual elastic modulus and strength compared to air. This indicates that the thermal shock in water was more severe, explainable by the better heat transfer of water compared to compressed air.

The difference in the elastic modulus and strength between the samples shocked from 950 °C and those shocked from 1200 °C to room temperature is less pronounced as it is within the standard deviation.

*Figure 1. Residual elastic modulus and strength of $Al_2O_3$ samples after thermal shock*

As the quench medium proved to be the parameter with the highest impact, the next part of the study utilizing industrial samples only had the quench medium as a variable.

### Thermal shock of industrial filter materials

For the industrial filter materials, the water quenching procedure resulted in lower values of elastic modulus (Figure 2) and strength (Figure 3) compared to the air quenching procedure indicating a more pronounced thermal shock when using water. Thermal shock through air-quenching only had a small impact as shown in the residual elastic moduli (Figure 2) of > 76 % for foams and > 93 % for bulk materials and residual strength (Figure 3) of > 80 % for

foams and >83 % for bulk samples. The reason for the small impact is the small size of the samples – the foam samples possess struts with a diameter of < 1 mm and the bulk samples of 70 x 7 x 7 mm³ causing a fast cooling of the whole volume and consequently only marginal stresses due to low temperature gradients.

*Figure 2. Residual elastic modulus of industrial foam and bulk samples*

*Figure 3. Residual strength of industrial foam and bulk samples*

In the next step, the ranking of the materials was assigned. As quenching with water is the most severe thermal shock, the results of this procedure were chosen.

An important question is if the chosen material should have a high strength after quenching or a high residual strength after quenching. The former means that with a high initial strength despite a major change, the strength after thermal shock is still sufficient, ensuring no failure of the sample. The latter represents a low level of damage. The rankings regarding crushing and residual strength can be found in Table 1. $ZrO_2$ ranks high in both cases, which is consistent with the fact that $ZrO_2$ filters are typically used for steel filtration with operating temperatures of up to 1650 °C. SiC also shows a high residual strength. Surprisingly, the crushing strength of SiC after quenching is the lowest even with its typical use in aluminum, copper and iron melt.

*Table 1. Ranking of measured and calculated thermal shock resistance of foams using different criteria.*

| Sample | Ranking of residual strength | Ranking of crushing strength | Thermal expansion coefficient of the struts $\alpha_S$ ($10^{-6}$ K$^{-1}$) | Thermal shock resistance $R_{foam}$ (K) |
|---|---|---|---|---|
| Al$_2$O$_3$ | 5 | 5 | 10.1 | 50 |
| ZrO$_2$ | 2 | 1 | 4.4 | 226 |
| Al$_2$O$_3$-ZrO$_2$- | 4 | 2 | 7.0 | 107 |
| Al$_2$O$_3$-P | 3 | 3 | 7.6 | 131 |
| SiC | 1 | 4 | 4.7 | 217 |

With Equation (1) [5] the thermal shock resistance (Table 1) was estimated. Due to the low thermal expansion coefficients, SiC (4.7 $10^{-6}$ K$^{-1}$) and $ZrO_2$ (4.8 $10^{-6}$ K$^{-1}$) possess the highest calculated thermal shock resistance $R_{foam}$. In contrast, the reference Al$_2$O$_3$ sample has a low-thermal shock resistance, $R_{foam}$ of 50 K due to a thermal expansion coefficient of 10.1 $10^{-6}$ K$^{-1}$. The thermal expansion coefficient is the decisive factor in Equation (1). Comparing the results of the calculated $R_{foam}$ and the residual crushing strength results in a coefficient of determination of $R^2$=0.84 which is not a very good correlation, but it shows a certain linking. Thermal expansion causes mechanical stresses during heating and cooling when temperature differences are present in the sample. As shown before, this is not necessarily the case for ceramic foams as the struts are very thin and the temperature increase and decrease proceed very fast.

## CONCLUSIONS

Among the hot thermal shock test parameters, heating mode, thermal shock temperature, and quench medium, the latter has the highest impact on the residual mechanical properties (thermal shock resistance). Due to the low thermal expansion coefficients of SiC (4.7 $10^{-6}$ K$^{-1}$) and $ZrO_2$ (4.8 $10^{-6}$ K$^{-1}$), the two materials possess the highest thermal shock resistance $R_{foam}$. The SiC and $ZrO_2$ foams also have the highest residual strength after quenching in water. $ZrO_2$ and SiC ranked the highest which is consistent with the fact they are typically used in high-temperature metal melt filtration.

# DEVELOPMENT OF A NOVEL THERMAL SHOCK PROTOCOL OF EXPERIMENT OF CARBON–BASED REFRACTORY MATERIALS

Kaoutar Anrhour[1]; Séverine Romero Baivier[2]; Andrea Piccolroaz[3]

[1]VESUVIUS/Trento university, Mons, Belgium; [2]Vesuvius group plc, Department of Advanced Refractories, Ghlin, Belgium; [3]University of Trento, Department of Civil, Environmental and Mechanical Engineering, Trento, Italy

Ladle shrouds, tundish nozzles, slide gates, and other flow control refractory materials play an important role in ensuring good production and quality of products in the continuous casting of steel; however, their chemical, mechanical, and thermal degradation and wear mechanism can lead in some cases to disastrous social, environmental, and financial effects in the steel-making plants. Therefore, it is both important and challenging to understand and characterize their behavior at a laboratory scale. This study aims to show the primary steps of investigating the thermal shock resistance of flow control products and mainly carbon-based ladle shroud mixes. The adopted approach for the novel testing protocol is to use induction as a heating source to produce an ascending thermal shock and assess the resultant damage. The preliminary results confirm the experimental protocol feasibility and ability to measure strain evolution and crack initiation as a function of time and temperature; furthermore, the microstructure of the tested specimens will be inspected to allow a better and complementary understanding of their behavior under thermal shock test.

## ABSTRACT

Our group is developing a new test system called "Ultra-high speed heating test system". This apparatus is a hot observation system with the greatest feature of ultra-high-speed, ultra-high-temperature heating. Currently, we are examining various applications of this system as the multi-purpose evaluation system. As part of this work, we will report about the investigation of the wettability of refractories/metal/slag systems with this system.

Blast furnace slag formed the spherical liquid phase at 1450 °C on Fe powder. At 1550°C, Fe started to melt and the temperature decreased for the endotherm reaction. Molten Fe moved on slag until the end of the test. On the other hand, the spherical liquid phase slag wetted with the SiC brick and spread.

As a result of observed the three phase interface of brick/Fe/slag, it was found that iron reacted with SiC grains to decompose the brick, and Slag reacted with the liquid phase in the brick to penetrate the brick. From the above results, the developed new test system may be able to visualize Marangoni convection.

## INTRODUCTION

Fig.1 show the photograph of newly developed testing system called "Ultra-high speed heating test system". This system was primarily to focus on the observations at high temperature and to be operational at ultra–high temperatures and ultra–high speeds of heating[1-3]. For this purpose, the system employed a distinctive heating method in which the specimens are placed on the carbon heater directly. In addition, this test system was equipped with four observation windows so that temperature measurement and state changes of sample could be observed from various angles. In this study, the wettability of SiC bricks/Fe/blast furnace slag system was observed with this test system.

## EXPERIMENTS

Fig.2 show the schematic diagram of test method. □15×t2mm of SiC bricks (table 1) set on bottom carbon heater. Reagent-grade electrolytic iron powder (purity of >99.99%) set on the brick, and blast furnace slag powder (table 1) set on the iron. The volume ratio

*Fig.1 the photograph of newly developed testing system.*

*Fig.2 Schematic diagram of test method.*

*Tab. 1 : Chemical compositions of SiC bricks and Blust furnace slag.*

|  | SiC brick | Blast furnace slag |
|---|---|---|
| SiC | 80.3 |  |
| $SiO_2$ | 16.5 | 34.7 |
| $Al_2O_3$ | 2.49 | 14.2 |

| S |  | 1.09 |
| Other |  | 0.83 |

Mass%
of iron and blast furnace slag were 1:9-9:1. The samples were heated to 1600°C at a rate of 500°C/min for 30s in Ar using top and bottom carbon heaters. The Temperatures were measured at the 3point of Fe powder area (temperature 1), bottom heater (temperature 2) and top heater (temperature 3) during test. In addition, the state change of samples were photographed from the side throughout with a digital camera.

After heating, the center of the test samples were cut and embedded in epoxy resin. After mirror polishing, the cross sections were observed by SEM-EDS.

## RESULTS AND DISCUSSION

Fig.3 show the photographs of the SiC brick/30vol%-Fe/70vol%-blast furnace slag system at various test temperature. The slag deformed by the formation of liquid phase from 1250°C formed spherical at 1450°C on the Fe powder. Spherical slag on Fe powder indicates poor wetting of both. At 1550°C, Fe started to melt and

the temperature decreased for the endotherm reaction. Molten Fe moved on slag until the end of the test. On the other hand, the spherical liquid phase slag wetted with the SiC brick and spread. This behavior suggests that the wettability between slag and brick is better than that between Fe and brick. And, Although the true density of slag is lower than that of Fe, Fe floats on the slag. We reaffirmed that the repulsive force (interaction force) due to the poor wetting is greater energy than imagined energy.

Fig.4 show the microstructure of tested sample. At the three phase interface, the disintegration of the brick structure and the decomposition of SiC grains were observed. In the EDS analysis(Fig.5), Al, Si and Ca were detected in the disintegrated part, and Fe and Si were detected in the decomposed part. From these results, it is seemed that the disintegration of the brick structure was caused by slag penetration through the sintering additive (liquid phase), and that the decomposition of SiC grains was caused by Fe erosion. This phenomenon is similar to the Marangoni convection, and it is thought that the visualization of the Marangoni convection is possible with this test system.

*Fig.3 Photographs of the sample at various test temperature.*

*Fig.4 microstructure of tested sample.*

*Fig.5 Element mapping images of tested sample.*

## CONCLUSIONS

Our group is developing a new test system called "Ultra-high speed heating test system". From the investigation of the wettability of refractories/metal/slag systems with this system, the developed new test system may be able to visualize Marangoni convection.

# HOT THERMAL SHOCK TESTING USING TOM_WAVE

Kirsten Schulze, Jens Baber, Holger Friedrich

Fraunhofer-Centre for High Temperature Materials and Design HTL, Bayreuth, Germany

## ABSTRACT

The capability of refractories to withstand thermal shock is usually tested by a series of rapid cool downs from high temperature (ASTM-C-1171). In these so-called cold thermal shock tests, however, the local cooling conditions are so imprecisely defined that no material properties usable for a simulation can be derived or model predictions verified. More controlled temperature changes can be introduced via hot thermal shock: e.g. by means of metal melts applied to the test specimens [1] or by means of burners [2]. After thermal shock, the damage is evaluated by fracture mechanics tests or non-destructively. Precisely quantifiable heating of samples is possible via induction, IR/halogen lamps and especially lasers [3, 4, 5]. In addition, the later conditions during usage are often better represented by a hot thermal shock. For example, in melting metallurgy hot metal is poured into the refractory which could be already at an elevated temperature.

Knowledge about the behaviour of refractories under operating conditions is important to choose the material that will have the longest life time in the production line. A well-chosen material can both reduce the cost for material replacement and machine down time and reduce the $CO_2$ footprint of the production line.

The thermo-optical measuring system TOM_wave developed as part of the EnerTHERM project has the option of using lasers to generate a hot thermal shock at a controlled furnace temperature [6]. Int this paper we present results for laser induced hot thermal shock measurements at high temperature for two commercial refractory materials.

## EXPERIMENTAL PROCEEDURE

For a laser induced thermal shock at high temperature, the sample is heated in a furnace to the chosen target temperature. In-situ laser radiation on the sample induces an additional hot thermal shock on the sample. Different parameter can be used to customize the experimental conditions to specific needs: Furnace temperature, laser diameter, laser pulse and relaxation time and the laser power.

### TOM_wave

The TOM_wave is a thermo-optical measuring device equipped with a $CO_2$ laser. The furnace can reach a base temperature up to 1750 °C in a controlled atmosphere (Air, $N_2$, Argon).

*Fig. 1: View into the muffle of TOM_wave. Visible in the centre is a sample that is heated to glow by laser radiation. This picture is taken at room temperature.*

Up to five samples can be placed in a special rotatable holder. This allows the user to make comparative measurements in terms of material or thermal shock. The temperature profile of the furnace during heating, experiment and cool down is identical for all samples. The samples used are disk-shaped, and the laser is directed on the bases (figure 1). Sample dimensions can vary with a maximum of 15 mm in height and 40 mm in diameter. These sample volumes are big enough for representative measurements on heterogenous materials. The Laser diameter can be varied between 3 and 16 mm. From the laser power and the laser pulse time (milliseconds to several minutes), the energy applied to the sample can be calculated and can be varied with these two parameters. Thermal shocks can be applied either from both sides or on either of the bases. The sample position is optically observed, and the formations of cracks or the destruction of the sample can be detected. The change in temperature on the sample is measured with two pyrometers on the base and the circumference of the sample.

## ACCOMPANYING ANALYTICS

Besides the standard parameters such as mass, dimensions und density, several other experiments and analysis methods are used in our lab before and after the thermal treatment for evaluation. The following techniques are ex-situ measurement at room temperature. The list can be extended to all techniques that are applicable on disk-shaped samples.

### Computed tomography

Computed tomography (CT) as a non-destructive 3D imaging method is used for the detection of structural defects induced by thermal shock. Crack propagation can be followed throughout the entire volume.

### Impulse excitation techniques

Impulse excitation techniques is used to analyse changes of the vibration modes of the sample due to thermal shock treatment. For disk-shaped samples, this method can also be used to measure the E- and G-Modulus.

### Mechanical tests

Destructive mechanical tests are performed in reference to samples that have not been thermally treated. Examples for such tests on disc-shaped samples are ball on ring or ball on three balls.

## RESULTS

Three laser induced thermal shock experiments conducted in TOM_wave on refractory materials will be presented in the following. The materials used are one Bauxite-type refractory and one based on synthetic magnesia spinel, they will be referred to as B80 and SP78 in the following. All samples had a diameter of 33 ± 0.2 mm and a thickness of 5 ± 0.2 mm.

### Comparative hot thermal shock measurements on B80 and SP78 at room temperature

Two refractory materials were thermally treated with the same laser conditions. On both bases of the sample, 80 W of laser power were radiated on a laser spot of 10 mm in diameter simultaneously. Five thermal shocks with a duration of 0,5 s were applied. Between the shocks, the laser was blocked for 1 s. The furnace was at room temperature.

The temperature was monitored on one base with a pyrometer, and the data is presented in figure 2. For the first two laser pulses (black), the change in temperature for B80 (blue) and SP78 (red) show a similar progression. From the third pulse on, the temperature of SP78 increases more compared to B80. This is related to crack formation in the sample during the third thermal shock. During the experiment, the crack formation could be observed both optically and acoustically. The lower thermal shock resistance of SP78 compared to B80 is in accordance with the manufacturer's specifications.

*Fig 2: The change in temperature on B80 and SP78 refractory material during five rounds of laser induced thermal shock.*

## CT analysis of thermal shock damage of SP78 at room temperature

For CT analysis another sample of SP78 was treated with a single thermal shock of 17 s and 80 W on both of the bases of the sample. The laser spot was 10 mm in diameter, and the furnace was at room temperature. During the experiment, crack formation in the sample could be observed both acoustically and optically. After recovery, the sample showed signs of melting on the point where it was hit by the laser. A crack from one of the melting spots to the rim of the sample is also visible. CT images of the sample were made before and after the thermal treatment, figure 3.

*Fig 3: Three slices of CT images of SP78 before and after thermal shock treatment. At the top, the direct comparison of the base of the sample before (left) and after (right) the thermal treatment is shown. The area of plastplatication from the laser spot highlighted in red is also visible in the cross section shown below.*

The direct comparison of the images shows the areas of melting (marked in red) and in the cross section their depth profile. The crack is also well visible and propagates downwards from the melted area to the rim in the top right image. In the 3D visualisation of the CT images, the crack can be followed through the entire sample. Its path goes, as expected, trough the matrix and bypassing the larger grains of the refractory.

## Hot thermal shock of B80 at 1500 °C

A hot thermal shock experiment at 1500 °C furnace temperature in air was performed on a sample of B80. Three laser pulses of 17s duration were applied on both sides with a power of 80 W and a laser diameter of 10 mm. Between the pulses, a 120 s laser dead time was set to let the sample cool down to the furnace temperature. During and after the experiment, no signs of cracks could be detected.

The temperature at the location of the laser spots has reached well beyond 1700 °C, as the sample shows extensive melting features (figure 4) on both sides. The pattern of the melted area suggests that during the laser heating this part of the sample was molten and quenched to a solid phase after the thermal treatment.

*Fig 4: A B80 sample after three rounds of thermal shocks at 1500 °C furnace temperature. At the laser spot, the sample is molten during laser impact and quenched to an amorphous phase after the thermal shock.*

## CONCLUSIONS

TOM_wave was used to treat samples with well-defined and reproducible laser induced hot thermal shocks at 1500 °C furnace temperature. The relatively large sample size of almost 20 mm$^3$ is representative also for heterogeneous materials. The application can range from thermal cycling with low laser power and large diameters of the heated area to concentrated thermal shocks with small laser spots and high energy input. The laser parameters can be selected in such a way that they simulate the conditions of the application. The well-defined heating condition enables the usage of data for simulations and model prediction verification. With the rotatable sample holder, comparative measurements of up to five samples are possible.

Well defined heat treatments in combination with further characterization of the sample can be used to choose the optimal refractory for a specific application and help to understand the cause of material failure and how to prevent it.

## ABSTRACT

This study focused on the development of an an environmentally friendly binder system based on lignin and collagen for uniaxially-pressed MgO-C refractories. The aim was to explore sustainable alternatives to resin and pitch binders commonly used in refractory materials. Additionally, were partially utilized as raw materials MgO-C recyclates obtained from steelmaking plants. The physical and mechanical properties of the developed refractory materials were compared with those of reference batches containing only fresh (no recyclates) magnesia. The results showed that the binder system is characterized by reliable binding properties of the MgO-C, although the recycled MgO-C exhibited higher porosity, slightly lower density, and lower strength compared to the reference batches without recyclates. However, the application of antioxidants significantly improved the properties of the recyclate containing MgO-C samples. Scanning electron microscopy (SEM) analysis coupled with energy-dispersive X-ray spectroscopy revealed the formation of whiskers, as well as oxidation and nitridation of aluminum particles. This research highlights the potential of environmentally friendly binders and the utilization of recycled materials in MgO-C refractories to mitigate their environmental impact and enhances the environmental performance of carbon containing refractory materials.

## INTRODUCTION

Refractory materials used in contact with molten metal require particular properties such as high thermal shock resistance, corrosion and erosion resistance and sufficient mechanical strength at high temperatures[1, 2, 3, 4, 5]. Magnesia-carbon (MgO-C) bricks were initially developed for electric furnaces in the 1970s and later adopted as working linings for converters (BOF) and secondary refining processes. Traditional MgO-C bricks typically contain 10 wt.% or more carbon (graphite) and are bonded by phenolic resin or pitch [6]. Graphite plays a crucial role in inhibiting slag penetration into the brick structure due to its low wettability by slag. Moreover, the addition of graphite significantly enhances the thermal shock resistance compared to pure magnesia, due to its high thermal conductivity and low coefficient of thermal expansion [7, 8]. The choice of binder is essential for all refractory ceramics. A binder for carbon-containing refractories should meet following requirements [9]:

– environmental and health safety of both the binder and its reaction products
– good wetting of both the refractory grain and the carbon carrier
– long time stability storage
– stable viscosity behavior within the processing temperature range
– good processability (no sticking)
– high bonding strength after pressing (low springback during pressing)
– high strength after curing and after coking
– low thermal expansion during coking
– long coking range to keep the stresses within the brick low
– no softening during coking
– high residual carbon content (ratio between the mass of the coke residue after coking and the initial mass of the binders)

– graphite like structure after carbonization for better oxidation resistance [10]

A large variety of organic binders have been tested for carbon containing refractories. Apart from a few special applications, pitches and phenol formaldehyde resins nowadays dominate the market in the bonding of carbon-bonded products [11]. Their pyrolysis deliveres a three-dimensional cross-linked lattice, which is very hard, insoluble, and stable [12, 6]. There are two types of phenolic resins: a resol type, which is thermosetting, and a novolac type, which is thermoplastic. The curing process is based on the reaction of hydroxymethyl groups (-$CH_2OH$) in the system. Resol based binders already contain these groups and can be simply activated by heating, while novolac resins contain fewer phenol groups and thus require an additional hardening agent such as hexamethylenetetramine to promote the polymerization reaction. The polymerization process takes place at temperatures higher than 160 °C with the splitting off of water molecules (resol) or ammonia (novolac). None the less, it is well known that compounds such as phenol-formaldehyde resins and pitches are highly harmflul for human health and the environment as well. Formaldehyde has carcinogenic as well as suppressive effects on the nervous system. Phenol formaldehyde resins have harmful effects on the skin, causing dermatitis and eczema [13, 14, 15]. The pyrolysis of coal tar pitches results in the release of hazardous compounds, such as benzo[a]pyrene, benzoanthracene, and others. Such compounds are dangerous even at low concentrations because of their bioaccumulation properties [16, 17, 18]. In addition, the European REACH regulations impose strict protocols for transporting and processing of all polycyclic aromatic hydrocarbons (PAHs).

Consequently, current research aims at reducing the toxicity of binders while maintaining the relevant properties of the components. There a is great interest in developing new uses for biomass and its derivatives that can offer sustainable alternatives to petroleum-based materials [19]. In particular, a high coke yield [20], cross-linking of PAHs [21], and a high atomic C/H ratio [22] are desired. Considering naturally occurring materials, lignin is the second most abundant aromatic polymer which has been traditionally relegated to use as a low-grade fuel. However, clean lignin represents a novel candidate for the manufacturing of high-temperature binders and carbonized materials due to its appropriate structure and behavior [23, 24]. Lignin pyrolyzes through a free-radical chain-reaction mechanism, similar to the liquid-phase carbonization of coal tar pitch [25]. Free radical precursors, generated during the heat treatment of lignin, undergo crosslinking, aromatization, and rearrangement reactions leading to the formation of highly condensed aromatic rings and consequently heterogeneous carbon structures of graphitic nature [26]. Collagen is derived from the hides and residues from the meat-packing industry. Owing to its ampholytic character with ionizable groups and active sites for crosslinking reactions, collagen acts as a strong binder. Early studies revealed that it can be used in combination with other additives as a core binder for iron casting in foundries [27, 28, 29]. Collagen maintains favorable physical and mechanical

properties even at elevated temperatures. It also releases far fewer volatile organic compounds, hazardous air pollutants, and greenhouse gas emissions than conventional phenolic urethane-based binders [27, 28, 29]. Lignin and collagen were already used to bind anthracite fines into bricks, which exhibited superior unconfined compression strength in all thermal stages (up to 1400 °C) found in cupola foundry furnaces [30, 31]. Zhao et al. [19] have also used a system consisting of lignin and collagen as a binder for specialty graphites and electrodes.

The focus of the Research Training Group GRK 2802 ``Refractory Recycling: A contribution for raw material-, energy-, and climate-efficiency in high-temperature processes'' is to explore the material property spectrum as well as the limitations of new high-temperature materials based on refractory recyclates and enviromentally friendly binders with special thermo-mechanical, chemical, and functional properties in high-temperature processing in the metallurgy [32]. In particular, a reduction of $CO_2$ emission shall be achieved by refractory material recycling ($CO_2$-free approaches due to the removed need for calcination of new raw materials) and on the other hand by the development of new metal/ceramic composite materials, enabling the development of $CO_2$-poor metallurgical technologies. The recycling and upcycling of materials for high-temperature applications offer a great potential for the direct reduction of greenhouse gas emissions together with more economical production processes. In this study, the combination of lignin and collagen was investigated as binder system. The design of the batches corresponds to the patent with file number 10 2023 002 367.1 [33].

## MATERIALS AND METHODS
### Raw materials
The raw materials used for the preparation of the pressed samples included both fresh MgO and recycled MgO-C. The fresh MgO was sourced from Refratechnik Steel GmbH (Düsseldorf, Germany). Fused magnesia, with purity exceeding 97.5 %, was utilized in three different size fractions: 3-7 mm, 1-3 mm, and 0-1 mm. As for the recycled material, three fractions of MgO-C (3-6 mm, 1-3 mm, and 0-1 mm) were obtained from Refratechnik Steel GmbH (Düsseldorf, Germany). Obviously, the recycled MgO-C materials exhibited varying content of residual carbon and other impurities, depending on size fraction. To further enhance the properties of the refractory samples, fine fractions of either fused cast MgO (F, purity >97.5 %) or dead burnt magnesia (DBM, purity >97 %) were added. Both types of fines MgO, with particle sizes below 45 μm, were acquired from Refratechnik Steel GmbH (Düsseldorf, Germany). Additionally, the coarse natural flake graphite NFL 92/94 (Graphit Kropfmühl AG, Hauzenberg, Germany) served as a carbon source. Dealkaline lignin (L0045) and alkaline lignin (L0082) obtained from TCI Deutschland GmbH (Eschborn, Germany) and collagen (100 % pure bovine collagen hydrolysate) from FNW International GmbH (Horb am Neckar, Germany) were used as binders. Ethylene glycol with a purity of 99% from Grüssing GmbH (Filsum, Germany) was used as a substitute for deionized water. Several additives were employed to enhance the properties of the MgO-C refractory batches. Aluminum powder with a purity of ≥ 99% and a grain size below 160 μm was obtained from Carl Roth GmbH + Co. KG (Karlsruhe, Germany). Silica (purity 96% ± 1.5%) was purchased from RW silicium GmbH (Pocking, Germany) and consisted of primary particles (approximately 63%) with sizes ranging from 0.1 to 0.3 μm, along with 1.5% coarser grains with a maximum size of 45 μm. Finally, $TiO_2$ (purity >99%, particle size <0.045 mm) was obtained from Crenox GmbH (Krefeld, Germany).

### Batch design
The batches developed and investigated in this study are summarized in Table 1. The majority of the batches were formulated using MgO-C recyclates. However, to assess their influence, four additional batches were prepared using only fresh magnesia (referred to as 100-A-F, 100-A-D, 100-A-D-E, and 100-A-D-E2). All batches were produced with environmentally friendly binders. Furthermore, additives with the same proportion were incorporated into most of the batches to enhance the properties of the coked samples. To evaluate their impact, two batches (50-F and 50-D) were prepared without any additives.

The compositions of the individual batches were designed according to the state-of-the-art MgO-C bricks produced in the industry. For batches consisting completely of fresh MgO, a constant graphite content of 10 wt.% was applied, in compliance with current industrial practice. Since the recycled fractions already contained carbon, the graphite content was reduced to 5 wt.% in order to achieve a comparable carbon content after coking. A total of 3 wt.% enviromentally friendly binder (lignin and collagen) was added, reflecting the typical binder amounts used in the industry. Initial tests indicated that coked samples bonded with a lignin-to-collagen ratio of 4:1 exhibited superior cold crushing strength compared to samples bonded solely with lignin. The batches 50-A-D and 50-A-F presented in Table 1 correspond to the batches described in a recent patent by Aneziris et al. [33].

### Sample preparation
The batches were mixed using a conventional mortar mixer ``ToniMIX'' (Toni Baustoffprüfsysteme GmbH, Berlin, Germany) while maintaining a consistent mixing order to ensure reproducibility. The mixing process started with the dry mixing of the coarse grains (3-7 mm and 1-3 mm), followed by the addition of half of the deionized water or the ethylene glycol (0.5 wt.% relative to total solids). Subsequently, the graphite and fine magnesia (0-1 mm) were incorporated into the mixture. Next, the binders (lignin and collagen) and, when applicable, additives (Al, $TiO_2$, and $SiO_2$) were pre-mixed and added to the mortar mixer. The remaining deionized water or the ethylene glycol was then introduced, followed by the finest MgO fraction (<0.045 mm), which could be either fused MgO (F) or DBM (D). The batch was mixed for 5 minutes, and the walls of the mixing container were scraped to ensure thorough mixing. An additional stirring of 5 minutes followed. Cylindrical samples (50 mm in diameter 50 mm in height) were pressed with a uniaxial press ``ES 270'' (RUCKS Maschinenbau GmbH, Glauchau, Germany). To minimize the risk of cracks due to entrapped air, the chamber was degassed twice at 1/3 and 2/3 of the maximum pressure of 150 MPa. After the pressing, the samples were dried at a temperature of 85,°C with a heating rate of 10 K/min and a holding time of 2 h, in a drying furnace ``P330'' (Nabertherm GmbH, Lilienthal, Germany). Subsequently, the samples were subjected to a curing process at 300 °C with a heating rate of 55 K/h and a dwell time of 1 h, allowing the lignin to soften and fill the gaps during the curing treatment. To approach reducing conditions, all samples were then coked inside retorts filled with calcined petcoke. The schedule involved a heating rate of 100 K/h up to the maximum temperature of 1000 °C, which was maintained for 3 h before free cooling.

**Sample characterization**

After coking, the MgO-C refractory samples were subjected to various characterization procedure to assess their properties. The open porosity and bulk density of cylindrical samples were determined using the toluene immersion method, following the European Standard DIN EN 993-1. The cold crushing strength (CCS) of the refractory samples was measured in accordance with the European Standard DIN EN 993-5 using a testing machine ``TIRAtest 2280'' (TIRA GmbH, Schalkau, Germany). 10 cylinders from each batch were subjected to compression testing after the coking process. The collagen and lignin binders were analyzed using simultaneous thermal analysis (STA-MS) combined with mass spectroscopy. Setsys Evolution apparatus (Setaram, Mougins, France) under dynamic air atmosphere conditions. The samples were heated with a rate of 5 K/min up to a temperature of 800 °C, and the gases evolved during heating were analyzed using a mass spectrometer OmniStarTM (Pfeiffer Vacuum, Asslar, Germany). In addition, thermogravimetry was conducted on cylindrical samples to determine their oxidation resistance. Flat alumina disks were placed on the cylindrical end faces of the samples, to minimize edge effects during oxidation and account for the anisotropic orientation of graphite flakes resulting from the pressing process. This setup ensured that the oxidation predominantly occurred from the lateral surface of the samples. The evaluation of the oxidation resistance was performed on cylindrical samples coupled with a laboratory scale. The samples was continuously recorded throughout the thermal cycle, which involved heating the samples in air up to a temperature of 1000 °C at a rate of 5 K/min. Subsequently, the samples were cooled to room temperature at a rate of 10 K/min, without any dwell time. In order to estimate the oxidation depth, the cylinders were broken lengthwise in the center after the oxidation tests. The Images of fractured surface were taken and the oxidation depth (OD) was measured digitally, using the software ``ImageJ''. 10 individual measurements per sample were carried out to determine the oxidation depth. To exclude the influence of edge effects, the oxidation depth was not measured directly at the edges. As specimens ``50-F'' and ``50-D'' failed during the cutting process, only photographs of the front surface, taken in advance, are available for both samples. To determine the oxidation depth for these two samples, the measured oxidized thickness on the face was subtracted from the total radius. Furthermore, differential scanning calorimetry (DSC) with thermogravimetry (TG) was performed on ground samples using simultaneous thermal analysis STA 409 PC/PG (Netzsch-Gerätebau GmbH, Selb, Germany). The samples were heated up to 1400 °C under an artificial air atmosphere, utilizing a heating rate of 10 K/min. Finally, fracture surfaces of the 100-A-D sample (taken as exemplary sample) were glued to sample holders and sputtered with Pt/Pd. In addition, a similar sample was embedded in epoxy resin, vibration polished for 20 h, and finally sputtered with Pt/Pd. SEM analysis ``AMBER'' (Tescan, Brünn, Czech Republic) combined with EBSD (Bruker Nano GmbH, Berlin, Germany) was performed on the prepared sample to gain information about morphology and phase composition.

**CONCLUSIONS**

In the present study, an environmentally friendly binder system based on lignin and collagen was developed to achieve effective bonding in MgO-C refractory samples. Moreover, as raw materials MgO-C recyclates obtained from steelmaking plants were partially used. The physical and mechanical properties of the developed refractories were comprehensively investigated and compared to reference batches with the same binders but without any recyclates. Batches comprising recycled MgO-C generally exhibited higher open porosity, slightly lower bulk density, and reduced cold crushing strength (CCS) in comparison to the reference batches. However, the application of antioxidants significantly improved the mechanical strength of the samples and provided effective resistance against oxidation in an air atmosphere. Scanning electron microscopy analysis revealed the presence of whiskers in the coked samples containing antioxidants. Oxidation of antioxidants resulted in the formation of an alumina layer on the surface of the aluminum particles, while specific regions were identified as AlN, indicating the reaction between aluminum and the surrounding atmosphere. Furthermore, replacing ethylene glycol in preliminary investigations yielded promising findings, relating to higher CCS. This alternative approach should be pursued in further studies. Generally, the successful development of the lignin and collagen binder system, along with the utilization of MgO-C recyclates and antioxidants, shows a clear potential for the development of sustainable and high-performance MgO-C refractories. Other research should focus on increasing the proportion of recycled materials, and exploring alternative typed of lignin and collagen binder systems to further enhance the properties and performance of enviromentally friendly refractories. By combining environmentally friendly with advanced material design, it is feasible to achieve sustainable and cost-effective refractory materials, contributing to the decarbonization of the steel industry.

[2]Hochschule Koblenz, Höhr-Grenzhausen, Germany

Natural andalusite is an important refractory raw material that is widespread in use for manufacturing industrial refractory unshaped products and fired brick materials. However, andalusite cannot be synthesized for refractory purposes and natural ressources are limited. FGF, Hochschule Koblenz and InisMa together investigate in depth the thermal phase evolution and, in parallel, the thermomechanic properties to understand the outstanding properties of andalusite bearing refractory castables. It is well known that andalusite decomposes at temperatures above ~1300 °C, resulting in dense, felted aggregates of mullite and a highly viscous silica phase. Theses aggregates still provide high refractoriness and mechanical strength. The volume increase of about 4.5 % during this transformation works against high temperature shrinkage.

The phase changes occuring with increasing temperatures, involving the andalusite transformation that can be influenced by other components of the castables, as well as reactions of transformed andalusite with the surrounding matix, influence the thermomechanical properties of the castables. With the aim to develop alternatives to andalusite bearing castables, these processes must be entirely understood.

The method of monotonic heating reveals important mineralogical phase changes in two commercial castables (ULCC and silica-gel bonded) in the temperatures up to 1620 °C, including transformation of andalusite and melt formation.The nature of observed phase transformations is verified by XRD and SEM using samples of the castables that were treated between 900 and 1600 °C at a step size of 100 K. RUL and CREEP was determined for correlating the thermal softening of the castables with the described phase evolution.

# THE ROLE OF ANDALUSITE IN REFRACTORY CASTABLES AND POSSIBLE SUBSTITUTIONS PART 2: CHANGES IN CERAMIC STRUCTURE DURING HEAT–UP

J. Paul[1], O. Krause[1], K. Abdelgawad[1], R. Simmat[2], K. Hauke[2], C. Dannert[2]

[1]Koblenz University of Applied Science, Höhr-Grenzhausen, Germany; [2]Forschungsgemeinschaft Feuerfest e. V. at the European Centre for Refractories, Höhr-Grenzhausen, Germany

Andalusite bearing castables are widely used in the process industry due to their outstanding corrosion resistance and thermo mechanical properties. Typical applications are biomass and waste incineration and permanent linings of vessels in the steel industry.

However, andalusite is a natural raw material with limited supply. An approach to mitigate this risk is to develop alternative refractory castables which have the same outstanding properties like andalusite refractory castables, but do not contain andalusit e. However, the high temperature behaviour of andalusite refractory castables is not fully understood yet. Especially, a better understanding of the role of andalusite in the matrix of refractory castables is necessary to develop suitable substitution refr actories.

To better understand the behaviour of andalusite in refractory castables, two commercial castables (ULCC and silica gel bonded) were investigated by scanning electron microscopy and X ray diffraction analyses after thermal treatment at different temperatures and for different durations. The results diverge significantly from former data reported in the literature. Unexpectedly, mullite is not a stable high temperature phase in the matrix of the ULCC. In the presence of CaO from the cement binder, anorthite and liquid phase are being formed instead.

This paper presents SEM and XRD investigations of the heating experiments and shows mineralogical and chemical differences during thermal treatment.

# THE ROLE OF ANDALUSITE IN REFRACTORY CASTABLES AND POSSIBILITIES FOR ITS SUBSTITUTION.
# PART 3: FIRST ATTEMPT TO REDESIGN REQUIRED PROPERTIES WITHIN THE PARAMETERS OF  ANDALUSITE FREE CASTABLES

Kariman Abdelgawad[1]; Olaf Krause[1]; Juliane Paul[1]; Ralf Simmat[2]; Christian Dannert[2]

[1]Koblenz University of Applied Sciences, building-art-materials (materials technology glass and ceramics), Höhr-Grenzhausen, Germany; [2]Research Association Refractory e.V., Höhr-Grenzhausen, Germany

The andalusite transformation and accompanied thermal induced phase transformations in ultra-low cement and no-cement-high alumina refractory castables are described in the first part of this joint contribution. The andalusite transformation is accompanied by volume expansion and the formation of an amorphous silica-rich phase. Observation by SEM anticipatesa great benefit of the silica-rich phase by hampering crack propagation, thus improving the mechanical properties and of the castables at high temperatures.

Nevertheless, the high demand for andalusite in refractory markets raises concerns regarding long-term supplies. The observed mechanisms guide the way in developing alternative, andalusite-free and sustainable castables.

In this work, model low cement castables based on tabular alumina with additions of SiC, kyanite or luting sand (as a fine particle < 45 um) were developed to achieve a similar microstructures and thermo-mechanical properties as andalusite based castables. SiC enhances the formation of mullite through oxidiation and in the presence of alumina in the matrix . The role of kyanite is 1. to support the mullite formation and 2. To compensate shrinkage by the volume expansion during transforms to mullite + $SiO_2$ during heating.

The model castables were fired at 1000, 1200, 1300, 1400, and 1500 °C for 8 hrs. The refractoriness under load and creep under compression in combination with mineralogical and microscopic analysises were used to investigate the influence of SiC, Kyanite and luting sand on the microstructural and thermo-mechanical properties of the castables

# REFRACTORY INK-COATED POROUS INSULATORS TO PREVENT MICROWAVE PLASMA DISCHARGES FOR HIGH-TEMPERATURE MICROWAVE HEATING

## ABSTRACT

The refractory industry known for its high energy consumption, can greatly benefit from the implementation of microwave processing techniques to reduce energy usage. Nevertheless, a proper insulating system is of paramount importance for microwave sintering. Careful selection of its composition and structure impact directly the performance of the insulator. A plain alumina porous insulator is a suitable candidate to fulfill some of the requirements. However, this type of insulator may cause plasma discharges during microwave sintering, hindering the process's effectiveness. In this study, the use of a refractory ink coating on a commercial plain alumina foam insulator was evaluated. The performance of the ink-coated insulator was compared to the uncoated one, under the same microwave heating conditions. A coated insulator promoted a more homogeneous and controlled heating, displacing the effect of plasma discharges for higher temperatures.

## INTRODUCTION

The discovery and utilization of ceramics are one of the most relevant accomplishments in human history, and firing is a crucial step in their processing to achieve a dense and resistant ceramic body. Microwave heating was conceived in the last century, around the 1950s, and developed mainly as a technique to heat food, however ceramic materials were explored more extensively in microwave processing around the late 1980s [1]. Several aspects must be considered to implement microwave heating on an industrial scale for ceramic sintering. One of the most challenging aspects to overcome is to find a suitable thermal insulator system that is transparent to microwave (at room and high temperatures) while simultaneously withstand high temperatures without melting or deforming and presenting high resistance to thermal shock damage. To solve this issue, a plain alumina ($Al_2O_3$) porous insulator is a potential candidate for the application. Alumina is transparent to microwave radiation in a wide temperature range. Alumina foam insulators can fulfill two out of three requirements: transparency to microwave and refractoriness [2,3]. However, using porous materials might lead to the generation of plasma discharges within the pores. This phenomenon occurs when a high-frequency electromagnetic field is applied to a porous material with a pore size close to the microwave wavelength [4]. The presence of plasma discharges hinders the heating effectiveness of the target because the plasma absorbs a substantial amount of the input power, and the larger the plasma region generated through this phenomenon, the larger the power absorbed by the plasma. This work aims to develop a refractory aluminum oxide-based ink to coat a thin layer of the porous insulator, preventing the formation of plasma discharges on the surface pores of the insulator during the sintering process in microwave ovens while maintaining its insulating properties, microwave transparency, and refractoriness.

## EXPERIMENTAL PROCEDURE

In this work, the material used to produce the refractory ink is alumina (CT3000SG, Almatis). The ink was produced by mixing the alumina with distilled water, surfactant (Castament FS60, BASF), polyvinyl alcohol (PVA 72000, Synth), and polyethylene glycol (PEG 8000, Union Carbide). After mixing in a mechanical stirrer for 15 minutes, the suspension was milled using zirconia spheres for 3 hours to ensure complete homogenization.

The insulator used for the deposition of the produced ink is a lightweight plain aluminum oxide foam (Norfoam, Saint-Gobain) designed for high-temperature applications [5].

Two sintering methods were applied to consolidate the ink onto the insulator surface: conventional or microwave sintering (Cober Electronics MS6K, 2.45 GHz, 6kW). In the former, the heating ramp is as follows: 300 °C for 1h with a 3 °C/min heating rate, followed by heating to 500 °C for 1h with a 3 °C/min heating rate, and after, heating up to 1600 °C for 2h with a 5 °C/min heating rate. In the latter, the samples were sintered while in use as insulators in the microwave cavity, with a 50 °C/min heating rate up to 1100 °C, and with a scheduled 20 °C/min heating rate up to 1450 °C with no holding time. The temperature measurement in the microwave oven was carried out using an optical pyrometer (Raytek MA2S Marathon Series).

The deposition of the produced ink on the insulator surface was made by dipping the insulator in a 1-millimeter-deep bath of the produced ink, ensuring that only a thin layer of the insulator surface would be coated by the ink. After the deposition, the ink-coated insulator was left to dry at room temperature for 24 hours.

The microwave oven cavity view is shown in Fig. 1. The grey piece in the center of the image is silicon carbide used as a microwave susceptor material to absorb the microwave and heat the system, and the red dot is the pyrometer target pointer. After sintering, the coated insulator surfaces were analyzed in an optical microscope (Zeiss Stemi 2000-C).

*Fig. 1: Side view of the inside of the microwave oven cavity.*

## RESULTS AND DISCUSSION

After sintering, the coating was well attached to the porous scaffold, as seen in Figure 2. It is possible to observe that different sintering methods resulted in changes on the surface morphology of the ink layer. For the 78% solid content ink microwave sintered composition (Fig. 2a), it is noticed the smaller size of plate-like surfaces with a higher number of cracks. This was expected [6,7] given the much shorter time to thermally decompose the additives used for the ink preparation (due to the high heating rates and no holding times) and the sample's lower temperature in the microwave sintering process. The same can be accounted for the 80% solid content ink microwave sintered (Fig. 2b). However, changing the formulation of the ink has given rise to a slightly

different surface morphology. The latter depicted more homogeneous sized although bigger plates, and slightly larger crack widths. For the 80% solid content ink conventionally sintered composition (Fig. 2c), the same trend happened to a higher extent, resulting in even bigger plates and crack widths. However, comparing the different formulations of the depositions over the insulator surface during use in the microwave oven, the different morphologies of the plates and crack widths did not seem to affect the heating or the unfolding of plasma discharges (what is not desirable in this case) during the process.

*Fig. 2: Optical microscopies of (a) 78 microwave sintered, (b) 80 microwave sintered, and (c) 80 conventionally sintered.*

The microwave sintering time of the refractory ink coating was significantly lower compared to the conventional sintered one (approximately 10x lower, comparing 55 minutes to 600 minutes, respectively). The surface morphologies obtained did not present outstanding differences regarding the sintering method (except for the size of the plates). This suggests the potential of sintering this type of coating already in use during the thermal treatment in the microwave oven. It might lead to substantial energy savings likewise the already-known benefits of microwave sintering related to this aspect [8,9].

Using the insulator with no ink deposition in the microwave sintering system usually generated plasma discharges between 950~1020 °C. When a stable plasma forms, the measured temperature decreases by approximately 100 to 150 °C, resulting in an increase in the incident power rise to 4 kW. One would expect a significant temperature rise because the silicon carbide susceptor is an excellent microwave absorber [10] and would absorb most of the incident power, however, this does not occur promptly. After the temperature drops and stabilizes, it rises at a slightly lower rate after a couple of minutes. The reason behind this is that the plasma absorbs a significant amount of microwave power, as alumina is mostly transparent to microwaves at this temperature range. This absorption of the microwave power by the plasma can be described by equation (1), which highlights the electric energy absorbed by the electrons and ions in the plasma [11].

$$P_{abs} = n_e . A_{eff} . E^2 \qquad (1)$$

where $P_{abs}$ is the power absorbed in the plasma in watts, $n_e$ is the plasma electron density, $A_{eff}$ is the effective area for power absorption and depends on the plasma properties such as the electron and ions temperature, and $E$ is the electric field intensity.

In the aforementioned event (using an insulator with no ink deposition), the maximum temperature reached was 1350~1370 °C. When the insulator used in microwave heating is coated with the refractory ink, the maximum temperature achieved is 1430~1450 °C. This is accompanied by a considerably higher heating rate once the temperature recovers from the initial decline caused by the

absorption of the microwave power by the plasma. Using the coated insulator, the plasma discharges begin above 1180 °C (at least 160 °C higher) with the temperature falling approximately 70 °C (at least 30° less).

**CONCLUSIONS**

The results obtained pointed out that using ink-coated insulators enabled reaching a higher temperature in the microwave oven system. The plasma discharges could not be avoided or prevented as expected, but in addition to being displaced to a higher temperature, the overall heating speed was better controlled and presented a higher recovery heating rate after the plasma discharges were initiated. The use of ink-coated porous ceramics can be a promising technological improvement for cheap and easy-produced insulators used for microwave sintering in addition to shielding the insulator and increasing its lifespan.

# HIGH–TEMPERATURE DAMAGE AND MECHANICAL BEHAVIOR OF NIOBIUM–ALUMINA REFRACTORY COMPOSITES UNDER COMPRESSION AND BENDING

G. Günay, T. Zienert, C. G. Aneziris, H. Biermann, A. Weidner
TU Bergakademie Freiberg, Germany

B. Kraft, S. Wagner
Karlsruhe Institute of Technology, Karlsruhe, Germany

## ABSTRACT

In the present study, $Nb-Al_2O_3$ refractory composite materials produced by slip casting and extrusion methods were studied in terms of their mechanical behaviour at high temperatures under compressive and bending loading conditions. In addition, materials with lower porosity manufactured by field-assisted sintering technique (FAST) were tested to explore the effect of porosity on mechanical behaviour of these composites. Within the scope of this study, compression tests were performed up to 1300 °C. To understand damage behaviour, bending tests were performed together with acoustic emission measurements. Fractured surfaces were characterized with stereo microscopy and scanning electron microscopy. The results show that temperature has a significant effect on brittle to ductile transition associated with deformation in these materials. As the temperature increased, these composites exhibited higher plasticity and showed more pronounced creep behaviour, in particular at 1500 °C. Furthermore, acoustic emission measurements were applied at RT and for the first time also at high temperatures.

## INTRODUCTION

Refractory composites have become increasingly popular in recent years as promising candidates owing to their ability to withstand extreme temperatures, mechanical stresses, and corrosive atmospheres [1-4]. Refractory composites typically consist of a combination of refractory materials, such as alumina ($Al_2O_3$), together gathered with refractory metals like tantalum and niobium. Among these composites, $Nb-Al_2O_3$ composites have gained significant attention due to their unique combination of properties, including high strength, thermal stability, low shrinkage, and high resistance to harsh operating conditions [1-2]. Nb, with its high melting point, excellent mechanical properties, and notable chemical stability, presents an ideal candidate for improving the overall performance of refractory materials. Forming a composite of Nb together with $Al_2O_3$ can lead to synergistic effects, resulting in enhanced high-temperature mechanical properties and improved dimensional stability.

$Nb-Al_2O_3$ composites are particularly effective when combined with various coating technologies, owing to their ability to provide good bonding between the metal particles and the ceramic matrix [5-7]. Furthermore, the shrinkage behaviour of these composites during the sintering process plays a crucial role in hot temperature applications [2]. Given these inherent benefits, these materials are expected to see increased utilization in the near future, particularly in applications where exposure to high temperatures is a critical factor while minimizing the environmental impact.

The performance and reliability of refractory composites at elevated temperatures heavily rely on their mechanical behaviour. To effectively employ these composites in demanding applications, a comprehensive understanding of their high-temperature mechanical properties is crucial. Previous studies of the authors group [3, 8] have focused on conducting compression experiments to evaluate the high-temperature properties of $Nb-Al_2O_3$ composites in various compositions for the first time. Thorough understanding of the properties and performance of these composites can provide valuable insights for designing and implementing environmentally sustainable materials in different applications.

In the present study, we aim to investigate the mechanical properties of $Nb-Al_2O_3$ composites in a more comprehensive manner. This study provides the high-temperature damage and mechanical behaviour of $Nb-Al_2O_3$ composites, which are produced through slip casting and FAST (Field-Assisted Sintering Technique). The utilization and effects of different alumina powders in two different grain sizes will also be evaluated, considering their contributions to costs and the mechanical behaviour of these composites. Mechanical properties, such as strength, hardness, and deformation behaviour of the composites, were assessed through compression tests. Furthermore, we performed bending experiments on the composites produced through two different sintering regimes for comparison. These experiments were supplemented by acoustic emission measurements in order to evaluate the damage and fracture behaviour. It is essential to conduct these experiments, including acoustic emission measurements, at high temperatures to gain comprehensive insights into the material's behaviour under extreme conditions.

## EXPERIMENTAL PROCEDURE

### Materials

Within the scope of these studies, $Nb-Al_2O_3$ refractory composite materials, containing 60 vol % refractory metal niobium and 40 vol % alumina, were investigated. These composites were fabricated using slip-casting and FAST, utilizing the raw materials with particle sizes provided in Table 1.

Tab. 1: Particle size distributions of the raw materials.

| Production | Raw materials | Particle Size [µm] | | |
|---|---|---|---|---|
| | | $d_{10}$ | $d_{50}$ | $d_{90}$ |
| SLIP-CASTING | Niobium powder | 9.1 | 31 | 64.7 |
| | Alumina CT9FG | 2 | 5.5 | 20.6 |
| | Alumina CL370 | 0.2 | 0.5 | 5.8 |
| | Alumina Alodur | 42.3 | 96.3 | 163.7 |
| FAST | Niobium powder | 10.8 | 37.6 | 75.6 |
| | Alumina CT9FG | 0.8 | 4.4 | 11.9 |
| | Alumina Alodur | 44.8 | 95.8 | 162.4 |

*Castables*

The slip-cast refractory composites were produced by two different sintering processes, namely single-sintered and double-sintered. Single-sintered refractory composites were produced using Nb powder (EWG Wagner, Germany) and alumina powders (CT9FG, Almatis, Germany, and Treibacher Alodur WRG, Imerys Fused Minerals Zschornewitz, Germany). Before the experiments, open porosity and density of each specimen were measured using the Archimedes method. Detailed information regarding the production process can be found in a recent study of Zienert et al. [2].

The double-sintered $Nb-Al_2O_3$ composites were produced by a two-step manufacturing process. In the first step, single-sintered refractory composite prisms were produced and sintered. Subsequently, these prismatic materials underwent a crushing

process, and Nb-Al₂O₃ aggregates were classified to different grain size through the process of sieving. During this process, CL370, a finer-grained alumina powder, was added to aid in better sintering and improved interlocking. After selecting the proper grain size, the mixture was sintered at 1600 °C for 4 hours under an argon atmosphere. The resulting materials were referred to as double-sintered refractory composites. Detailed information related to the process is given in [9].

*FAST*

In the FAST technique, the materials were produced with the aid of different-sized alumina powders, namely the fine-grained CT9FG and the coarse-grained Alodur. The process entailed a dry mixing of Nb powder and alumina powder using a Turbular Tumbler type T2C (WAB AG Maschinenfabrik, Switzerland). The mixture was transferred into a polyethylene (PE) bottle and mixed for 10 minutes without any further additions. Subsequently, the powder mixture was processed using a FAST system type HP D25/1 (FCT Systeme GmbH, Germany). The samples were sintered at a controlled temperature with a heating rate of 100 K/min and then held for 5 minutes. During this process, an axial pressure of 50 MPa was applied. After this period, the axial pressure was released, and the samples were cooled down to RT at a cooling rate of 100 K/min. Before the mechanical testing, open porosity and density measurements were conducted on each specimen using the Archimedes method. For comprehensive details regarding the production route, refer to the study conducted by Kraft et al. [10].

**Specimen preparation**

For the compression tests, the materials produced using two different techniques were investigated. Single-sintered castable cylindrical samples in dimensions of Ø 12 mm × 20 mm height were used for compression tests. These materials were prepared by drilling of the single-sintered castable prismatic bars used for bending tests (in dimensions of 25 mm × 25 mm × 150 mm). Fig 1 shows the castable specimens utilized for the compression (Fig. 1a) and bending tests (Fig. 1b), respectively.

*Fig 1. Single-sintered castable refractory composite specimens used for the compression tests (a) and bending tests (b).*

The specimens produced via FAST technique had a size of Ø 2.5 mm × 2.5 mm height and were used for the compression tests. These specimens were prepared using waterjet cutting method from the composite discs produced with FAST technique.

Table 2 shows the initial open porosities of the materials used for the compression and the bending tests.

Table 2: Specimens and the initial open porosities.

| Type of test | Material | Open porosity [%] |
|---|---|---|
| Compression | 60/40 (Nb/CT9FG) FAST | 0.1 |
| | 60/40 (Nb/Alodur) FAST | 0.6 |
| | 60/40 (Nb/CT9FG) Cast | 36.5 |
| | 60/40 (Nb/Alodur) Cast | 41.9 |
| Bending | 60/40 (Nb/CT9FG) Cast Single-sintered | 37.1 |
| | 60/40 (Nb/CT9FG) Cast Double-sintered | 34.8 |

**Mechanical testing**

The experimental investigation of the mechanical properties of the test specimens was carried out at an elevated temperature of 1300 °C using an electromechanical high-temperature testing machine (Z020, Zwick Roell, Germany) equipped with a protective gas chamber (Maytec, Germany). The heating process was conducted by inductive heating via a medium-frequency induction generator (Hüttinger HF 5010, Germany) with a heating rate of 30 K/s. In order to measure the temperature of the specimen directly, a pyrometer (Sensortherm Metis MS09, Germany) with a wavelength of 0.9 µm attached to the chamber and assuming an emission coefficient of 0.93 was used. The system was evacuated twice to a pressure of 0.7 mbar and swept twice with argon gas at ambient pressure to prevent oxidation. In addition, all experiments were carried out in an argon environment, and the presence of oxygen level in the system was monitored using an O₂ sensor (Stange Elektronik, Germany).

The compression tests and 4-point bending tests were conducted using two different testing setups shown in Figure 2. The cylindrical single-sintered castable and FAST specimens were used for the compression tests. The test specimen was placed between susceptor plates and in a susceptor cage made of Mo alloy TZM. The strain measurement was carried out using a short Al₂O₃ rod integrated to the upper susceptor and two long Al₂O₃ rods. The heating process was accomplished using an induction coil around the testing area. The loading on the specimen was applied through Si₃N₄ punches. Prior to the experiments, the lower piston was raised at a rate of 0.1 mm/min, and a pre-load of 5 N was applied to the specimen. Before all experiments, the test specimens were held for 5 minutes at the test temperature to achieve a homogeneous temperature distribution throughout the specimens. All compression tests were conducted at an initial strain rate of $7.5 \times 10^{-4}$ s$^{-1}$.

*Fig. 2: Testing setups used for the compression tests (a) and 4-point bending tests (b).*

4-point bending tests were conducted using the testing setup depicted in Figure 2b. The specimen was positioned in the region where the heating process takes place using the induction coil, and the bending tests were performed using four supports, two on the top and two on the bottom, shown in Fig 2b. The bending was measured using three Al₂O₃ rods in contact with the test specimen. Prior to the experiments, the lower piston was raised up at a rate of 2 mm/min, and then a pre-load of 10 N was applied to the specimen. It is important to note that, prior of all HT bending tests, the specimens were subjected to a holding period of 15 minutes at the test temperature, to ensure that a homogeneous temperature distribution was achieved throughout the specimen.

Acoustic emission measurements were conducted simultaneously with 4-point bending tests to better understand the damage behaviour of the materials both at RT and at high temperatures. For this study, two different types of transducers were selected. Both are piezo-electric resonant sensors, however, with different frequency response ranges. The two sensors (both from MISTRAS, USA) are low frequency narrow band sensors, R15S and R6S. Both sensors have a very high sensitivity and a good frequency response over the range of 50-400 kHz (R15S) and 35-100 kHz (R6S), respectively.

They are, therefore, ideal candidates for applications requiring high sensitivity to AE signals at medium (R15S) and low frequencies (R6S). Both sensors feature a rugged steel construction with an integrated coaxial cable exiting on the side with a BNC connector. The temperature application range is -65 °C to 177 °C. The size of the sensors (Ø 16.5 mm for R15S and Ø 19 mm for R6S) makes them suitable for application at RT directly on the bending specimens with a width of 25 mm ensuring that the entire sensor area is connected to the specimen surface. The areas of sensor location were manually smoothed by grinding with SiC paper. Small droplet of vacuum oil was used as a coupling medium. The sensors were securely mechanically clamped at the specimen using two alumina cases. Figure 3a and 3b show the 4-point bending testing setup for acoustic emission measurement at 1300 °C. Since the operating temperature range of the sensors was significantly lower than the test temperature, two $Al_2O_3$ waveguides of the same length were connected to the specimen using ceramabond (Kager GmbH, Germany) to ensure signal transmission. In addition, two identical adapters were used to transmit the signals from the waveguides to the sensors and vacuum oil was applied between the sensor surfaces and the adapters as a coupling medium. This allowed the sensors to be kept far away from the high-temperature region, and the signals from the specimens could be obtained through this setup.

*Fig. 3: Acoustic emission measurements; testing setup (a) and a specimen during high-temperature test (b).*

## RESULTS AND DISCUSSION

Figure 4 shows the results obtained from the compression test conducted at 1300 °C. The specimens, which were fabricated using the FAST technique, showed superior strength when compared to the single-sintered castable materials. This is expected, as it is in accordance with the initial porosity values of the specimens, given in Table 2. The materials produced using the FAST technique possessed a lower level of porosity, thereby leading to an overall higher level of strength. Conversely, the castable materials exhibited a lower level of strength due to their higher initial porosity of about 40%. However, after surpassing the yield strength, these materials did not undergo any significant damage or failure. Once the maximum strength was achieved, a significant softening became noticeable, in particular in the material that contained fine-grained alumina of type CT9FG. Moreover, the materials that contained fine-grained alumina CT9FG displayed higher strength when compared to those containing coarse-grained alumina Alodur, regardless of the production techniques employed.

Figure 5 depicts the results of the 4-point bending tests carried out at a temperature of 1300 °C. It is evident that the single-sintered composite exhibited superior bending strength in comparison to its double-sintered counterpart.

*Fig 4: Compression test results for cast single-sintered composites and FAST Nb-Al₂O₃ composites with two different chemical compositions each.*

A critical observation from these findings is that the initiation of damage in the double-sintered material occurred at significant lower stress levels compared to the single-sintered material. The double-sintered composite showed minimal bending before suffering damage and failure. Conversely, the single-sintered composite exhibited different behaviour, as it did not fail abruptly after achieving the maximum bending strength but continued to exhibit bending before finally failing at higher bending limits than the double-sintered composite. These results indicate that the single-sintered composite possessed higher bending strength, even if it had similar porosity levels before the bending tests, as given in Table 2. A more comprehensive analysis would be worthwhile to investigate the regions where damage occurred and crack propagation took place. This would provide valuable insights into the specific locations where crack initiation occurs and contribute to a better comprehension of the influence of grain size on bending strength, and is planned for future work.
*Fig 5: Results of bending tests at 1300 °C.*

RT bending tests were performed in combination with AE measurements on notched bending bars of both single and double-sintered Nb-Al₂O₃ composites. Figure 6a shows the load vs. time plot of both bending tests, whereas Figure 6b shows, in addition to the load vs. time curve of the double-sintered material, the two AE data streams of the two AE transducers R15 (black) and R6 (red), respectively. Similar picture was obtained also for the single-sintered specimen. Both AE data streams consisted of a huge number of transient signals throughout the entire loading process. Moreover, high amplitude AE signals of both sensors corresponded well with the serrations in the load vs. time curve caused by damage of the material. The AE data streams were transferred from the time domain into the frequency domain via a Fast Fourier Transformation (FFT) [11]. As a result, power spectral density functions with different characteristics were obtained resembling that throughout the bending process different AE sources were activated. It is clearly visible that clusters with different values of the parameters 'energy' and "median frequency' were separated (Figure 7a).
*Fig 6: Compression tests at RT on notched bending bars of single- and double sintered Nb-Al₂O₃ composite (a) in combination with acoustic emission measurements exemplarily shown for double-sintered specimen (b).*

Two of these clusters contain signals with a very low energy and a wider range of median frequencies (black, red). Two other clusters contain high energy signals in a very narrow band of median frequencies. From the evolution of these clusters during the entire bending experiment it turned out that the red and black cluster are related to different levels of noise starting right before the bending experiment: (i) machine noise in load-free condition (black), (ii) machine noise under preload of 10 N. The two high-energy clusters are related to friction (blue) and to cracks (green). The signals related to friction start directly at the beginning of the bending tests, whereas signals related to cracks appear somewhat later pronounced jump in the cumulative energy of signals belonging to this cluster appears together with severe serrations in the load vs. time curve (Figure7b).

*Fig 7: Results of the AE data analysis in terms of median frequency and AE power as a result of power spectral density functions obtained from the Fast Fourier analysis. Exemplarily for single-sintered material and AE sensor R15S.*

The first high-temperature bending test at 1300 °C on a single sintered material was accompanied by in-situ acoustic emission measurements. As the RT measurements revealed different sources of acoustic emission such as (i) machine noise, (2) friction during bending, and (3) initiation and propagation of cracks, the situation at high temperature, however, is much more complex due to the damping of the acoustic emission signals at high temperatures, the application of wave guides as well as thermal expansion of material during heating up to 1300 °C. Thus, Fig. 8 shows the complete HT deformation test including the heating and the bending part of the experiment. Thus, the black curve gives the load vs. time, whereas the red curve shows the temperature vs. time and the green curve the tool separation vs. time. The continuously recorded AE data stream is plotted in blue. It is obvious that prior to the bending test, significant number of transient signals occurred, already in the heating regime. However, it is not yet clear what is the reason of these in parts high-amplitude signals. AE sources could be either (friction between specimen and bending tool or processes in the material caused by the heating itself. Here, further tests had to be done for clarification.

## CONCLUSIONS

The high-temperature mechanical behaviour of Nb-Al₂O₃ composites (60 vol.% Nb + 40 vol.% Al₂O₃) manufactured via castable and FAST techniques was studied. Compression as well as bending tests were performed at 1300 °C in order to study the influence of temperature on mechanical behaviour.

*Fig 8: Bending test at 1300 °C on single-sintered Nb-Al₂O₃ composite in combination with acoustic emission measurements.*

It is observed that the initial open porosity of composites produced using different manufacturing methods significantly influences the mechanical properties. Composites produced using the FAST technique exhibited higher strength due to the low porosity being less than 1%. Additionally, material produced using the same manufacturing method but containing different grain sizes exhibited different behaviour at high temperature. Despite having the lower open porosity, the single-sintered refractory composite demonstrated superior strength and plasticity at high temperatures than the double-sintered composite.

# COMPARISON OF SOLIDIFICATION BEHAVIOR OF SYNTHETIC MULLITE AND MULLITE-FORMING RAW MATERIALS BY AERO-ACOUSTIC LEVITATION

Dirk Mühmer, Jonas Niessen, Thorsten Tonnesen, Jesus Gonzalez-Julian
Chair of Ceramics, Institute of Mineral Engineering, RWTH Aachen University, Germany

## ABSTRACT

Fused mullite is used in refractories and as an abrasive due to its suitable properties. Mullite is formed over a wide range in the $Al_2O_3$-$SiO_2$ phase system, preferably as 3:2 or 2:1 mullite. There are several options to tailor the features of fused mullite, and consequently its properties. In that sense, solidification at different $Al_2O_3$:$SiO_2$ ratios, undercooling, and impurity content have a major influence on the microstructure.

This report focuses on the difference between synthetic high-purity fused mullite and mullite-forming raw materials kyanite and andalusite, which are commonly used in refractories. The synthesis of high-purity samples is possible by applying containerless levitation. The used aero-acoustic levitator allows the melting and solidification of samples in a gas stream without any contamination from the crucibles. A high-speed camera enables the observation of molten samples and their solidification, while a pyrometer monitors the apparent temperature of the sample. This allows the continuous monitoring of the solidification process in terms of temperature, crystallization, and reaction during the whole process, including the release of latent heat. Further analysis is carried out by Scanning Electron Microscope (SEM) to examine the microstructure of the mullite phases and X-ray diffraction (XRD) to confirm the presence of mullite. Thermodynamic considerations are used to discuss these results.

## INTRODUCTION

Refractory materials play a critical role in the energy transition, as they are required in any heat-intensive production process. Especially for the steel industry, which is facing new challenges in providing hydrogen technologies for the decarbonization of industrial heating processes. In that sense, some of the most used compositions are mullite and mullite-forming raw materials due to their determinant response at high temperatures and under aggressive environments such as creep resistance, chemical stability, and thermal shock resistance [1].

In the mid-1900s, mullite was processed by reaction sintering of mixed minerals. This resulted in poor homogeneity. The use of high-purity powders increased the technical applications of mullite [1]. So far, mullite can be synthesized in many different forms, such as single crystals, fibers, or fused bricks. [2]. Rodrigo et al. [3] studied the reaction sintering of amorphous silica and α-alumina, emphasizing the important role of the alumina-to-silica ratio. They obtained almost dense ceramics (97%) by firing the samples up to 10 h at 1600°C. The highest density and the finest microstructure were observed with the molar ratio of 3:2 $Al_2O_3$ to $SiO_2$.

Andalusite and Kyanite are anhydrous minerals containing mainly alumina and silica. They have the same molar ratio (1:1) of $Al_2O_3$ to $SiO_2$, which results in an ideal composition of 62,92 wt% $Al_2O_3$ and 37,08 wt% $SiO_2$ [4]. In natural deposits, impurities are found in these aluminosilicates. Besides their same chemical composition, they have different crystallographic structures. Both aluminosilicates are not stable at 1 atm pressure. They are in equilibrium at high pressures and elevated temperatures. These conditions are found inside the earth. Therefore, they can be found in many parts of the world. [4]. On the contrary, mullite is at equilibrium at atmospheric pressure. However, it is rarely found in nature and then only as an intrusion [4][5]. Mullite is the only stable compound at higher temperatures in the $Al_2O_3$- $SiO_2$ phase system [6]. This leads to the industrial relevance of andalusite and kyanite. At higher temperatures, they decompose to mullite and silica. Since the molar ratio of alumina to silica of andalusite and kyanite compared to 3:2 mullite is shifted to silica, there has to be

residual $SiO_2$ after the phase transition. Andalusite transforms to mullite in the range of 1500 – 1600°C [7]. Kyanite decomposes at lower temperatures between 1150 – 1350°C [8]. Both phase transitions result in a microstructure of mullite and mostly amorphous $SiO_2$. At high temperatures, these $SiO_2$ precipitations are the weak spot of the microstructure due to the lower melting point of 1713°C [9] in contrast to mullite (1890±10°C) [6]. Mullite precipitates over the entire range between pure $SiO_2$ and pure $Al_2O_3$. The $Al_2O_3$- $SiO_2$ phase system has a peritectic reaction at the stoichiometric composition of 2:1 mullite (77 wt% $Al_2O_3$, 23 wt% $SiO_2$), where liquid and $Al_2O_3$ react to form mullite [6].

The use of pure powders is problematic for experiments at elevated temperatures. Ceramics are known to have a very high melting point. Therefore, crucibles that can withstand very high temperatures are required. Even if they do not melt at the melting point of the ceramic used, some of the crucible material will diffuse into the ceramic melt. By incorporating impurities into the melt of the pure powders, the advantage of working with expensively produced pure powders is diminished. Therefore, to explore ceramic systems at high temperatures, even in the molten state, a containerless heating device is required. To meet this challenge, we used an aero-acoustic levitator to study synthetic mullite down to the liquid phase.

## EXPERIMENTAL

The synthetic mullite was made of high-purity alumina and amorphous silica: $Al_2O_3$: Baikowski, Malakoff works, United States; BMA15, >99.99 wt% $Al_2O_3$; Amorphous $SiO_2$: pyrogene silica Aerosil 90, Evonik; crystalline >99.8 wt% $SiO_2$. These powders were mixed to the composition proportion of $3Al_2O_3$ $2SiO_2$. For the mullite-forming raw materials were Virginia Kyanite from Kyanite Mining Corporation and Andalusite from Imerys, South Africa, used.

The mixtures were processed into beads up to 3 mm in diameter with the help of a water-cooled copper hearth and $CO_2$-laser beam by melting. The round shape is necessary for the experiments in the aero-acoustic levitator.

*Fig. 1: Aero-acoustic Levitator in operation. An inserted sample is levitating in front of the pyrometer. The golden tubes are ultrasonic transducers.*

The aero-acoustic levitator (Fig. 1) enables the levitation of the ceramic bead. The position of the ceramic bead is fixed above the Bernoulli nozzle by a nitrogen gas stream and by the acoustic waves of ultrasonic transducers. The transducers get feedback from

a diode laser positioning system to settle the turbulence of the levitated sample. Two 240W $CO_2$ lasers (SynradInc, Mukilteo, WA, USA) heat the oxide samples above their liquidus temperature. The power of the lasers is adjustable to control the temperature of the samples, which is recorded by a pyrometer (Exactus BF 8402, Bayer Catalysts LCC, Rome, Italy) at a frequency of 1000 Hz. The experiments are observed by a high-speed camera (V 5.2, PhantomVision Research Inc., Wayne, NJ, USA) with a sampling rate of up to 2600 frames per second. It is equipped with a long-distance lens to capture full-scale images of the samples.

## RESULTS AND DISCUSSION
### Chemical composition
Tab. 1 shows the oxide chemical compositions of the used materials. Andalusite and kyanite were analyzed by X-ray fluorescence. The raw materials were mixed appropriately to a 3:2 $Al_2O_3$:$SiO_2$ ratio for the synthetic mullite material. In addition to the main constituents, andalusite contains smaller amounts of $Fe_2O_3$ and $K_2O$. In kyanite, these are $TiO_2$ and $Fe_2O_3$. No XRF was performed on the synthetic mullite because the raw materials have a purity of >99.99 wt% and 99.80 wt%, respectively.

*Tab. 1: Chemical composition by X-ray fluorescence analysis in wt%. The 3:2 mullite sample, marked with an asterisk, was not measured, but its initial composition is shown.*

| Oxide | Andalusite | Kyanite | 3 2 Mullite* |
|---|---|---|---|
| $SiO_2$ | 36,80 | 40,60 | 28,20 |
| $Al_2O_3$ | 62,05 | 57,16 | 71,80 |
| $Fe_2O_3$ | 0,60 | 0,75 | 0,00 |
| $TiO_2$ | 0,16 | 1,13 | 0,00 |
| $CaO$ | 0,06 | 0,00 | 0,00 |
| $MgO$ | 0,01 | 0,02 | 0,00 |
| $K_2O$ | 0,23 | 0,10 | 0,00 |
| $Na_2O$ | 0,05 | 0,02 | 0,00 |
| $P_2O_5$ | 0,00 | 0,13 | 0,00 |
| $ZrO_2$ | 0,01 | 0,03 | 0,00 |
| $ZnO$ | 0,03 | 0,04 | 0,00 |
| $SrO$ | 0,00 | 0,02 | 0,00 |

### Surface morphology
The samples were placed in the aero-acoustic levitator and heated by the lasers until they were completely molten. For solidification, the lasers were turned off and the temperature dropped. Due to homogeneous nucleation, the molten sample undergoes high undercooling before crystallization starts. During the solidification, latent heat is released and raises the temperature for a period of time.
Fig. 2 shows the surface of a kyanite sample. The highlighted areas (1-3) define different surface morphologies. Solidification begins in area 1 and progresses through areas 2 and 3. The surface of the initial solidification stage shows a smooth but uneven surface. The images taken by the high-speed camera showed a highly viscous melt before solidification began. This type of shape could be the result of crystallization in a highly viscous melt. During further solidification, associated with an increase in temperature due to the release of latent heat, the surface morphology changes into small branched needles. The facetted needles are randomly oriented. In area 3, the surface structure has changed to larger needles growing in the same direction. This structure solidified at the highest temperature.
The results are consistent with the findings of Li et al. [10]. They stated that for a smaller undercooling the solute redistribution can occur during growth, resulting in facetted rods without any branching. This needle morphology is similar to area 3. As the melt is further undercooled, the atomic diffusivity decreases, and the

crystal growth rate increases. This results in the growth of feathery, facetted dendrites, comparable to area 2.

*Fig. 2: Backscattered electron scanning microscope image of the surface of kyanite. The surface is divided into three different areas with different morphologies.*

## CONCLUSIONS AND OUTLOOK
The undercooling determines the surface morphology of the levitated samples. The exceptional experimental conditions in the aero-acoustic levitator lead to a large undercooling of the samples due to the homogeneous nucleation. The differences are shown by three different surface structures: (1) higher undercooling, smooth but uneven surface, (2) medium undercooling, small branched needles, (3) smaller undercooling, larger needles growing in one predominant direction.

A detailed elaboration of the topic as a scientific article can be found in the journal "Open Ceramics".

# CARBON-FREE ELECTRICALLY HEATABLE COARSE-GRAINED COMPOSITE MATERIALS CONSISTING OF (NB/TA)-AL$_2$O$_3$ AND ALUMINA

Patrick Gehre, Dirk Endler, Nora Franke, Tilo Zienert, Jana Hubálková, Christos G. Aneziris
TU Bergakademie Freiberg, Institute of Ceramics, Refractories and Composite Materials, Freiberg, Germany

## ABSTRACT

Due to actual challenges such as the way to carbon neutrality and limited access to raw materials and fossil fuels, material researchers have to develop environmentally friendly, efficient materials and resource-saving processes. Moreover, modern high-temperature processes require smart refractories with, e.g. electric properties besides a superior thermo-mechanical behaviour. The Research Unit FOR 3010, supported by the German Research Foundation DFG, investigates and develops a new generation of coarse-grained refractory composites based on the electrically conductive and ductile refractory metals niobium and tantalum with the corrosion- and thermal shock-resistant refractory ceramic Al$_2$O$_3$ [1]. A concept of a carbon-free electrically heatable functional component implies a coarse-grained core based on the (Nb/Ta)-Al$_2$O$_3$ refractory composites protected by a coarse-grained alumina shell with excellent stability even in hydrogen- and steam-containing atmospheres up to 1700 °C. The shaping of such a heat shield or stopper component was realised by utilising slip casting and sequential pressure slip casting. In dependence on the water and binder content, the rheological behaviour of the slips was investigated with a rheometer and a pressure strainer. With 1.0 wt.% binder (konjak flour and welan gum) and 15 wt.% water, sufficient dewatering with an applied pressure of 6 bar was achieved. After shaping and sintering, the microstructure and interface of the (Nb/Ta)-Al$_2$O$_3$ core and Al$_2$O$_3$ shell were investigated. After sintering at 1600 °C, no makrocracks along the interface could be detected due to a low shrinkage and a similar thermal expansion of the Al$_2$O$_3$ and Nb-Al$_2$O$_3$ (60 vol.% Al$_2$O$_3$) components.

## MATERIAL AND METHODS

Coarse-grained aggregates with 60 vol.% metal were produced from fine-grained castables based on commercially available standard raw materials, e.g. the alumina CT9FG from Almatis and an Nb-powder with -325 mesh particle size distributions as shown in figure 1.
After sintering at 1600 °C and crushing, the aggregates were sieved to particle sizes <3150 μm and were characterised by means of porosity (Archimedes method, mercury intrusion porosimetry), chemistry (XRD, SEM/EDS/EBSD) and morphology (laser scanning microscopy) [2]. For the latter, a statistical approach [3] was used to identify the morphology parameters radius $r_0$, ovality $o$, the height of first-order peaks $h_p$ and the number of peaks $n_p$ defined by

$$r(phi) = r_0 * (1 + h_p*\cos(phi*n_p) + o*\cos(2phi)) \qquad (1)$$

## RESULTS

An example of one fit of equation (1) to a determined outer contour of a synthesised particle can be seen in figure 2 and the derived statistics on the example of the particle radii in figure 3.

$r_0 = 493.1 \ \mu m$     $n_p = 6$
$h_p = 0.033$     $o = 0.147$
Fig. 2: Morphology fit on the outer contour of a synthesised particle.

X-ray powder diffraction revealed the presence of NbO and beta-Nb$_2$C after sintering the Nb-Al$_2$O$_3$ composite material. Due to sintering in a graphite-based furnace, the formed sintering atmosphere was Ar with traces of CO/CO$_2$, which caused the formation of the mentioned intermediate phases. Niobium carbide formed especially on the free surfaces of the aggregates, which is more pronounced on particles with a large value of open porosity like the alginate-based beads [4]. Such chemical reactions were proven by EBSD measurements after focused ion beam preparation of the sample, as shown in figure 4.

Fig. 1: Particle size distribution of the used raw materials.

807
Fig. 3: Obtained particle radii distribution using the statistical approach.

808

Fig. 4: SEM micrograph of a Nb-Al$_2$O$_3$ composite bead showing the formation of beta-Nb$_2$C at the particle surface.

The electrical conductivity of the casted composite material was 40-60 S/cm, which is only three orders of magnitude below the values of pure niobium [1], whereas the dense-sintered material (using SPS) showed values of 5-10 kS/cm [5].

**CONCLUSIONS**

An electrical and thermal conductive composite material based on Nb-Al$_2$O$_3$ for refractory application was developed. The refractory composite is especially suitable for heating cores in typical ceramic-based refractory applications.

## ABSTRACT

Development and utilization of novel manufacturing route for composite inert anodes containing 60:40 volumetric ratio of 316L stainless steel and MgO powder obtained from spent MgO-C lining bricks has been conducted. After burning residual carbon from recycled MgO-C powder, MgO and steel were granulated and pre-sintered in order to create agglomerates of composite material that played the role of coarse grains of composite material, hindering sintering-related shrinkage. These granules were mixed with raw steel and MgO powders in order to form dense particle distribution and subsequently cold isostatically pressed in the form of electrodes. All manufactured anode samples underwent sintering at 1350 °C and pre-oxidation under different temperatures – 800 °C, 900 °C, and 1000 °C. Mechanical and electrical properties of the manufactured electrodes were characterized. The results show that upcycling of the spent MgO-C bricks enables manufacturing of sophisticated electrode products, which can be applied in the aluminum industry.

## INTRODUCTION

Refractories are commonly used in high-temperature applications in particular, production of metal, cement, glass, and ceramics. Despite significant amounts of refractory materials being used every year, recycling of such products gained attention only during recent years, recycling rate for refractories is estimated to be only 7% of raw material demand. It is expected that recycling rate of refractory materials to have increased up to 10% by 2025. Production costs of refractory materials rise every year, as well as energy prices, moreover, necessity of environmental protection becomes more and more clear. Besides recycling of the refractory materials, another possible way to decrease disposal rate of refractories is utilization of the spent materials (ones that came to the end of their life cycle), is to produce more profound and complicated functional parts, specifically, upcycle the refractories.

In metal industry the largest part of refractories is dolomite, followed by magnesite, fireclay and bauxite. MgO-C lining bricks have been gaining more and more attention over recent decades and nowadays they are widely used in basic oxygen furnaces, electric arc furnaces, and steel ladle furnaces due to their excellent resistance to thermal shock, slag penetration, and corrosion; as well as their outstanding properties at elevated temperature. Around 40% of the original converter lining is wearing out, and approximately half of the remaining material is recyclable refractory material. According to Moritz et al., MgO-C bricks that contain recyclate perform comparatively good in comparison with the fresh MgO-C bricks in terms of thermal shock resistance, even with content of recyclates up to 80 % by mass. However, due to decrease in CMOR and RUL at high content of recyclate, such material could be suitable for applications with relatively low refractory requirements [1]. Among the application fields of MgO-containing materials that do not require outstanding refractoriness there are composite materials that were studied recently: in field of plasma resistance for semiconductors application, and in field of corrosion resistance against molten aluminium alloys. According to Malczyk et al., steel-ceramic composite material based on 316L stainless steel with addition of MgO powder after certain thermal treatment exhibited outstanding corrosion resistance against molten aluminium alloys [2], due to the formation of MgO-FeO solid solution on their surface [3]. Thus, it might be possible to utilize spent MgO-C bricks for aluminium production, where corrosion resistance is of more importance than refractoriness of the material, specifically for inert electrodes for the alumina-cryolite electrolytic cell process.

There are few metal oxides which do not co-deposit in the aluminum by electrochemical deposition or chemical displacement. Preferred metal oxides are MgO, SrO, La2O3, CaO, etc. However, these oxides have significant solubility in cryolite. Nowadays, most commonly used electrodes for production of aluminum-silicon alloys in cryolitic melts are consumable graphite anodes. Galasiu and Thonstad give comprehensive overview of inert anodes for electrowinning of aluminium [4], dividing them into three categories:

1. Ceramic inert anodes, especially based on SnO2 with doped with CuO and Sb2O3, which are being prepared from oxides and therefore do not oxidize during electrolysis.

2. Cermet inert anodes, which combine two phases: ceramic phase which is resistant to oxidation, however lacks electrical conductivity; and metallic phase added to increase conductivity. The major disadvantage of such materials is the oxidation of the metallic part during the electrolysis process.
3. Metallic inert anodes that utilize specific alloys that undergo a surface oxidation during electrolysis, forming oxide layers with low solubility in the electrolyte. The surface layer of such electrodes has to be electrically conductive and impermeable to oxygen.

There is an increasing argument that the introduction of inert anodes would have a little to none environmental benefits due to higher DC energy consumption with inert anodes. However, research studies continue in present. For production of such electrodes it is important to note that fine-grained metal ceramic composites suffer from the high shrinkage during sintering process, which drastically limits dimensions of the manufactured body. A concept of coarse-grained composite materials was recently introduced [5]: fine powders of raw materials are used to create aggregates of desired size. Such aggregates then undergo pre-sintering process, forming an analogue of coarse grains of the composite material. These sintered aggregates have already experienced shrinkage caused by sintering process. Therefore, after mixing with fine powders to form a dense body, they will significantly decrease shrinkage of the manufactured product.

This research focuses on the utilization of the crushed spent MgO-C lining bricks to manufacture cermet inert composite anodes for the aluminium cryolite electrolytic cells. Furthermore, this research studies further implementation of the novel manufacturing process, namely, pre-sintering of coarse-grains (aggregates) of composite materials in order to decrease the sintering-related shrinkage of the products. The research also includes characterization of the produced parts, including E-modulus, splitting tensile strength, electrical conductivity at room temperature, as well as

809

microstructural analysis by means of REM and EDS analysis of the manufactured electrode samples.

## METHODS AND MATERIALS

### Materials

Crashed MgO-C bricks were provided by Refratechnik Steel GmbH with particle size of 0-1 mm. For the manufacturing of the anode samples as well as for the granulate production, the finest MgO-C fraction – less than 125 μm – was sieved out and only this fraction was used throughout the whole research. Carbon content of the powder was estimated to be approximately 19.3 % by mass during the oxidation test: Nabertherm LHT 04/16 SW oven (Nabertherm GmbH, Lilienthal/Bremen, Germany) is equipped with weigh that allows to continuously measure mass of the sample during the heating process to desired temperature. 12.5 g of the sieved fine fraction of MgO-C material were slowly heated up with heating rate of 2.5 K/min until mass of the sample stabilizes (approximately 6.5 h, reaching 950 °C). Therefore, 24 h at 1000 °C was chosen as the sufficient thermal treatment to burn out all the residual carbon (conducted in Nabertherm N 20/14 ventilated oven under air). The true density of MgO powder is 3.58 g/cm3, particle size D90 < 109 μm.

The steel powder of gas-atomized 316L-FeCr18Ni10Mo3 stainless steel (TLS Technik, Bitterfeld-Wolfen, Germany) was used as a metallic part for ceramic metal composite. Chemical composition of the steel is provided in Table 1. True density of the 316L stainless steel is 7.62 g/cm3, particle size D90 < 51 μm.

Table 1. Chemical composition of the 316L stainless steel in wt.%.

| Steel | Fe | Cr | Ni | Mo | Mn | S | Al |
|-------|---------|------|------|-----|-----|------|------|
| 316L | Balance | 16.9 | 10.5 | 2.1 | 0.9 | 0.01 | 0.07 |

Carbonless recyclate powder was then used to produce steel-ceramic composite material with volumetric ratio 60 vol.% 316L stainless steel powder + 40 vol. % carbonless MgO recyclate powder. For the coarse-grain aggregates formation, granulation process was chosen. Binder material for the granulation process was water solution of the fructose syrup 70% (Gellmi, Hanseatische Zuckerraffinerie GmbH & Co. KG, Hamburg, Deutschland) in proportion 30 wt.% fructose syrup to 70 wt.% deionized water. Such binder was chosen due to the fact that fructose is environmentally friendly binder material and this correlates with the concepts of the sustainability and upcycling of the conducted research.

### Aggregates preparation

Eirich EL-1 laboratory mixer (Maschinenfabrik Gustav Eirich, Hardheim) was used to mix and to granulate the mixture of the powders of carbonless MgO-recyclate, 316L stainless steel, water and binder material. Granulation process included addition of 1 wt.% of de-ionized water and seven consecutive steps of addition of 1 wt.% of binder material, with one minute mixing at 300 min$^{-1}$ between each step, followed by granulation for 100 seconds at 600 min$^{-1}$.

After the granulation, the material was dried at 110 °C for 24 hours, with further debinding at 500 °C under air for 30 minutes in Xerion Entbinder- und Sinter Sonderofen (XERION ADVANCED HEATING Ofentechnik GmbH, Freiberg, Germany). Parameters of the debinding process were: heating rate 2 K/min to 200 °C, 0.5 K/min to 500 °C and cooling rate 0.5 K/min to 100 °C followed by free cooling to room temperature. After debinding, material was directly transferred to Xerion XGRAPHIT Hochtemperatur-Vakuum-Ofensystem sintering oven, and sintered at 1350 °C for 2 h. Sintering was conducted under argon atmosphere with heating rate 5 K/min to 1350 °C, cooling rate 5 K/min to 300 °C followed by free cooling to room temperature.

### Electrodes manufacturing and testing

Sintered granules of composite material were sieved through the sieving tower with mesh-sizes 8 mm – 6.3 mm – 3.15 mm – 2 mm – 1 mm – 500 μm – 250 μm. Small amount of sintered granulate material was embedded in epoxide and polished in order to conduct XRD analysis. Results for granulate that contains carbonless MgO were then compared to the results of XRD analysis of granulate prepared in the same way, with the same composition 60 vol.% 316L stainless steel powder + 40 vol.% MgO powder, but with fresh fused MgO powder (Refratechnik GmbH, D90 < 100 μm), used instead of recycled material.

After sieving, the sintered granulate was split into three categories, coarse particles in range 2 - 6.3 mm, medium size particles in range 0.5 - 2 mm, and fine particles containing mixture of 316L stainless steel powder with carbonless MgO recyclate powder in a respective volumetric ratio 60:40. Mass ratio coarse:meduim:fines was chosen to be 2:1:2 in order to obtain sufficient densification of the material during pressing. As a pressing aid, Zusoplast G63 (Zschimmer & Schwarz GmbH & Co KG Chemische Fabriken, Lahnstein, Germany) in an amount of 0.5 wt.% of the material mixture was added. Electrodes were pressed in a latex form with diameter 35 mm and height 155 mm under 150 MPa pressure using EPSI CIP 300-250*1000 Y cold isostatic press (Engineered Pressure Systems International NV, Temse, Belgium). After the pressing electrodes were debinded and sintered with the same thermal treatment regimes and in the same Xerion ovens as granulated composite material.

Four cylindrical specimens with height of 70 mm and diameter around 35 mm (depending on the diameter of the parts after pressing) were cut from the sintered electrodes (Fig. 1). Three specimens were pre-oxidized under 800 °C, 900 °C, and 1000 °C. Reference specimen in the as-sintered state and three pre-oxidized specimens were used for E-modulus acoustic measurement with UltraTest Ultrasonic Tester BP-700 (UltraTest GmbH, Achim, Germany) before and after oxidation process. After non-destructive E-modulus test, the same set of specimens was tested for splitting tensile strength at Toni Technik 40-4000 kN testing press (Toni Technik Baustoffprüfsysteme GmbH, Berlin, Germany). Tests were conducted with speed of 0.06 N/mm2/s according to DIN EN 12390-6.

Electrical conductivity was measured with a Keithley 220 Programmable Current Source (Keithley Instruments, Cleveland, OH, USA) and a Keithley 2000 Multimeter (Keithley Instruments, Cleveland, OH, USA) using four-point-measurement setup. Testing was performed by applying electrical currents of 1 mA, 10 mA, and 100 mA and measuring the resulting voltages. For application of the sputter coated layer of gold a Quorum Q150T ES was used. To reduce the influence of surface roughness and to ensure a continuous electrode over the whole sample surface, an additional layer of Pelco Colloidal Silver (Plano GmbH, Wetzlar, Germany) was added. For this setup, four prisms with dimension of 8 mm in height and 9 mm x 9 mm in cross-section were cut from the sintered electrode samples. A set of four prisms was prepared in the same way – reference prism in the as-sintered state and the three other prisms pre-oxidized under 800 °C, 900 °C, and 1000 °C.

Due to the fact that new MgO-FeO based phases appear on the surface of the specimens during pre-oxidation test, none of the specimens underwent grinding or polishing of the surface.
*Fig. 1: Prism for electrical conductivity test (left) and cylinder for spitting tensile test (right) prior to oxidation.*

Another set of four disks with height of 8 mm were cut from the sintered electrode. Three of the disks were pre-oxidized under 800 °C, 900 °C, and 1000 °C, fourth was used as a reference as-sintered sample. After pre-oxidation, all four disks were cut in half, embedded into epoxide and vibro-polished for REM and EDS analysis in order to estimate surface oxidation rate and depth.

## CONCLUSIONS

Spent MgO-C lining bricks after burning residual carbon can be utilized to produce inert anodes based on metal-ceramic composite with 60 vol.% of 316L stainless steel and 40 vol.% of recycled MgO material. In order to manufacture comparatively large parts, additional step of agglomerating and sintering fine powders in an analogue of coarse-grains has to be taken. Such step decreases shrinkage caused by sintering from around 4 % for fine powders up to 0.75% in length direction for mixture of fine-powders (40 wt.%) with pre-sintered agglomerates (60 wt%).

Described composite material forms protective inert oxides layer during pre-oxidation thermal treatment. Such protective layer mostly contains FeO-MgO solid solution phases. Results of the mechanical tests as well as electrical conductivity showed that the most suitable pre-oxidation temperature for the material studied is 900 °C. Anodes pre-oxidized at such temperature had electrical conductivity at the room temperature almost 150 S/cm, which lays in range of inert anodes for aluminium-cryolite electrolytic cells. Since oxide phases created during oxidation thermal treatment are semi-conductive and metal matrix composite of inner volume is electrically conductive, it is believed that at elevated temperatures conductivity of the system will decrease less compared to graphite.

The research is still ongoing, for the nearest future electrical conductivity tests under elevated temperatures and electro-chemical analysis of the results of the corrosion tests are planned.

# ENGINEERED REFRACTORY AGGREGATES COMPRISING HIGHER GRADE SHELL AND LOWER GRADE CORE

Dengrunyu Xie, Shaowei Zhang
University of Exeter, Exeter, UK

**ABSTRACT**
Aimed to save the expensive high-grade refractory raw materials and/or improve properties, in particular, corrosion resistance, of low- or medium grade refractory raw materials, a novel strategy has been proposed in this work, i.e., developing a new class of core-shell structured refractory aggregate comprising a higher grade/purer material shell and a lower grade/ less pure material. Based on this, a range of refractory aggregates with various shell and core combinations can be prepared, including, for example, alumina covered bauxite, spinel covered magnesia, higher-grade bauxite covered lower-grade bauxite, higher-grade magnesia covered lower-grade magnesia, and magnesia, $CaZrO_3$, or $CaTiO_3$ covered doloma or lime. To illustrate the feasibility of such an aggregate design/engineering strategy, in this work, a new type of aggregate with a higher-grade bauxite shell covering a lower-grade bauxite was used as a working tool. Its slag penetration resistance was tested and compared with that of the counterpart aggregate made of solely lower-grade bauxite or higher-grade bauxite. The results indicated that the conventional "naked" lower-grade bauxite aggregate exhibited the worst slag resistance whereas the core-shell structured bauxite aggregate exhibited much better slag resistance, similarly to the "naked" higher-grade bauxite aggregate.

## INTRODUCTION

As multifunctional materials, refractories are used extensively to line many important high temperature industrial vessels. Except for electrocast ones, refractory materials from powder processing typically contain large amounts of relatively large sized aggregates which are bonded together by much less amounts of fine matrix phase (Fig. 1[1]). The structure and quality of these two constituent parts have great effects on microstructure, property, and performance of refractory materials, although traditionally the matrix has been paid considerably more research attention than its aggregate counterpart. To make a refractory more corrosion resistant, highly pure high- grade raw materials are often preferentially used to make both constituent parts, which not only leads to increased production cost but also hinders the proper use of low- and medium-grade raw materials. This is actually not always necessary. As well known, in a refractory system, the matrix is much weaker than the aggregate, so when a refractory is exposed to a corrosive environment during its service, the matrix part would be attacked preferentially, after which the aggregate part which have only partially corroded will be simply washed away by the liquid slag/metal and then wasted. This has been confirmed by both lab corrosion test and post-mortem analysis of spent refractories [2 &3]. Given this, it might not be necessary to make the entire aggregates by using highly pure high-grade materials.
Based on this, a novel designing concept has been proposed in the present work, i.e., developing core-shell structured aggregates comprising a higher-grade/purer material shell and a lower-grade/less pure material core. It would be expectable that such a core-shell structured aggregate, in terms of slag corrosion resistance, would perform at least equivalently to its counterpart entirely made of the higher-grade material, and perform much better than its another counterpart entirely made of the lower-grade material. The benefits of making and using such an engineered type of aggregate are obvious, including: 1) enabling the comprehensive utilisation of low- and medium-grade raw materials; 2) leading to reduced production cost of both aggregates and refractory product; 3) applicability to a range of combinations of core and shell materials; and 4) potential in solving or alleviating some longstanding problems, e.g., hydration of doloma and lime based materials.

Several types of such core-shell structured refractory aggregates have been designed and preliminarily prepared via granulation and subsequent firing at an appropriate temperature for requisite time, including alumina covered bauxite, higher-grade bauxite covered lower-grade bauxite, higher-grade magnesia covered lower-grade magnesia, and magnesia, $CaZrO_3$ or $CaTiO_3$ covered doloma or lime. In this paper, the results from a proof-concept study on core-shell structured aggregates composed of a higher-grade bauxite shell and a lower-grade bauxite core are presented and discussed.

## EXPERIMENTAL

### Raw Materials

Two grades of bauxite powders (~45μm in size) were used as the main raw materials and pure water was used as the temporary binder for the granule formation. The higher-grade bauxite used to form the shell contained 85.7% $Al_2O_3$ (referred to as "85-bauxite") and the other lower-grade one contained about 75.8% $Al_2O_3$ (referred to as "85-bauxite"), as provided by the supplier.

### Aggregate Preparation

– Core or conventional "naked" aggregate

The bauxite powder was added to a Ø300mm disc granulator rotating at 45 rpm, and an appropriate amount (typically ~15wt% in total) of water was sprayed to assist in granules formation. The whole process, involving wetting and nucleation, consolidation and growth, breakage and attrition [4], lasted for 60 min, after which, reasonably high-quality green granules were prepared (Fig. 2).

– Core-shell structured aggregate

After sieving to remove the residual powder, the core granules made of the lower-grade 75-bauxite were reintroduced into the granulator still rotating at 45 rpm. Water was then sprayed to wet granules surface before the higher-grade 85-bauxite powder was introduced to further form the shell. The total processing time for this step was about 30min.

*Fig. 1: A schematic of typical microstructure of a refractory resultant from powder processing [1].*

*Fig. 2: A flow chart of formation process of green bauxite granules entirely made of 75-bauxite or 85-bauxite.*

– Drying and sintering process

The prepared green aggregates were left in air at room temperature for 8 h and then dried in a convection oven at 110ºC for 12 h.  The

dried aggregate samples were contained in an alumina crucible and then placed in the centre of an electronic chamber furnace. The furnace was heated at a rate of 8ºC/min to the target temperature between 1600-1650ºC and held at the temperature for 3 h.

**Corrosion Test**

– Model slag

A model slag with the composition shown in Table 1 was prepared using reagent-grade $CaCO_3$, $MgCO_3$, $Al_2O_3$, $Fe_2O_3$, and $SiO_2$ powders which were pre-mixed in a ball-mill for 3h. The resultant mix was then fired/melted at 1450ºC for 1 h to form the model slag.

Tab. 1: Batch Composition of Model Slag

| Oxide | $Al_2O_3$ | $SiO_2$ | CaO | $Fe_xO$ | $CaO/SiO_2$ |
|---|---|---|---|---|---|
| Content (wt%) | 13.72 | 25.8 | 35.57 | 19.21 | 1.38 |

– Slag test

As-prepared aggregates were placed into an alumina crucible containing premelted slag (aggregate:slag=1:3 (weight ratio)) and heated at 10ºC/min to 1450ºC and held for 1 h before cooling to room temperature at 10ºC/min.

**Microstructural Characterisation and Slag Resistance Evaluation**

The aggregates before and after the corrosion test were mounted in cold-setting epoxy resin, and then ground and polished using different grades of SiC grinding paper and diamond paste. After chromium coating, the cross-sectional microstructures of the aggregate samples were observed by using a scanning electron microscope (SEM) linked with an Energy Dispersive X-ray Spectroscope (EDS). To assist in the phase identification and slag resistance comparison, apart from secondary electron image (SEI), backscattered electron image (BEI) was taken, along with EDS. Based on the SEIs and BEIs, and correspondong EDS, the slag penetration depth was evaluated.

**RESULTS AND DISCUSSION**

**Microstructure of As-prepared Aggregates**

Fig. 3, as an example, shows the low magnification image of an individual aggregate composed of a higher-grade 85-bauxite shell and a lower-grade 75-bauxite core. The shell appeared to be continuous and the core appeared to be homogeneous, and both were overall integrated well, showing no obvious gap between them, though some pores were seen at their interface. As the main purpose of the present work was to compare the relative slag resistance of the three types of aggregates. No further detailed phase and microstructural characterisation on high magnification was carried out at this stage.

Fig. 2: Low magnification SEM image of an individual fired aggregate composed of an 85-bauxite shell and a 75-bauxite core.

**Corroded Microstructure**

Fig. 3 shows SEM images of the three corroded aggregate samples. The part on the left was the residual slag, and that on the right was the corroded aggregates. To reveal more clearly the slag penetration into the aggregate samples, the corresponding EDS mapping of Ca

element (indicated by pink coloured spots) is also shown together with (overlapped with) the microstructural images (Fig. 3). As seen from Fig. 3a, slag Ca penetrated most deeply into the "naked" 75-bauxite aggregate, with a penetration depth of ~230µm. However, the aggregate sample comprising an 85-bauxite shell and a 77-bauxite core, and the "naked" 85-bauxite aggregate suffered from much less slag penetration, with a similar penetration depth of <100µm. These results suggested that a core-shell structured aggregate comprising a higher-grade material shell and a lower-grade material core could have a much better slag resistance than an aggregate comprising solely the lower-grade material, and perform equivalently to its counterpart comprising entirely the higher grade material, confirming preliminarily the feasiblity of the strategy proposed in this work, although lots of future work are still required to verify it further.

Fig. 3: SEM images (along with EDS mappings of Ca element) of corroded microstructures: a) "naked" 75-bauxite aggregate; b) "naked" 85-bauxite aggregate; c) core-shell structured aggregate comprising an 85-bauxite shell and a 75-bauxite core.

813

## CONCLUSIONS

In summary, a novel designing strategy has been proposed for the first time for developing new types of core-shell structured aggregates comprising a higher grade/purer material shell and a lower grade/less pure material core. A proof-concept work was carried out by using aggregate composed of a higher-grade bauxite material (85-bauxite) shell and a lower-grade bauxite core (75-bauxite) as a working tool. Such core-shell structured bauxite aggregates were prepared via granulation and subsequent high temperature firing. To compare, aggregates entirely made of the lower-grade bauxite or higher-grade bauxite were also prepared. These three types of as-prepared aggregates were exposed to a model slag with a CaO/SiO$_2$ of 1.38 at 1450°C for 1h, and their slag resistance were evaluated and compared. The results indicated that after 1h slag attack at 1450°C, the "naked" lower-grade bauxite aggregate suffered from the most severe slag penetration (up to ~230μm), whereas the core-shell structured bauxite aggregate suffered from much less penetration, performing equivalently/ similarly to its "naked" counterpart comprising solely the higher-grade bauxite. These results confirmed preliminarily the feasibility of the proposed aggregates design strategy, although lots of future work be still required to verify it further.

## ABSTRACT

Magnesium aluminate spinel (MAS) based refractories are widely used in the linings of high temperature industrial equipment because of their special performance. In this study, MAS powder, flake graphite, silica powder, phenolic resin and an iron-containing catalyst were used as main raw material for the preparation of whiskers and crystal carbon by *in-situ* chemical vapour deposition (CVD) at 1273 K for 3 h in a reducing atmosphere. The results showed that the carbon content of samples increased by 4%, their porosity after heat treatment decreased by 4%, and their modulus of rupture increased by 10%. Additionally, their cold compression strength (CCS) increased by 10%. In high-temperature performance investigations, the reinforced samples exhibited no cracks after five cycles of thermal shock resistance testing and the cold compression strength retention rate was 93%. The hot modulus of rupture of trial samples increased by about 8% compared to standard ones. The results of the study could be extended to commercial use and the applied method increase the performance of products.

## INTRODUCTION

In the process of steel smelting, slag and molten steel are the two most common corrosive components that are in direct contact with refractory materials. MAS based refractories are used in the lining of high temperature industrial equipment such as ladles, electric furnaces, and cement rotary kilns due to their high hardness, high mechanical strength, good thermal shock resistance and excellent slag corrosion resistance [1]. Besides, MAS enhanced material has been used in flow control refractories recently because of its better performance than that of original alumina-based refractory [2][3]. With the development of the steel industry, longer service life and lower material cost are required and become a target for all refractory practitioners [4].

As a kind of inorganic non-metallic material, refractory material can improve its strength in a similar way than other types of ceramic. In MAS-based carbon-containing refractories designed for the steel industry, fibre-strengthening has been widely researched for achieving better performance. A commonly used strengthening method for carbon-containing refractories is characterized by catalytic formation of whiskers and carbon nanotubes (CNTs) whereas the catalysts are various compounds of members of the iron group (Fe, Ni & Co) [5]. However, different heat treatment processes and carbon sources lead to gaps in the understanding of the mechanism of fibre-reinforced MAS-based refractories [6].

In this study, a phenolic resin and an iron-group compound were used as carbon source and catalyst, respectively. The sample investigation focused on the formation of whiskers and other fibre-structured matter and the MAS-based refractories' physical and chemical properties. Results of the study indicate the opportunity of using fibre-reinforced refractories for continuous casting in the steel industry.

## EXPERIMENTAL METHOD

### Experimental material

All raw material used in this study were sourced from local enterprises. Table 1 and 2 show their typical physical and chemical properties. In general, samples were prepared by using fused MAS, anti-oxidation additives, graphite, and phenolic resin. The catalysts used stem from iron-group elements among which an iron-type was predominantly chosen due to being eco-friendly when compared to other choices.

Table 1: Typical chemical properties of a refractory sample [wt.%]

| Item | $SiO_2$ | $Al_2O_3$ | MgO | C | LOI |
|---|---|---|---|---|---|

### Experimental methods

*Mixing and forming*

At the beginning of the experimental session, a quantitative study was necessary to determine the optimal catalyst content in the resin. Previous research has shown amounts of about 1 wt. % of the resin by molar mass calculation seem to be appropriate. Hence, in this study, the catalyst's molar mass content was designed to be 0.5%, 0.75%, 1% and 1.25% of the resin mass to investigate the material properties and to determine the quantity of catalyst. In addition, a standard batch with no catalyst was prepared for comparison. The catalyst was added to the resin and stirred after being fully dissolved in water.

All raw material was dosed into the mixer for high-speed mixing. The mixing process could be divided into dry mixing with no resin and wet mixing after dosing the resin. The resin was preheated to a certain temperature for better fluidity. To investigate the property differences between standard and catalyst-containing grade, all mixing parameters were kept the same. The material was tested on the day of mixing and 24 h after mixing for green properties, then isostatically pressed into a standard design test stopper.

*Heat treatment*

The subsequent heat treatment was the same for all trial samples and could be divided into two parts. First, the green test stopper was cured in a kiln at 515 K for inducing initial strength by the reaction between resin and hexamine. Afterwards, samples were fired in a shuttle kiln at 1273 K.

*Sample investigation*

Cold modulus of rupture (CMoR) and cold compression strength (CCS) were measured by using standard device equipment, bulk density (BD) and apparent porosity (AP) were measured by vacuum method under water (ISO 18754:2020).

X-ray fluorescence (XRF) and loss on ignition (LOI) were used for element determination and carbon content. Besides, Energy Dispersive Spectroscopy (EDS) and X-ray diffraction (XRD) were also used to determine the phase of samples. For microstructural investigations, scanning electron microscopy (SEM) and transmission electron microscopy (TEM) were used as techniques.

For use in continuous casting, the performance of all products in a high temperature environment needs to be investigated. Therefore, thermal shock resistance (TSR) testing and hot modulus of rupture (HMoR) were applied. The TSR followed a national standard cycle test method which requires a 20 min-heating of samples at 1373 K, then cooling for 10 mins in water at 298 K and subsequent drying for 5 mins in air at 298 K. In addition, the CCS of samples after the TSR test were also used for a comparison with standard samples to monitor the situation between heats during casting.

## RESULTS AND DISCUSSION
### Chemical properties
The chemical analysis of all investigated samples with and without catalyst revealed no significant difference among them (Fe-catalyst 0.50%-1.25%). However, samples with catalyst showed a higher LOI and a lower mass loss than standard samples without catalyst. The details are listed below in Table 3.

Table 3: Chemical properties of samples [wt.%]

| Item | Standard sample | Sample with 0.5% Fe-catalyst | Sample with 0.75% Fe-catalyst | Sample with 1.0% Fe-catalyst | Sample with 1.25% Fe-catalyst |
|---|---|---|---|---|---|
| $SiO_2$ | 4.58 | 4.52 | 4.56 | 4.49 | 4.65 |
| $Al_2O_3$ | 72.37 | 71.98 | 72.87 | 72.49 | 72.61 |
| MgO | 22.16 | 22.43 | 22.19 | 22.30 | 22.81 |
| C | 13.00 | 13.32 | 13.31 | 13.17 | 13.39 |
| LOI | 11.74 | 11.81 | 12.31 | 12.14 | 12.08 |
| Mass loss | 3.72 | 3.67 | 3.53 | 3.59 | 3.61 |

Samples with catalyst appeared to have a higher carbon fixation than those without catalyst.

### Physical properties
*Physical properties at room temperature*
The investigation showed that properties like AP, CMoR and CCS were optimised when catalyst amounts of 0.75 and 1% were used, whereas bulk density results remained within the margin of error of measurements (table 4). All samples with catalyst had a lower AP and better mechanical properties compared to standard ones, which indicates their potential superior performance in slag resistance and long-life casting.

Table 4: Room temperature physical properties of samples

| Item | Standard sample | Sample with 0.5% Fe catalyst | Sample with 0.75% Fe catalyst | Sample with 1.0% Fe catalyst | Sample with 1.25% Fe catalyst |
|---|---|---|---|---|---|
| BD, g/cm³ | 2.71 | 2.69 | 2.70 | 2.69 | 2.68 |
| AP, % | 16.25 | 16.24 | 14.51 | 14.28 | 15.95 |
| CMoR, MPa | 5.61 | 6.32 | 6.48 | 6.53 | 6.81 |
| CCS, MPa | 20.35 | 22.57 | 22.83 | 23.59 | 22.63 |

*Physical properties at high temperatures*
Results of high temperature investigation showed that the CCS of samples before and after the TSR treatment was significantly higher than for samples without catalyst. Higher CCS values of catalyst samples even persisted after the TSR test. HMoR tests revealed an optimal catalyst amount of 0.5% and 0.75%, respectively. Details of the high temperature physical properties are listed below in Table 5.

Table 5: High temperature physical properties of samples [MPa]

| Item | Standard sample | Sample with 0.5% Fe catalyst | Sample with 0.75% Fe catalyst | Sample with 1.0% Fe catalyst | Sample with 1.25% Fe catalyst |
|---|---|---|---|---|---|
| CCS before TSR | 20.21 | 22.39 | 22.49 | 23.37 | 21.48 |
| CCS after TSR | 19.82 | 21.45 | 21.11 | 21.88 | 19.98 |
| HMoR | 5.13 | 5.53 | 5.53 | 4.87 | 5.01 |

### Phases and microstructure
*Phase investigation*
Phase investigation by XRD revealed expected mineral phases like MAS, graphite and antioxidant (Fig.1).

*Fig. 1: XRD results*

*Microstructural investigation*
All samples were analysed by means of SEM and TEM. Results as summarized below:

- No fibre structure and crystalline carbon appeared in samples without catalyst (Fig. 2).

*Fig. 2: TEM images of samples with no catalyst*

- All samples with catalyst exhibited a whisker structure. By means of EDS, the whiskers were identified as MAS-whiskers.

*Fig.3: TEM result of samples with 0.75% Fe-catalyst*
*Fig.4: Mapping results of samples with 0.75% Fe-catalyst*

The TEM and EDS results indicate that a large amount of iron was enriched at the bottom of the whiskers. It was assumed that the MAS whiskers were generated after heat treatment at 1273K, and catalyst nanoparticles reduced the activation energy of the whiskers' nucleation. The whiskers in matrix could act as bridge in the refractory material matrix and reduce its porosity, which means they would not only improve the mechanical strength of the material but also its refractoriness and resistance during casting. The carbon fixed in the matrix was identified as crystalline carbon (Fig. 5 and Table 6).

*Fig. 5: TEM image of crystalline carbon*

Table 6: crystalline carbon [wt.%]

| Element | C | O | Si | Al | Mg |
|---|---|---|---|---|---|
| Atomic concentration percentage | 59.89 | 24.00 | 10.33 | 4.61 | 1.17 |

The use of the Fe-catalyst improved the residual carbon rate of the resin via *in-situ* chemical vapour deposition (CVD) and transformed it to crystalline carbon. Fine crystalline carbon could be considered as an additional phase that was well distributed in the matrix. Moreover, it may also play a role in high-temperature melt resistance by lowering the AP of materials. Future investigations will also focus on the role of the crystalline carbon.

## CONCLUSIONS

The *in-situ* catalysis as described can be used for the formation of MAS-whiskers and crystalline carbon in the matrix of carbon-containing refractories. The mechanism of catalysis and strength improvement of refractories were analysed and explored, respectively. The assumption was made that whiskers and crystalline carbon from *in-situ* catalysis and CVD may deflect microcracks, thus improving the strength of refractory material. Moreover, the whiskers deposited in the matrix might delay crack formation. The well-distributed crystalline carbon in the matrix may also act as material reinforcement (Fig. 6). Both factors combined led to an improvement of mechanical properties at room and elevated temperature. Moreover, improved mechanical properties will have a better resistance to material washout during casting.

*Fig. 6 Schematic of strengthening mechanism*

During casting, the Marangoni effect [7] can lead to the erosion on the boundary of steel, slag and refractory, especially in carbon-containing refractories. Also, alkali metal can infiltrate into the matrix with pores, which leads to an expansion during new phase formation and structure peeling from matrix to grains [8]. A matrix with whiskers and crystalline carbon could better withstand the wash-out from the structure. In addition, low porosity means less infiltration by alkali metal vapor and lower volume expansion thus increasing the product's life expectation during continuous casting.

## ABSTRACT

Compositionally Complex Ceramics (CCC) are a relatively new class of materials with promising properties, including strong corrosion stability. Therefore, CCC are interesting for corrosion-resistant coatings. CCC are an extension of the also quite new material class of High Entropy Ceramics (HEC) and extend them by medium entropy and non-equimolar compositions.

As part of the EU project FORGE, a corrosion-resistant CCC coating has been developed for refractory materials in a continuous roller kiln for firing ceramic tiles. The development was based on a combination of Machine Learning (ML) assisted high throughput material development. A large number of bulk samples with different elemental compositions were prepared from oxide powder mixtures to form medium or high entropy ceramics. The CCC were sintered and subsequently characterized by XRD, CT, SEM and EDS. The results from the CCC development were then transferred to the development of a corrosion-resistant coating. The coatings were applied on refractory bricks using a slurry coating technique. Corrosion tests were carried out on coated refractories under laboratory conditions, but also directly in the kiln. The results of the corrosion tests are presented.

## INTRODUCTION

Compositionally Complex Ceramics (CCC) were first proposed in 2020 by Wright et al. as an extension of the new material class, the High Entropy Ceramics (HEC) [1, 2].

The HEC are defined as single-phase ceramics consisting of at least four different anions or cations in equimolar composition [3, 4]. In their unit cell, the same number of different elements is uniformly distributed. As a result of the high number of different elements in the unit cell, the configurational entropy is maximized leading to an additional stabilization of the equimolar mixture [4]. The first HEC was produced in 2015 from the oxides MgO, NiO, CoO, CuO and ZnO and had a rocksalt structure [4, 5]. In addition to oxides, HEC can also be produced from borides, carbides, nitrides, boron carbides, carbonitrides, sulfides and fluorides, and in addition to the rocksalt structure, spinel, perovskite, fluorite, pyrochlores, bixbyite, rutile and garnet are also potential structures for HEC [1, 6, 7].

The reason for the increased interest in HEC is their unique properties, such as high hardness, high lithium-ion conductivity, tunable magnetism, high dielectric constant and low thermal conductivity [1, 8, 9]. As a result, there is a large number of potential applications for HEC, such as the use as catalysts, as battery materials, in thermoelectronics, as thermal barrier coatings and as wear and corrosion resistant coatings [4, 10].

As noted above, CCC are an extension of the HEC. Besides high entropy compositions, the CCC also include medium entropy compositions with non-equimolar compositions [1]. This allows an even broader range of possible compositions and thus the potential for a more specific adjustment of the various properties that can be achieved by entropy stabilization [1]. Compared to the HEC, the CCC can achieve further improved properties, such as lower thermal conductivities or better mechanical properties [2, 11]. Due to the wide range of applications and outstanding properties of CCC, they are a promising area for the development of new materials.

In the EU project Forge, CCC coating materials have been developed for the use as corrosion protective coatings on refractory bricks for an industrial gas-fired roller kiln for ceramic tiles. Corrosive atmospheres occur in this kiln at temperatures between 650 °C and 1200 °C, which lead to impairment of the refractory bricks, as can be seen in Figure 1. In some parts of the furnace a protective coating mainly composed of zirconia is applied on the refractories. However, corrosion due to combustion gases and gases coming from the decomposition of the ceramic product was observed in all refractories, with and without protective coating. The corrosion is mainly attributed to Na and K cations and Cl and $SO_3$. As corrosion advances, delamination of the refractory materials occurs, and small pieces and dust fall onto the tiles, causing defects in the fired product.

*Fig. 1: Appearance of a JM26 wall refractory after operating at 1185°C for 5 years.*

Due to the corrosion, regular maintenance of the roller kiln is necessary to replace the wall and vault refractory bricks. This means long downtimes and also high energy consumption due to the slow start-up of the relatively large kiln. A suitable coating for corrosion protection can ensure that the refractory bricks have a longer service life and thus the kiln has longer periods of use; currently applied state of the art coatings do not yet achieve the expected improvement.

In the following, the results of the development of CCC with a spinel crystal structure for the use as a corrosion protection coating will be presented. The properties of the CCC coatings, such as corrosion resistance, coefficient of thermal expansion etc. are adjusted in such a way that the service life of the refractories in the roller kilns will be significantly increased. To achieve this, the development was done with high throughput experiments combined with machine learning to narrow down the wide range of possible elements and compositions to find a suitable coating material for refractory bricks.

### CCC development using machine learning

Oxide CCC with spinel structure should be produced using the elements that are already present in the kiln. This means that the elements of the refractory materials as well as elements present in the furnace atmosphere are responsible for the corrosion. A screening for possible cations in literature and databases was done for oxide spinels. The candidates obtained were narrowed down to cations with similar ionic radii. The restriction to equal ionic radii was made because it is known that HEC and CCC form preferentially with equal ionic radii of the individual cations [6]. For the selection of the cations, availability, price and environmental compatibility were also considered. The following cations were selected:

Li, Mg, Al, Si, Ti, Cr, Fe, Cu, Zn, Sn

The CCC coatings are designed to protect the refractories from corrosion at high temperatures. Therefore, the coating material must meet several requirements. These include corrosion stability in the furnace process, matching coefficient of thermal expansion CTE to the aluminosilicate refractory materials JM23 and JM26, high temperature stability, phase stability, chemical compatibility with the refractory materials etc.

In order to find a previously unknown material from a very large compositional range of elements that covers all these properties, high-throughput experiments were combined with machine learning. Since CCC is a relatively new field, there is only a limited amount of published data available. For this reason, the ML was first trained with information from the literature and databases (COD) on normal spinels and in a later step with experimental data on CCC spinels [12-19].

In parallel to setting up an ML model, high-throughput experiments were carried out. For this, however, the CCC were not prepared as coatings but as bulk samples. This was done to save time time for sample preparation and characterization. Based on the experimental and the ML results, one material was later selected for testing as a coating. Starting from the selected cations, an experimental matrix was set up for all possible compositions, with the following preconditions:

- The charges of the cations are balanced to give an AB$_2$O$_4$ type spinel
- Each variant consists of at least 6 cations
- Cation amounts are multiples of 0.25 mole-%

This resulted in a matrix of 22,236 compositions. 67 compositions were randomly selected from the matrix for preparation, following the processing steps shown in Figure 2. Oxide or hydroxide powders were used as starting material. These were first milled to a mean particle size of d$_{50} \leq 5$ μm. Subsequently, the milled powders were weighed and mixed in a SpeedMixer® according to the experimental matrix. After mixing, the powders were pressed into compacts. For a good pressing result and to protect the pressing tool from abrasive wear, pressing aids were added. The samples were pressed with 5 tons to samples with a diameter of 15 mm. The sintering was carried out in a batch furnace up to 1500 °C. The heating rate was 2 K/min, the dwell time was 1 hour and the cooling rate was 5 K/min. During the sintering process, the samples were placed on ZrO$_2$ sand.

*Fig. 2: Processing steps for CCC sample preparation.*

The crystal phases of the sintered CCC samples were analyzed using an X-ray diffractometer (XRD, SmartLab, Rigaku, Japan) with CuKα radiation. Figure 3 shows exemplary diffractograms of two samples with different compositions.

*Fig. 3: X-ray diffractograms of CCC samples with different compositions: Al$_{0.5}$Si$_{0.5}$Ti$_{0.5}$Cr$_{0.25}$Fe$_{0.25}$Cu$_{0.5}$O$_4$ (left) and Si$_{0.25}$Ti$_{0.5}$Cr$_{0.5}$Fe$_{0.5}$Cu$_{0.5}$Zn$_{0.5}$O$_4$ (right) after sintering at 1500 °C.*

The sample in Figure 3 on the left with the composition Al$_{0.5}$Si$_{0.5}$Ti$_{0.5}$Cr$_{0.25}$Fe$_{0.25}$Cu$_{0.5}$O$_4$ consisted of multiple phases after sintering. In contrast, the sample with composition Si$_{0.25}$Ti$_{0.5}$Cr$_{0.5}$Fe$_{0.5}$Cu$_{0.5}$Zn$_{0.5}$O$_4$, in Figure 3 on the right, is composed only of spinel. I.e., a CCC with the spinel structure can be successfully obtained by using the right composition. The phase content was determined for all 67 prepared samples by Rietveld analysis using the SmartLab Studio II program (Rigaku, Japan). The samples were then evaluated for their degree of spinel formation. Hereby, a total of 32 samples showed a spinel content of more than 95 %. The spinel contents for a selection of the samples are shown in Figure 4.

In addition, the CTE was measured from room temperature to 1200 °C or until softening using a push rod dilatometer (NETZSCH DIL 402 C, NETZSCH-Gerätebau GmbH, Germany). This evaluation was focused on selected compositions with a spinel content of > 95 %. Figure 4 shows the CTE from room temperature up to 1000 °C and up to 1200 °C for a selection of the 67 samples prepared. Part of the samples showed softening above 1000 °C. For these specimens, no CTE could be determined for 1200 °C. In this case, an "x" is shown. As can be seen, the different spinel compositions show a wide range of CTE values. This means that spinels are available for different types of substrates with different expansion behavior. This is often a problem, as the difference in the CTE of the coating and the substrate should be $\leq 1 \times 10^{-6}$ K$^{-1}$. The composition Mg$_{0.5}$Al$_{0.5}$Si$_{0.25}$Ti$_{0.5}$Fe$_{0.5}$Cu$_{0.5}$O$_4$ is highlighted in green, because its CTE is closest to that of the refractory material used in the industrial roller kiln.

| Composition Oxides | 95-100% Spinell | CTE 1000 °C [10$^{-6}$ K$^{-1}$] | CTE 1200 °C [10$^{-6}$ K$^{-1}$] |

*Fig. 4: Spinel phase fraction and CTE of CCC samples with different compositions.*

The experimental results together with literature and database information were used to train the ML to predict spinel formation, as mentioned above.

*Fig. 5: Selected physical input parameters for ML.*

Compositional data and physical properties of the spinel components were selected as design parameters. Out of 22 possible physical properties, 10 physical properties were selected, because

they showed minimum intercorrelation. The 10 selected physical properties are shown in Figure 5.

Besides the ML-model for predicting spinel formation, an additional ML-model was set-up to calculate the CTE of the spinels. However, in the experimental tests, only 26 samples of the 32 spinels were found without a softening up to 1200 °C. Because of this limited number of data, a simple linear model with the squared error as the cost function was used to predict the CTE. Despite these limitations on the input data, a good accuracy of $0.81 *10^{-6}$ $K^{-1}$ was achieved (see Figure 6).

*Fig. 6: CTE machine learning model precision graph.*

The two ML models were then used to calculate new compositions for the CCC. In this context, a CTE between $5 *10^{-6}$ $K^{-1}$ and $6 *10^{-6}$ $K^{-1}$ and the highest possible spinel phase fraction of at least 94 % should be obtained. The predicted compositions are shown together with their predicted spinel phase fraction and CTE and their experimentally determined values in Figure 7. It was found that a relatively high proportion of spinel was formed in all samples, confirming the high quality of the developed ML model. A comparison of the predicted and the measured CTE (performed only for compositions with more than 95 % spinel) also showed good results, although only limited data was available for ML training. This model can probably be further refined with additional experimental data.

*Fig. 7: ML predicted compositions with predicted and measured CTE and spinel content.*

To facilitate future CCC development, two API assisted tools were developed to calculate the probability of spinel phase formation for a given composition on the one hand and its coefficient of thermal expansion on the other hand. These two methods were then combined in one tool to retrieve a specific composition with the respective amounts of preselected cations to achieve a given target CTE.

Corrosion tests based on the elements in the gases coming from the decomposition of the ceramic product were carried out on all samples. For this purpose, a compound consisting of the elements K, Na, Cr, Fe and Zn was applied to the specimen top surface. The prepared samples were placed in a batch oven and heated to 1200 °C at a heating rate of 5 K/min. The dwell time was 10 h. After heat treatment, the samples were characterized by CT, SEM and EDS. It should be noted, that a very high amount of the different cations was applied to the samples to accelerate possible reactions, since the samples were exposed to short dwell times compared to the roller kiln. Figure 8 shows examples of SEM images of a corrosion resistant and a corroded material. No significant vi-sible changes in the microstructure were detected in the sample with the composition

$Mg_{0.5}Al_{0.5}Si_{0.25}Ti_{0.5}Fe_{0.5}Cu_{0.5}O_4$, even directly below the position where the corrosion compound was placed. In comparison, a sample with the composition $Al_{0.25}Si_{0.5}Ti_{0.5}Cr_{0.25}Sn_{0.5}Li_{0.5}O_4$ and without spinel phase, thus no CCC, is shown in Figure 8 on the left. In this case, a clear change in the microstructure was observed, indicating insufficient corrosion stability.

*Fig. 8: SEM images of CCC samples after a corrosion test up to 1200 °C.*

Of all the samples available, the CCC with the composition $Mg_{0.5}Al_{0.5}Si_{0.25}Ti_{0.5}Fe_{0.5}Cu_{0.5}O_4$ showed the best properties for the application as a coating material. The CCC meets the essential requirement that the coefficient of thermal expansion of this material is within the range of the CTEs of the substrates. The CTE of the CCC is $6 *10^{-6}$ $K^{-1}$. The CTE of the refractories JM23 and JM26 are $5 *10^{-6}$ $K^{-1}$ and $7 *10^{-6}$ $K^{-1}$, respectively. Due to the low deviation of the CTE, the CCC material is suitable as a coating for the refractory bricks. In addition, the CCC also showed no signs of corrosion in the lab corrosion test. Therefore, coatings were made from this material and are presented below.

**CCC coating application**

The coatings were applied by slurry spray coating. Various wall and vault refractory materials which are used in the ceramic kiln were coated. Figure 9 shows a wall and a vault material, respectively, and also the coating process.

*Fig. 9: Refractory materials and coating application procedure.*

Initially, a water-based CCC slurry for the oxide mixture $Mg_{0.5}Al_{0.5}Si_{0.25}Ti_{0.5}Fe_{0.5}Cu_{0.5}O_4$ was developed for its application on the refractory substrates. The raw materials for the selected composition were milled and mixed. To achieve stable slurries with defined rheological properties the viscosity and flow behavior was adapted for spraying using different dispersants and binders. The slurry stabilized in this way was applied to the substrates by spraying followed by subsequent drying and sintering.

Coatings without any cracking could be applied, dried and sintered in the case of the vault material by spraying and sintering at 1200 °C with a dwell time of 10 h. In the case of the wall material, an additional bond layer had to be developed and applied to the substrate. Otherwise, the coating thickness was too inhomogeneous due to the high surface roughness and the open porosity of the refractory material. By application of the bond coat, the open porosity was closed and a smoother surface could be achieved. The bond coat itself could be applied without any problems. Afterwards, the spray coating was greatly improved and only small cracks were detected after drying and sintering at 1200 °C with a dwell time of 10 h.

**Corrosion test in roller kiln**

After the successful application of the CCC coatings, their performance should be tested under real operating conditions in an

industrial roller kiln for production of ceramic tiles. For this purpose, the samples were prepared on a laboratory scale. The kiln and the samples placed in the kiln for testing are shown in Figure 10. The CCC coated samples are compared with uncoated refractory samples. As soon as the test phase is completed, the samples will be removed from the kiln and analyzed. In parallel, the coated samples will be subjected to thermal cycling tests, because the refractories are affected by thermal cycles that occur every time the kiln is heated up and down, and also when there is a gap in the production rate that causes some disturbances on the thermal stability of the kiln.

According to the results of the lab scale samples, the coatings will be applied and sintered directly in the furnace for further testing.

*Fig. 10: Industrial roller kiln and coated samples that were introduced into the kiln.*

## CONCLUSIONS

A Compositionally Complex Ceramic coating was developed for refractory bricks of a roller kiln.

It was possible to prepare CCC materials with spinel structure by using a simple powder mixing route. In addition, the development of an ML model to estimate the probability of spinel formation for ceramics and a linear model to estimate the CTE could be implemented. The ML models are used in a distributed computing backend that can be accessed via a REST API (https://forge.aeonx.ai/docs).

The sample with the composition $Mg_{0.5}Al_{0.5}Si_{0.25}Ti_{0.5}Fe_{0.5}Cu_{0.5}O_4$ was identified as a suitable material for the use as a protective coating for the refractories. A spinel was formed without significant other phases and the coefficient of thermal expansion was $6 *10^{-6}$ $K^{-1}$. Therefore, a CCC was formed with a CTE to match the refractories. In addition, laboratory corrosion tests showed no signs of corrosion of this material.

Water-based slurries for applying a CCC coating with the composition $Mg_{0.5}Al_{0.5}Si_{0.25}Ti_{0.5}Fe_{0.5}Cu_{0.5}O_4$ by spraying were successfully prepared and applied on refractories. However, it was found that bond coats are required for the application of spray coatings on the wall refractory with relatively high open porosity. The coatings are tested under real operating conditions in an industrial roller kiln.

## ABSTRACT

This work addresses a novel approach to improve the dispersion of nano $MgCr_2O_4$ and MWCNT- $Al_2O_3$ nanocomposite additives by functionalizing with silanol groups in Mag-chrome and Alumina-C refractories, respectively. In this way, Firstly, surface of nano additives have been modified with 3-(thriethoxsilyl) propyl amine (APTES) silanol group. Afterwards, 1% wt of nano additives (with and without functionalizing with silanol group) were added to matrix and compressed under a uniaxial press. Mag-chrome refractories were treated at firing temperature between 1400 and 1600 °C, and the firing temperature of Alumina-C refractories were 1450°C under reduced atmosphere. The presence of the silanol groups on the nano additives was approved by XRD, FTIR, and UV-visible spectroscopy. The physical and mechanical properties, such as permanent linear change, bulk density, apparent porosity, Cold crushing strength, and hot modulus of rupture were determined according to DIN standards. The results indicated that the surface modification and well distributed nano additives through the matrix of refractories not only promoted the secondary spinel phase formation in Mag-Chrome refractories, but also increased SiC formation in Alumina-C refractories. The mentioned phase formation increased CCS (from 886 kgf/cm$^2$ to 997 kgf/cm$^2$) and HMOR increased (from 57.5 kgf/cm$^2$ to 59.5 kgf/cm$^2$) of Mag-chrome sample due to higher secondary spinel formation. Also, it reduced 200°C of sintering temperature. In Alumina- C samples the CCS increased from (1370 kgf/cm$^2$ to 1560 kgf/cm$^2$), and HMOR (from 60 to 75 kgf/cm$^2$) due to promotion of higher SiC whiskers formation.

Keywords: Dispersion, Mag-chrome, Alumina-carbon, Nano Composite

## INTRODUCTION

Magnesia-chrome refractories have many potential uses including non-ferrous furnace linings, cement kiln linings and secondary metallurgy applications due to their high-temperature stability, low thermal expansion, and outstanding erosion-corrosion performance at high temperatures. Also, $Al_2O_3$-C refractories have been widely used as functional materials in a continuous casting process of iron and steel industry due to their excellent mechanical properties, thermal shock resistance, and corrosion resistance. However, despite these positive features in both refractories , a main drawback is their high sintering temperature and low mechanical properties specially at high temperature. This disadvantages could be solved by the use of suitable Nano-additives. Aneziris et al. [1] and Luo et al. [2] found that $Al_2O_3$-C refractories containing carbon nanotubes (CNTs) revealed better mechanical properties than those without CNTs. These achievements of superior properties originated from a combination of the nature of various nanocarbons and the in situ formation of ceramics in the specimens [3]. Azhari

also reported enhanced mag-chrome direct bonding in the presence of nano-sized iron oxide and attributed the enhancement to a drop-down in the liquid silicate phase viscosity, facilitating solid-state sintering and the formation of magnesioferite spinel at a lower temperature [4]. Despite many researches have been done in the field of nano additives of Oxide and Oxide-C refractories, there are two main problems with the use of nano additives: (1) the high-cost of their synthesis, and (2) the difficulty of homogeneously dispersing them in the refractory matrix. The first problem can be overcome by choosing a simple and inexpensive process such as the citrate-nitrate route as well as the lower consumption of nano materials. But the second problem requires a novel solution; one possibility is to functionalize the nano-additives with silanol groups. The use of silane groups to assist the dispersion of various nano-additives has previously been reported. Sabzi [5] used amino propyl triethoxy silane to modify the surface of $TiO_2$ nano-particles and reported their improved dispersion and mechanical properties. Dincer et.al [6] modified the surface of nano-$Fe_3O_4$ using various silane compounds and showed that the presence of silanol groups on the surface of the nano-particles could stabilize them and decrease their tendency for agglomeration. In another study, Peng [7] modified carbon nanotube particles with (3-aminopropyl) triethoxysilane (APTES) and reported the improvement of dispersion and chemical bonding in ceramic bodies based on the above literature [5-7].

The present study was undertaken to functionalize nano-$MgCr_2O_4$ and MWCNT-$Al_2O_3$ nanocomposite with silanol groups in order to facilitate its dispersion into a magnesia-chrome and Alumina-c matrix. Moreover, the effect of surface silanol treatment on the physical properties, mechanical properties and microstructure changes were investigated.

## EXPERIMENTAL PROCEDURE

### Functionalization of $MgCr_2O_4$ and MWCNT-$Al_2O_3$ nanoparticles

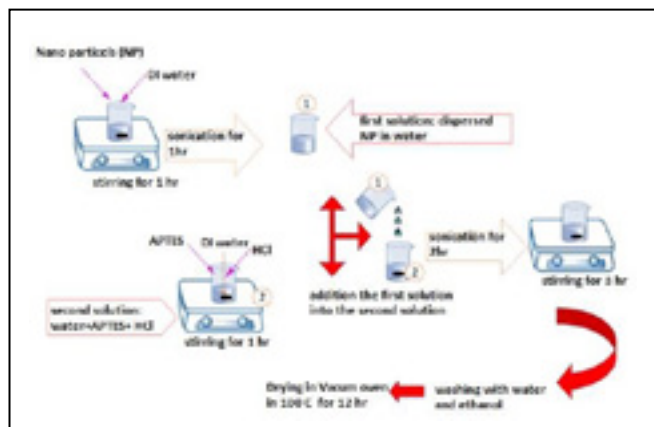
The $MgCr_2O_4$ nano-spinel particles were synthesized by the solution-combustion method and the MWCNT-$Al_2O_3$ nano composite were synthesized through the sol-gel method which was reported previously [8] The surfaces of these nano structures were then functionalized with (3-aminopropyl) triethoxysilane (APTES) silanol groups as follows: 1g of the $MgCr_2O_4$ and MWCNT- $Al_2O_3$ nanoparticles was dispersed in deionized water using an ultrasonic bath and magnetic stirrer for 2 h. The appropriate amount of silane was dispersed in water and acidified with HCl to assist chemical bonding and stirred for 1 h. This solution was then added to the solution containing the $MgCr_2O_4$ and MWCNT- $Al_2O_3$ nanoparticles, sonicated for more than 2h and stirred for 3h at 60 °C. Subsequently, the as prepared solution washed with ethanol and water, then dried at 100 °C for 12 h in a vacuum dryer. This procedure is shown schematically in (figure 1).


*Fig. 1: Schematic representation of the functionalization of MgCr₂O₄ and MWCNT- Al₂O₃ nanoparticles with APTES.*

**Preparation of the Magnesia-Chrome and Al₂O₃-C matrix containing functionalized MgCr₂O₄ and MWCNT-Al₂O₃ nanoparticles**

For Magnesia-Chrome refractories 1 wt.% of the functionalized and, for comparison, non-functionalized $MgCr_2O_4$ , nanoadditive were added to the calcium lingosulfonate solution and stirred for 30 min at added to the matrix of Mag-Chorme samples. Also 1wt.% of the functionalized and, for comparison, non-functionalized MWCNT-Al₂O₃, nanocomposite were added to the ethanol solution and stirred for 30 min. Then the obtained solution was added to the resin at 45 °C before its addition to the matrix. Finally, all samples compressed under a uniaxial pressure at 120 Mpa and dried overnight. Mag-Chrome samples fired at 1400 and 1600 °C for 5h and Alumina-C samples fired under reduced atmosphere at 1450 °C for 5h. The prepared sample labeled as table 1.

Tab. 1: Designation of samples.

| | Sample |
|---|---|
| Matrix formulation with 1% MgCr₂O₄, fired at 1600°C | M1-1600 |
| Matrix formulation with 1% functionalized MgCr₂O₄, fired at 1600°C | S1-1600 |

| Matrix formulation with 1% functionalize MgCr₂O₄, fired at 1400°C | S1-1400 |
| Matrix formulation with 1% MWCNT-Al₂O₃, fired at 1450°C | CA-1450 |
| Matrix formulation with 1% functionalize MWCNT-Al₂O₃, fired at 1450°C | SCA-1450 |

**Characterization of the samples**

Determination of the cold crushing strength (CCS) and hot modulus of rupture (HMOR) was carried out according to DIN standards 993-5 and 993-7 respectively, using a Universal testing machine (model GT-7001-L100) for the CCS measurement and an HMOR15-610p machine to determine the hot modulus of rupture. Bulk densities (BD) and apparent porosities (AP) were measured according to DIN 993-1 and the permanent linear change (PLC) was determined according to DIN 993-10. The presence of silane groups on the surface of the nanoparticles was studied by XRD (Asenware AW-DX300 diffractometer with Cu Kα radiation (λ = 1.54184 A°) in the 2θ range from 10 to 100 and FTIR using an Impact 400D spectrometer (NICOLET) on samples embedded in KBr discs. The effect of silane functionalization on the dispersion of the nanoparticles was observed at 190-2700 nm using a UV-visible spectrometer (JASCO V-670, Japan). Since the modified and unmodified MgCr₂O₄ & MWCNT-Al₂O₃ nanoparticles were added to the refractory matrix in a binder, their dispersion was characterized by UV-visible spectroscopy in water and ethanol. The

refractory matrices containing both the silanol-modified and unmodified nanoparticles were examined by SEM/EDS on gold-coated samples at an operating voltage of 20 kV using a Zeiss SEM and an FEI Quanta 200 electron microscope.

**RESULTS AND DISCUSSION**
**Investigation of the presence of the functionalizing groups in the MgCr₂O₄ & MWCNT-Al₂O₃ additive**

FTIR spectra of MgCr₂O₄ & MWCNT-Al₂O₃ nanoparticles and functionalized MgCr₂O₄ (MgCr₂O₄-S) & (MWCNT-Al₂O₃-S) depicted in (figure 2-a) between 500 to 4000 $cm^{-1}$. The peak at 615 $cm^{-1}$ in MgCr₂O₄ is attributed to the Cr(III)-O vibration mode and that at about 536 $cm^{-1}$ to the Mg(II)-O bond. These two peaks in MgCr₂O₄-S are not clearly resolved due to the presence of the silane groups on the surface of the nanoparticles. The peak at 1087 $cm^{-1}$ in MgCr₂O₄-S confirms the presence of the Si-OH group and that at about 641 $cm^{-1}$ corresponds to the silanol Si-O group on the surface of the nanoparticles. The NH₂ stretching peaks of the functionalizing APTES groups are present at 3300 and 3500$cm^{-1}$ in the MgCr₂O₄-S sample, but the broadness and intensity of these peaks obscures the OH vibration which is also present, as can be distinguished at 3300-3400 $cm^{-1}$, in the spectrum of unfunctionalized MgCr₂O₄ (figure 2-a). The increased intensity of the peak at 1603 $cm^{-1}$ in the MgCr₂O₄-S sample and the presence of an associated shoulder is also attributed to the NH₂ bending vibration of this group. These spectra confirm the successful incorporation of silanol groups on the MgCr₂O₄ nanoparticles.

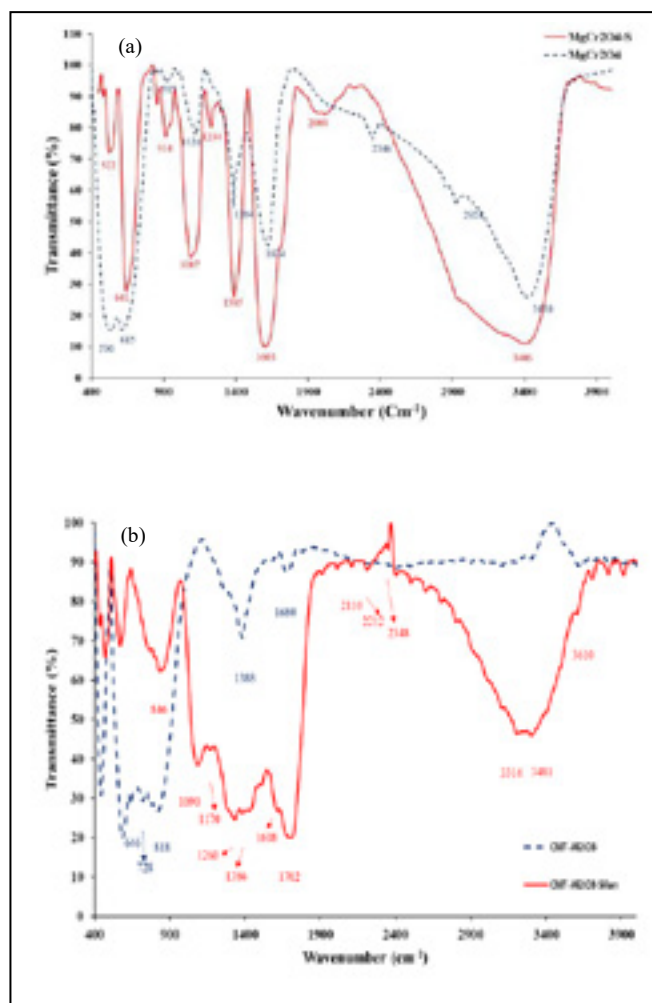

*Fig. 2: FTIR spectra of a) MgCr₂O₄, MgCr₂O₄-S, b) MWCNT-Al₂O₃ and MWCNT-Al₂O₃-S samples.*

Considering the functionalization of MWCNT-Al₂O₃ with 3-aminopropyltriethoxysilane (APTES) groups, the presence of NH2

and Si-OH groups in nanoparticles is obvious. As can be seen in (figure 2-b), the stretching peaks from 3300 cm$^{-1}$ to 3500 cm$^{-1}$ of MWCNT-Al$_2$O$_3$ sample related to the NH$_2$ group, on the other hand, the 1608 cm$^{-1}$ peak indicates the presence of NH$_2$ bending groups. The presence of a peak at 1090 cm$^{-1}$ in the functionalized MWCNT-Al$_2$O$_3$ sample is related to the Si-OH stretch bond which is an evidence for the presence of silane groups on the surface of the nanoparticles. This peak does not appear in the non-functionalized sample. The peak at 646 cm$^{-1}$ can be ascribe to Si-O bending mode. The peaks between 1170 cm$^{-1}$ and 1260 cm$^{-1}$ are related to the Si-C bond.

**The effect of silane treatment on the dispersion of MgCr$_2$O$_4$ & MWCNT-Al$_2$O$_3$ nanoparticles by UV-visible spectroscopic**
UV-visible spectroscopy at 200-330 nm is an appropriate method to investigate the dispersion of the silanol-functionalized nanoparticles. A great absorbance peak at the UV-visible region indicates better dispersion of nanoparticles in solution. MgCr$_2$O$_4$-S and MWCNT-Al$_2$O$_3$-S shows the remarkable UV-visible absorbance (figure 3), confirming the distinguished dispersion of functionalized sample in comparision to the others.
*Fig. 3: UV-visible spectra of samples a)MgCr$_2$O$_4$ , MgCr$_2$O$_4$-S, b)MWCNT-Al$_2$O$_3$ and MWCNT-Al$_2$O$_3$ –S.*

**Effect of the nano-additives on the magnesia-chrome and Alumina-C matrix properties**
*XRD patterns of magnesia-chrome and Alumina-C samples*

The XRD patterns of M1 and S1 fired at different temperatures (figure 4) show an increased intensity of the secondary spinel phase (Mg,Fe)Cr$_2$O$_4$ and (Mg,Fe)Al$_2$O$_4$ in sample S. This may result from the improved dispersion of nanoparticles which encourage spinel formation by the silanol groups as nucleating agents for the spinel phase. This will influence the high-temperature mechanical properties that is the same for both samples.

*Fig. 4: XRD patterns of magnesia-chrome samples fired at different temperatures.*

XRD pattern of Alumina-C samples is depicted in (figure 5). The sample functionalized with APTES, due to the better dispersion and uniform distribution of nanoparticles, the intensity of SiC peaks is higher and Si peak decreased. It could be concluded that the presence of MWCNT-Alumina nanocomposite and proper distribution increased the SiC phase which plays important role to improve mechanical properties.

*Fig. 5: XRD pattern of CA-1450 & SCA-1450*

*Physical and mechanical properties*

The physical and mechanical properties of the magnesia-chrome samples containing MgCr$_2$O$_4$ and MgCr$_2$O$_4$-S nano-additives fired at 1400 and 1600 °C (Table 2) show that the samples containing silanol-modified nanoparticles (samples S1) are superior to those with unmodified nano-additive (samples M1). Since the content of the additives is the same in all the samples, this improvement can probably be the result of improved dispersion and effectiveness of the silanol-modified nano-additive. On the other hand, the permanent linear change (PLC) results suggest that two mechanisms may be involved: 1- Shrinkage due to sample sintering, and 2- Expansion of the secondary spinel phase which was formed during the process. Thus, decrease of shrinkage may be a reflection of the greater expansion associated with secondary spinel formation.
The standard deviation of the cold crushing strength (CCS) results (about 60 Kgf/cm$^2$) indicates that these values for S1-1400 are similar to those of M1-1600 within the limits of error, suggesting that the addition of the silanol-functionalized nanoparticles could decrease the sintering temperature up to 200 °C. For further investigation, the hot modulus of rupture values (HMOR), determined for S1-1600 and S1-1400 samples. The result of HMOR

were the same for both samples (about 59.5 kgf/cm$^2$ and 57.5 kgf/cm$^2$ respectively). This confirmed that the presence of the silanol-functionalized MgCr$_2$O$_4$ additive can produce similar physical and mechanical results for sample S1-1400 which compatibale with sample S1-1600. In Aumina- C samples, the CCS is higher in SCA-1450 which could be related to better distribution and higher amount of SiC formation through the matrix. Nourbakhsh etal [9] reported that in nitride bonded SiC refractories ,the presence of fibrous phases and the proper distribution could increase the strenghth of the sample and specially CCS and CMOR, although the density decreased and the percentage of open porosity costant or slightly increased. In fact ,the results of both researches pointing out the fact that higher ratio of length to diameter of the fibrous phase will have a good effect on improving the mechanical properties.Therefore, the longe length of the fibers with suitable distribution process could be the main reason of CCS increase. Additionally, absence of low melting phase, may result in high HMOR. The above results confirmed by labaratory investigation and shown in Table(2).

Tab. 2: Physical and mechanical properties of magnesia-chrome and Alumina-C containing nanoadditives samples with and without silanol groups.

| Sample | Permanent linear change(%) | Cold crushing strength (Kgf/cm$^2$) | Apparent porosity (%) | Bulk density (g/cm$^3$) | HMOR (kgf/cm$^2$) |
|---|---|---|---|---|---|
| M1-1400 | -1.172±0.005 | 759±20.23 | 25.79±0.05 | 2.73 | - |
| S1-1400 | -0.611±0.003 | 886±14.17 | 25.89±0.15 | 2.73 | 57.5 |
| M1-1600 | -1.991±0.056 | 932±75.52 | 19.41±0.94 | 2.96 | - |
| S1-1600 | -1.537±0.108 | 997±85.64 | 22.70±0.64 | 2.86 | 59.5 |

*SEM of magnesia-chrome and Alumina-C refractories with and without APTES*

*Fig. 6: SEM of a) M1-1600, b) S1-1600, c)CA-1450, and d) SCA-1450 samples.*

Comparison of the SEM micrographs of M1-1600 and S1-1600 (figure 6-a,b) shows that silanol modification of the surface of the MgCr$_2$O$_4$ nano additive facilitates the formation and dispersion of the secondary spinels which are responsible for the development of mechanical strength specially at high temperature (HMOR).
Also, the SEM images of Alumina-C with and without silanized surface group (figure 6-c,d) containing 1%wt MWCNT-Al$_2$O$_3$ nano-composite confirmed the higher amount and more appropriate distribution of the SiC phase ,which plays an essential role to improve the high temperature mechanical properties (HMOR).

## CONCLUSIONS

The results approved the surface modification and well distributed nano additives through the matrix of refractories promoted both the secondary spinel phase formation in Mag-Chrome refractories and SiC formation in Alumina-C refractories. The mentioned phase formation increased CCS (from 886 kgf/cm$^2$ to 997 kgf/cm$^2$ ) and HMOR from (57.5 kgf/cm$^2$ to 59.5 kgf/cm$^2$) of Mag-Chrome sample due to higher secondary spinel formation. Also, it reduced 200°C of sintering temperature. In Alumina-C samples the CCS increased from (1370 kgf/cm$^2$ to 1560 kgf/cm$^2$), and HMOR (from 60 to 75 kgf/cm$^2$ ) due to promotion of higher SiC whiskers formation through the matrix.

# THERMOPHYSICAL PROPERTIES OF CA$^{2+}$−CR$^{3+}$−FE$^{3+}$ DOPED LAALO$_3$ HIGH EMISSIVITY CERAMIC

Qu Wang, Gang Wang*, Yifan Zhang, Penghui Du

State Key Laboratory of Advanced Refractories, Sinosteel luoyang institute of refractories research co.,ltd, Luoyang 471039

## ABSTRACT

Pure LaAlO$_3$ and Ca$^{2+}$-Cr$^{3+}$-Fe$^{3+}$ co-doped LaAlO$_3$ ceramic materials were prepared by high temperature solid-state reaction. The microstructure, infrared emissivity, thermal expansion coefficient and thermal conductivity of the samples were studied. The results reveal that 10 mol% Ca$^{2+}$, 5 mol% Cr$^{3+}$, and 5 mol% Fe$^{3+}$ co-doped LaAlO$_3$, namely La$_{0.9}$Ca$_{0.1}$Al$_{0.9}$Cr$_{0.05}$Fe$_{0.05}$O$_3$, has a greater NIR emissivity of 0.91 in the wavelength range of 0.76–2.50 μm, which is 296% greater than that of pure LaAlO$_3$ The thermal conductivity of LaAlO$_3$ can be reduced by Ca$^{2+}$-Cr$^{3+}$-Fe$^{3+}$ co-doping. The minimum thermal conductivities of LaAlO$_3$ and La$_{0.9}$Ca$_{0.1}$Al$_{0.9}$Cr$_{0.05}$Fe$_{0.05}$O$_3$ both appear at 1200 °C, and the minimum thermal conductivity of La$_{0.9}$Ca$_{0.1}$Al$_{0.9}$Cr$_{0.05}$Fe$_{0.05}$O$_3$ is 3.707 W·m$^{-1}$·K$^{-1}$, which is 20% lower than that of pure LaAlO$_3$. Ca$^{2+}$-Fe$^{3+}$ co-doping can improve the TECs of LaAlO$_3$. The mean TEC of La$_{0.9}$Ca$_{0.1}$Al$_{0.9}$Cr$_{0.05}$Fe$_{0.05}$O$_3$ was 10.86×10$^{-6}$ K$^{-1}$.

## INTRODUCTION

High emissivity energy-saving materials are a new type of material that is being widely used in high-temperature energy-saving fields. To improve the thermal efficiency of high energy-consuming equipment such as thermal furnaces, it is necessary to improve their radiation heat transfer capacities [1-4]. According to Wien's law and Plan's law, radiant heat at temperatures above 800 °C should be mainly concentrated in the near-infrared band of 0.76-2.5 μm. Therefore, research into the high-temperature energy-saving field pays special attention to the emissivity of the near-infrared band.

According to the optical absorption theory of semiconductors, introducing suitable impurities into a semiconductor matrix can form impurity energy levels corresponding to the infrared spectral region [5,6]. This will enhance the absorption property of the semiconductor in the infrared range. Kirchhoff's law of thermal radiation states that, for a body in thermal equilibrium, absorptivity and emissivity are equal in the same wavelength range. Therefore, one potential method for increasing near-infrared emissivity is to form an impurity level locally by doping ions of different valence states and valence bonds. This will enhance the possibility of free carriers from a given valence band to undergo band transition, and will therefore promote the valence band. This process will increase the concentration of free carriers (electrons, holes, etc.) and the transition between the band gaps, thereby increasing near-infrared radiance [7,8]. LaAlO$_3$ is a perovskite-type semiconductor with a high melting point (2180 °C), a high temperature stability, and a typical indirect transition band structure. The valences of its A and B ions are not necessarily limited to its positive trivalent. This is in line with the doping conditions for the preparation of near-infrared high-emissivity ceramic materials, and this semiconductor has therefore received extensive attention [9,10]. In this study, Ca$^{2+}$-Cr$^{3+}$-Fe$^{3+}$ co-doping LaAlO$_3$ with excellent infrared emissivity was successfully prepared. This material has the potential to foster a new generation of infrared radiation energy-saving materials with high emissivity, high temperature resistance, and oxidation resistance.

## MATERIALS AND METHODS

### Sample preparation

In this paper, La$_2$O$_3$ (purity ≥99.95 %), Al$_2$O$_3$ (purity ≥99 %), CaCO$_3$ (purity ≥99 %), Cr$_2$O$_3$ (purity ≥99 %), Fe$_2$O$_3$ (purity ≥99 %) were used as experimental materials, and the ingredients were weighed according to the stoichiometric ratio of LaAlO$_3$ and La$_{0.9}$Ca$_{0.1}$Al$_{0.9}$Cr$_{0.05}$Fe$_{0.05}$O$_3$. The detailed synthesis process is shown in Ref. [11].

### Sample characterization

The phase composites of the samples were identified using X-ray diffractometer (XPert Pro, Philips) with Cu Kα radiation. The X-ray diffractometry (XRD) data were refined using the Rietveld refinement method to calculate the unit cell parameters. The microstructure of the sample was observed using field emission scanning electron microscopy (FESEM, GeminiSEM 300, German Zeiss) equipped with energy-dispersive X-ray spectroscopy (EDS). Before the SEM observation, the samples were thermally etched at 1400 °C for 2 h to ensure clear grain boundaries. The spectral absorptivity of samples in the wavelength range 0.2–2.5 μm was indirectly measured by recording the intensity of infrared reflection using an ultraviolet-visible-NIR (UV-Vis-NIR) spectrophotometer (Lambda 750 S, PerkinElmer, USA) equipped with a barium sulfate integrating sphere. The average linear TEC was obtained from the changes in the length of the specimen from 300 to 1200 °C in an air atmosphere using a thermal dilatometer (RPZ-04P, China) with sample dimensions of Φ10 mm × 50 mm. The thermal diffusivity and specific heat capacity of the ceramic samples were tested using a laser thermal conductivity meter (Netzsch LFA 467, Germany) in the temperature range 25–1200 °C with a sample size of Φ12.7 mm×2.5 mm. The thermal conductivities of the samples were then calculated using the formula $\lambda = C_p \cdot k \cdot \rho$, where $\lambda$ is the thermal conductivity (W/m·K), $k$ is the thermal diffusion coefficient (mm$^2$/s), $C_p$ is the specific heat capacity (J/g·K), and $\rho$ is the bulk density (g/cm$^3$).

## RESULTS AND DISCUSSION

Fig. 1 XRD patterns of LaAlO$_3$ and La$_{0.9}$Ca$_{0.1}$Al$_{0.9}$Cr$_{0.05}$Fe$_{0.05}$O$_3$.

Fig. 1 shows the XRD patterns of LaAlO$_3$ and La$_{0.9}$Ca$_{0.1}$Al$_{0.9}$Cr$_{0.05}$Fe$_{0.05}$O$_3$. It can be seen from Fig.1 that the prepared samples have an orthorhombic perovskite structure with a space group of R-3c (167). No CaO, Cr$_2$O$_3$, Fe$_2$O$_3$ or other impurity phases were observed, indicating that most of Ca$^{2+}$, Cr$^{3+}$ and Fe$^{3+}$ ions were doped into the LaAlO$_3$ lattice. Compared with the peak of LaAlO$_3$, the diffraction peak of La$_{0.9}$Ca$_{0.1}$Al$_{0.9}$Cr$_{0.05}$Fe$_{0.05}$O$_3$ shifts to a lower angle, which is due to the increase of crystal plane spacing and lattice distortion after Ca$^{2+}$, Cr$^{3+}$ and Fe$^{3+}$ co-doping. This is consistent with the Rietveld refinement results of LaAlO$_3$ and La$_{0.9}$Ca$_{0.1}$Al$_{0.9}$Cr$_{0.05}$Fe$_{0.05}$O$_3$ cell parameters in Table 1.

Fig. 2 SEM images of (a) LaAlO$_3$, (b) La$_{0.9}$Ca$_{0.1}$Al$_{0.9}$Cr$_{0.05}$Fe$_{0.05}$O$_3$ and EDS spectra of points (c)1 and (d)2.

Fig.2 shows the microstructure of LaAlO$_3$ and La$_{0.9}$Ca$_{0.1}$Al$_{0.9}$Cr$_{0.05}$Fe$_{0.05}$O$_3$. The grain shape of ceramics is irregular and the grain boundary is clearly visible. Compared with LaAlO3, Ca$^{2+}$-Cr$^{3+}$-Fe$^{3+}$ co-doping makes the grain size of the sample smaller, indicating that Ca$^{2+}$-Cr$^{3+}$-Fe$^{3+}$ co-doping promotes grain refinement.

Table1 Lattice parameters and tolerance factor of LaAlO$_3$ and La$_{0.9}$Ca$_{0.1}$Al$_{0.9}$Cr$_{0.05}$Fe$_{0.05}$O$_3$

| | Lattice parameter/Å | | Unit cell volume/Å$^3$ | Tolerance factor(t) |
|---|---|---|---|---|
| | a=b | c | | |
| LaAlO$_3$ | 5.36698 | 13.13549 | 327.67 | 0.8294 |
| La$_{0.9}$Ca$_{0.1}$Al$_{0.9}$Cr$_{0.05}$Fe$_{0.05}$O$_3$ | 5.37975 | 13.15183 | 329.64 | 0.8274 |
*Fig. 3 Infrared emissivity of LaAlO₃ and La₀.₉Ca₀.₁Al₀.₉Cr₀.₀₅Fe₀.₀₅O₃.*

Fig. 3 shows the emissivity of $LaAlO_3$ and $La_{0.9}Ca_{0.1}Al_{0.9}Cr_{0.05}Fe_{0.05}O_3$ in 0.76-2.50 μm. It can be seen from Fig.3 that $Ca^{2+}$-$Cr^{3+}$-$Fe^{3+}$ co-doping can greatly improve the emissivity of lanthanum aluminate materials in 0.76-2.50 μm. The average emissivity of $La_{0.9}Ca_{0.1}Al_{0.9}Cr_{0.05}Fe_{0.05}O_3$ is 0.91, which is 296 % higher than that of pure $LaAlO_3$. According to the infrared radiation mechanism, infrared radiation in the near-infrared region (0.76-2.5 μm) is mainly related to free carrier absorption, impurity level, and electronic transition [7]. When $Ca^{2+}$, $Cr^{3+}$ and $Fe^{3+}$ ions enter the $LaAlO_3$ lattice, $Ca^{2+}$ occupies the $La^{3+}$ position, $Cr^{3+}$ and $Fe^{3+}$ ions occupy the $Al^{3+}$ position. Since the valence of Ca is lower than that of La, the compensation mechanism is mainly the valence change and oxygen vacancy of B-site ions in order to maintain the valence balance of the system. The valence change of ions and the generation of oxygen vacancies will form impurity levels in the band gap of the material.

*Fig. 4 Thermal expansion coefficient patterns of LaAlO₃, and La₀.₉Ca₀.₁Al₀.₉Cr₀.₀₅Fe₀.₀₅O₃ ceramics at different temperature.*

It is well known that the mismatch of TEC will lead to large interfacial thermal stress between the substrate and the ceramic coating, which is the main reason for the cracking and spalling of the ceramic coating. Therefore, it is very important to study the TEC of doped $LaAlO_3$ high emissivity ceramics. Fig. 4 shows the TECs of pure $LaAlO_3$ and $La_{0.9}Ca_{0.1}Al_{0.9}Cr_{0.05}Fe_{0.05}O_3$ ceramics at different temperatures. It can be seen from Fig.5 that $Ca^{2+}$-$Cr^{3+}$-$Fe^{3+}$ co-doping can improve the TECs of $LaAlO3$ ceramics. The mean TECs of $LaAlO_3$ and $La_{0.9}Ca_{0.1}Al_{0.9}Cr_{0.05}Fe_{0.05}O_3$ are $10.33×10^{-6}$ $K^{-1}$ and $10.86×10^{-6}$ $K^{-1}$, respectively. It is well known that the thermal expansion coefficient is inversely proportional to the lattice energy. The relationship between thermal expansion coefficient and lattice energy can be expressed as [12]:

$$U = \frac{N_0 M z^+ z^- e^2}{r_0}\left(1 - \frac{1}{n}\right), \qquad (1)$$

where $N_0$, $M$, $z$, $r_0$, $e$, and $n$ represent Avogadro's number, the Madelung constant, ionic charge, inter-ionic distance, electron charge, and Born exponent, respectively. It can be seen from Table 1 that the unit cell expands slightly after $Ca^{2+}$-$Cr^{3+}$-$Fe^{3+}$ co-doping, indicating that the average ion distance $r_0$ increases, which will lead to the decrease of lattice energy of $La_{0.9}Ca_{0.1}Al_{0.9}Cr_{0.05}Fe_{0.05}O_3$. Therefore, TEC of $La_{0.9}Ca_{0.1}Al_{0.9}Cr_{0.05}Fe_{0.05}O_3$ is higher than that of pure $LaAlO_3$.

*Fig. 5 The thermal conductivity patterns of LaAlO₃ and La₀.₉Ca₀.₁Al₀.₉Cr₀.₀₅Fe₀.₀₅O₃ ceramic bulks at different temperature.*

Fig.7 shows the temperature dependence of thermal conductivity of $LaAlO_3$ and $La_{0.9}Ca_{0.1}Al_{0.9}Cr_{0.05}Fe_{0.05}O_3$ ceramics. From 25 °C to 1200 °C, the thermal conductivity of $LaAlO_3$ and $La_{0.9}Ca_{0.1}Al_{0.9}Cr_{0.05}Fe_{0.05}O_3$ ceramics decreased with the increase of temperature, and the thermal conductivity of $La_{0.9}Ca_{0.1}Al_{0.9}Cr_{0.05}Fe_{0.05}O_3$ ceramics was significantly lower than that of pure $LaAlO_3$. The thermal conductivity of $La_{0.9}Ca_{0.1}Al_{0.9}Cr_{0.05}Fe_{0.05}O_3$ ceramics is 3.707-4.910 $W·m^{-1}·K^{-1}$ in the temperature range of 25 °C to 1200 °C, which is lower than that of pure $LaAlO3$ ceramics. At 1200 °C, the thermal conductivity of $LaAlO_3$ and $La_{0.9}Ca_{0.1}Al_{0.9}Cr_{0.05}Fe_{0.05}O_3$ has the lowest value. The lowest thermal conductivity of $La_{0.9}Ca_{0.1}Al_{0.9}Cr_{0.05}Fe_{0.05}O_3$ is 3.707 $W·m^{-1}·K^{-1}$, which is about 20 % lower than that of pure $LaAlO_3$ (4.628 $W·m^{-1}·K^{-1}$), indicating that $Ca^{2+}$-$Cr^{3+}$-$Fe^{3+}$ co-doping can effectively reduce the thermal conductivity of lanthanum aluminate ceramics.

## CONCLUSIONS

$Ca^{2+}$-$Cr^{3+}$-$Fe^{3+}$ co-doped lanthanum aluminate infrared radiation material was successfully prepared by high temperature solid state reaction method. The infrared emissivity of $La_{0.9}Ca_{0.1}Al_{0.9}Cr_{0.05}Fe_{0.05}O_3$ doped with 10 mol% $Ca^{2+}$, 5 mol% $Cr^{3+}$, and 5 mol% $Fe^{3+}$ in 0.76 ~ 2.5 μm is 0.91, which is 296 % higher than that of pure $LaAlO_3$. The lowest thermal conductivity of $La_{0.9}Ca_{0.1}Al_{0.9}Cr_{0.05}Fe_{0.05}O_3$ is 3.707 $W·m^{-1}·K^{-1}$, which is 20 % lower than that of pure $LaAlO_3$. The mean TECs of $LaAlO_3$ and $La_{0.9}Ca_{0.1}Al_{0.9}Cr_{0.05}Fe_{0.05}O_3$ ceramics are $10.33×10^{-6}$ $K^{-1}$ and $10.86×10^{-6}$ $K^{-1}$, respectively.

# HIGH ENTROPY TRANSITION METAL DIBORIDES POWDERS SYNTHESIZED VIA MOLTEN SALT METHOD

Haijun Zhang

Wuhan University of Science and Technology, The state Key Laboratory of Refractories and Metallurgy, Wuhan, Hubei Province, China

$(Hf_{0.2}Ti_{0.2}Ta_{0.2}Nb_{0.2}Mo_{0.2})B_2$, $(Ti_{0.2}Mo_{0.2}W_{0.2}Ta_{0.2}Nb_{0.2})B_2$, $(Hf_{0.167}Zr_{0.167}Ti_{0.167}Ta_{0.167}Nb_{0.167}V_{0.167})B_2$ powders were synthesized by molten salt/ boro-carbothermal reduction method. Compared with the temperatures (about 2000 °C) required by conventional methods, the firing temperature and energy consumption demanded by the present method were remarkably the milder. $(Hf_{0.2}Ti_{0.2}Ta_{0.2}Nb_{0.2}Mo_{0.2})B_2$ powders can be synthesized by the method at 1300 °C, by using $HfO_2$, $TiO_2$, $Ta_2O_5$, $Nb_2O_5$, $MoO_3$ $B_4C$ and amorphous carbon as reactants and NaCl-KCl salt mixture as reacting medium. $(Ta_{0.2}Ti_{0.2}Mo_{0.2}W_{0.2}Nb_{0.2})B_2$ powders with a uniformly distributed elemental composition were synthesized via the method at 1473 K/3 h with salt/reactant weight ratio of 5/1. $(Hf_{0.167}Zr_{0.167}Ti_{0.167}Ta_{0.167}Nb_{0.167}V_{0.167})B_2$ six-principle-component high-entropy powders can be synthesized at 1400 °C/20 min by using $HfO_2$, $ZrO_2$, $TiO_2$, $Ta_2O_5$, $Nb_2O_5$, $V_2O_5$, $B_4C$ and amorphous carbon as reactants and NaCl-KCl salt mixture as reacting medium, with a $(n(HfO_2/ZrO_2/TiO_2/Ta_2O_5/Nb_2O_5/V_2O_5/B_4C/C))$ molar ratio of 2.0:2.0:2.0:1.0:1.0:1.0:9.6:21.0 and a salt/reactants weight ratio of 2.0. The as-synthesized six-principle-component high-entropy powders had high elemental distribution uniformities, well-defined hexagon-platelet-like morphology.

# REFRACTORY COMPOSITE AGGREGATES BASED ON NB–AL$_2$O$_3$ USING 3D PRINTING TECHNOLOGY

Tilo Zienert,  Dirk Endler, Jana Hubálková, Christos G. Aneziris
TU Bergakademie Freiberg, Institute of  Ceramics, Refractories and Composite Materials, Freiberg, Germany

**ABSTRACT**

Refractory composites based on Nb-Al$_2$O$_3$ or Ta-Al$_2$O$_3$ are promising functional materials, regarding their thermal and electrical conductivity, used for refractory applications at temperatures above 1500 °C [1]. The composites show ductile behaviour at application temperature. In addition, large components with low shrinkage on sintering can be produced using standard technology, e.g. castables with aggregate sizes up to 3 or 5 mm. Using 3D printing, the shape and materials composition of the aggregates can be produced in a defined way.

The work demonstrates how 3D-printing can be used to produce layered composite material of Al$_2$O$_3$/Nb-Al$_2$O$_3$ that combines the corundum refractoriness with the metal's thermal and electrical conductivity in combination with ductility to increase the thermal shock resistance of the composite material.

**MATERIAL AND METHODS**

Paste extrusion is used in combination with a modified clay printer for utilising the samples (figure 1). Standard refractory raw materials (e.g. the alumina CT9FG from Almatis) with particle sizes up to 100 µm (figure 2) are mixed with an organic binder based on cellulose, xanthan and oelic acid with a total water content of 50 vol.% water to obtain a extrusion-ready mass. By applying dual-extrusion, it is possible to fabricate coarse particles with layered morphologies.

*Fig. 2: Particle size distribution of the used raw materials.*

# USE OF METALLURGICAL RESIDUES AS POTENTIAL RAW MATERIALS FOR HIGH PERFORMANCE REFRACTORY CASTABLES

Mathilda Derensy

RWTH Aachen University, Institute of Mineral engineering , Marsac-sur-l'Isle, France

Extractive metallurgy processes are not suitable for lower-grade resources with impurities. Therefore this study aims at advanced metal-extraction and recovery methods of slags from metallurgical processes. In order to produce nearly zero-waste results, it focuses on upcycling the residual matrices into engineered refractory products, namely alternative calcium aluminate binders and alumina-spinel castables for refractory linings. In order to test the engineered refractory materials into industrial conditions, assessment of thermomechanical behaviour of the refractory castables in service conditions is in regard. This work is just currently starting and it is part of the CESAREF European Project focusing on sustainable applications of refractories

Infrared radiation ceramics are generally recognized as energy-saving material for thermal equipments. In this work, as novel infrared radiation ceramics, $Co^{2+}$ doped $LaAlO_3$ ceramics were synthesized via a solid-phase reaction method, and the influence of the $Co^{2+}$ doping concentration on the infrared emissivity of ceramics was systematically investigated. The original Al element position was replaced by Co element in $Co^{2+}$-doped $LaAlO_3$, leading to lattice distortion, oxygen vacancy generation and "$Co^{2+} \rightarrow Co^{3+}$" transformation. The increase of doped Co content leads to enhanced impurity absorption, freecarrier absorption and lattice vibration absorption, which significantly improve infrared emissivity. The average emissivity values in the 0.76-2.5 μm and 2.5-14 μm bands of the $LaAl0.6Co0.4O3$ specimen (40 mol% Co) are 0.89 and 0.86, respectively, which are 324% and 28% higher than those of pure $LaAlO_3$. This kind of infrared ceramic with high infrared emissivity has significant application prospects for energy-saving applications of thermal equipment. This $Co^{2+}$-doped $LaAlO_3$ ceramic is a potential candidate material of high-temperature furnaces (< 1700 °C) for energy-saving applications.

# EFFECT OF THE IMPREGNATION WITH LIQUID GLASS ON THE PROPERTIES OF REFRACTORY CASTABLE

Jurgita Malaiskiene, Valentin Antonovic, Renata Boris, Rimvydas Stonys

Institute of Building Materials, Laboratory of Composite Materials, Vilnius Gediminas Technical University, Vilnius, Lithuania

## ABSTRACT

In this study, the impact of liquid glass (sodium silicate) impregnation under vacuum on the physical, mechanical properties, and alkali resistance of fireclay-based conventional castable (CC) and medium cement refractory castable (MCC), which are using in boilers for biomass combustion, was analysed. In research standard test methods for physical and mechanical properties (EN ISO 1927-6), as well as scanning electron microscope (SEM), testing methods for alkali resistance (ASTM C 454–83) and thermal shock resistance by evaluating changes in ultrasound pulse velocity were used.

The results of the investigation have shown that the alkali resistance of CC as well as MCC can be improved by impregnation with liquid sodium silicate glass under vacuum. Impregnated refractory castables have lower porosity (7–9%), higher cold crushing strength (up to 18%). The structure of impregnated samples is denser compared with that of nonimpregnated refractory castables. The SEM images showed that the impregnated samples pores are partially filled with the sodium silicate.

Alkali resistance tests showed that a glassy protective layer (width approximately 1 mm) formed on the surfaces of refractory castables, thus reducing further penetration of alkali (potassium) into deeper layers of the samples. However, impregnated refractory castables are less resistant to thermal shock cycles.

## INTRODUCTION

In biofuel combustion boilers, the operating temperature is usually less than 1100°C, so refractory castables with aluminosilicate fillers for example fireclay could be used in their lining [1]. One of the main reasons for the disintegration of the refractory castable layer of the linings of these boilers, when burning conventional and especially alternative biofuels, is their low resistance to the effects of alkali at sufficiently low temperatures. It has been established [2] that potassium carbonate begins to decompose into $K_2O$ and $CO_2$ and forms new compounds at a temperature of 600°C. At higher temperature, $K_2O$ reacts with components of refractory castables, forming a low viscosity melt that penetrates deep into the layers of the refractory castables and such corrosion products as leucite, kalsilite, and other compounds with volume exceeding the initial volume of the material are formed [3-5]. In order to reduce the harmful effects of alkalis, refractory castable can be impregnated with special coatings to reduce surface porosity and prevent the penetration of potassium compounds into the deeper layers of refractory castable [6]. The penetration of alkalis into the structure of the refractory castable depends especially on its porosity parameters: the degree of corrosion is significantly lower in materials with lower porosity and gas permeability [7-9]. The impregnation material should be selected considering the potential compounds formed at a certain temperature and their possible viscosity, which should be quite high. In our previous works [6, 10], positive results were obtained in reducing the disruptive alkaline effect in the refractory castable when milled quartz sand (2.5%) was used in the composition of the refractory castables, and these castables were additionally impregnated with $SiO_2$ sol. However, especially when a larger amount of milled quartz sand was used (5-7.5%), the thermal shock resistance of the samples decreased by up to 70% [3].

This paper aims to evaluate the change in the main properties of refractory castables (cold crushing strength, porosity, microstructure, alkali and thermal shock resistance) when the refractory castable is impregnated with a liquid sodium silicate glass under vacuum. It is known that liquid glass, when used as a binder in refractory castables, acts as a flux at high temperatures and lowers the operating temperature of aluminosilicate refractory castables up to 200-300°C. However, research results show that the operating temperature of refractory castables with a liquid glass binder can be 1100-1300°C and higher [11].

## MATERIALS AND METHODS

For castable CC, the calcium aluminate cement Istra40 (ISTR) produced by Calucem GmbH and for MCC the G70 cement produced by Gorka Cement Company and different types of fireclays aggregate FA35 (~35% of $Al_2O_3$, $Al_2O_3/SiO_2$ (A/S) ratio 0.68 (CC-1, MCC-1) and $Al_2O_3$ content ~45%, A/S ratio 0.89 FA45 (CC-2, MCC-2)) were used in this investigation. Additionally, microsilica MS, RW-Fuller; RW Silicon GmbH, reactive alumina RA, CTC 20, Almatis containing 99.7% $Al_2O_3$ and calcined alumina CA, CT 19 containing 99.8% $Al_2O_3$, milled quartz sand MQS from SC Anykščių kvarcas were used for samples preparation. The compositions of the refractory castables are presented in Table 1.

Tab 1. The composition of refractory castables

| Composition,% | Cement G70 | Cement ISTR40 | MS | FA 35 <0.14 mm | FA45 <0.14 mm | FA35 <4 mm | FA45 <4 mm | RA | CA | MQS | Water |
|---|---|---|---|---|---|---|---|---|---|---|---|
| CC-1 | - | 25 | 2.5 | 10 | - | 60 | - | - | - | 2.5 | 11.3 |

| MCC-2 | 12 | - | 5 | - | 8 | - | 60.5 | 5 | 7 | 2.5 | 7.1 |

*Water - up to 100%

The castables were labelled CC-1, CC-2 and MCC-1, MCC-2 respectively. The specimens 70×70×70mm of refractory castable were prepared, dried (105±2°C) and burnt (1100±2°C for 5h) according to the LST EN ISO 1927-5:2013 requirements. The burnt samples were impregnated under vacuum (1atm) in liquid sodium silicate glass, the density of which is 1.33g/cm³. Physical mechanical characteristics were established according to LST EN ISO 1927-6:2013 and thermal shock resistance was determined by evaluating changes in ultrasound pulse velocity, when samples are cyclically heated (1100 ° C) and cooled (between 2 metal plates filled with water). Before testing ($U_o$), after 3 ($U_{3c}$) and 7 ($U_{7c}$) cycles, the ultrasound pulse velocity was measured and the relative thermal shock resistance $R$ was calculated according to the formula:

$$R = \frac{\sqrt{U_{3c} \times U_{7c}}}{U_o} \times 100\% \qquad (1)$$

The crucible method ASTM C 454-83:2007 was chosen to assess the influence of alkali attack on the structure of the castable [6] using 9 g $K_2CO_3$ and firing at a temperature of 1100°C for 5 hours. After 6 cycles (upon adding 9 g of $K_2CO_3$ for each test), the samples were cut vertically, visually inspected and an appearance of microcracks and penetrated zone depth in them were recorded.

A SEM JEOL JSM-7600F scanning electron microscope device (Japan) was used for control and impregnated sample microstructure comparison tests.

## RESULTS AND DISCUSION

The results of the cold crushing strength CCS (Fig. 1) show that the strength of all types of refractory castables impregnated in liquid sodium silicate glass increased from approximately 10% to 18%. The increase in CCS of the impregnated samples was determined due to the formation of a denser structure and a decrease in porosity. It was found that after impregnation the porosity of all types of refractory castables decreased by about 10%, because the pores were filled with sodium silicate and the sintering of material at 1100°C temperature also took place more intensively. The influence of refractory castable porosity on the cold crushing strength, presented in Fig. 2, is significant because the determination coefficient $R^2$ is very close to 1 [12]. The porosity of the refractory castables, as can be seen, is quite different when comparing between the refractory castable compositions and varies from approximately 16% to approximately 29%. This difference in the compositions of refractory castables was chosen to evaluate the effectiveness of impregnation for different refractory castables.
Fig. 1. CCS of control and impregnated samples after firing at 1100°C
Fig. 2. Influence of CC and MCC porosity on the CCS

SEM images (Fig. 3 and Fig. 4) show that the microstructure of the impregnated samples, regardless of composition and initial porosity, especially on the surface (Fig. 3), is denser. The porosity was reduced when the refractory castable was exposed to liquid glass under vacuum, and the resulting sodium silicate partially filled the pores and capillaries. Such a densification of the microstructure also led to a higher cold crushing strength of the impregnated samples [13].

Fig. 3. The surface of the impregnated MCC-1 sample

Comparing the refractory castables of each composition (Fig. 4), it can be seen that after impregnation the microstructure of the samples became denser and the diameter of many pores decreases, because the sodium silicate partially filled them. The most visible changes in the microstructure were established for the MCC-2 impregnated samples, the zones of blowed sodium silicate in pores are visible.

The densified microstructure of the surface, taking into account the conclusions presented in the literature [14-16], should increase the alkali resistance of refractory castables with fireclay fillers at high temperatures. In Fig. 5 images of cut impregnated and control refractory castable samples are presented after 6 cycles of alkaline exposure.
Fig. 4. The images of control and impregnated samples: a) CC1- impregnated, b) CC2- impregnated, c) MCC1- impregnated, d) MCC2- impregnated, e) CC-1 control, f) CC-2 control, g) MCC-1 control, h) MCC-2 control

A clearly visible glassy barrier with a width of about 1mm was formed on the surface of the impregnated samples holes into which the $K_2CO_3$ reagent was added. At high temperatures, sodium and potassium compounds react with the refractory compounds and form a sodium alumina silicate and potassium alumina silicate layer. According to the $Na_2O−Al_2O_3−SiO_2$ phase diagram [17], liquid sodium silicate can further react to form albite ($NaAlSi_3O_8$) and nepheline ($NaAlSiO_4$). It was determined [18], that $Al_2O_3$ can influence the viscous glass melting temperature and its viscosity; therefore, the melting temperature and viscosity values tend to increase. Then the formed glassy layer became higher in viscosity and could not penetrate deeper to the material and also work as a protective barrier. In the control samples, such a barrier was also formed due to the addition of milled quartz sand; only of the CC samples after 6 cycles this barrier was already damaged and became ineffective: the corrosion products penetrated deep into the sample and melted the outer layer. The damage of the control MCC samples is insignificant; only partial melting of the sample is visible in the upper part of the MCC-1 samples, which changed the shape of the hole.

Fig. 5. The images of control and impregnated samples: a) CC1- impregnated, b) CC2- impregnated, c) MCC1- impregnated, d) MCC2- impregnated, e) CC-1 control, f) CC-2 control, g) MCC-1 control, h) MCC-2 control

Impregnation of refractory castables with liquid sodium silicate glass increased the cold crashing strength, reduced porosity, compacted the microstructure, increased modulus of elasticity and increased resistance to alkali, but impregnation of refractories often leads to a lower resistance to thermal shock [6]. Thermal shock resistance (Fig. 6) of impregnated samples compared to control samples decreased from approximately 8% (CC-2, MCC-2) to 12% (CC-1, MCC-1). In article [19] it was established that material with a high modulus of elasticity will have lower thermal shock resistance and the thermal shock resistance of castables improves by reducing the modulus of elasticity.
Fig. 6. The comparison of thermal shock resistance of control and impregnated samples

## CONCLUSIONS

Research of refractory castables in the resistance to alkali attack at 1100°C temperature showed that the use of 2.5% of milled quartz sand and the impregnation of the samples with a liquid sodium silicate glass (density 1.33g/cm$^3$) resulted in the development of a pronounced barrier of about 1mm width that prevented further penetration of alkali and stopped further disintegration of the refractory castables.

The cold crushing strength and resistance to alkali attack of refractory fireclay castables can be improved by impregnation of refractory castables with liquid sodium silicate glass. Sodium silicate densifies the microstructure and decreases the porosity of refractory castables by partially filling the pores and connecting capillaries through which liquid and/or gaseous-phase potassium (and sodium) can easily penetrate. The cold crushing strength of the impregnated samples increased by 10-18% according to composition and porosity decreased by approximately 10%.

The thermal shock resistance of the impregnated samples compared to the control samples decreased about 10%.

## ABSTRACT

The infiltration of the molten steel into the porous bricks was simulated in terms of the finite volume method (FVM) using a three-dimensional pore structure obtained by the X-ray computed tomography (CT). The effect of structure of the porous bricks on the infiltration phenomenon of the molten steel into the pores was discussed kinetically with comparing the results to those obtained in the analysis performed by simplifying the pore to a cylindrical shape using both Washburn's and Hagen-Poiseuille's equations. In the simulation, the rate of infiltration of the molten steel for four kinds of porous bricks correlated well to the mean pore size determined by the X-ray CT image analysis among the other structure parameters like the porosity or the maximum pore size. The infiltration rate and labyrinth coefficient both determined also in the simulation were about one-third (34 to 45%) and about half, respectively, of those in the analysis using the simplified pore shape. The simulation results facilitating to understand the infiltration of the molten steel into the bricks were obtained with a great assist of an accurate structure of the porous bricks. Further validation with improvements of the analysis enables to a prolonged life of the porous bricks for the plug.

## INTRODUCTION

Porous bricks are refractories used for porous plugs, which are attached to the bottom of the molten steel ladle during the steelmaking process. Porous plugs are used to blow gas into the molten steel, but there are intervals when the gas supply is stopped, such as during casting. It is known that the pores of the bricks are infiltrated with metal due to the molten steel head pressure. Since the infiltrated metal blocks gas blow, operations to remove the infiltrated layer in the brick, such as oxygen cleaning, are required when the porous plug is reused [1]. Therefore, it is important to control metal infiltration in order to improve the total performance of the porous plugs.

In this study, we discussed phenomenon of metal infiltration in simplified model and examined the difference from the actual infiltration in the porous bricks. Furthermore, the mechanism of a molten steel infiltration into actual porous bricks was investigated by a numerical fluid analysis using the finite volume method (FVM), on the three-dimensional structure of porous bricks obtained by the X-ray computed tomography (CT).

## THEORETICAL BACKGROUND

It is generally known that oxide raw materials used for porous bricks, such as $Al_2O_3$ and $MgO$, are less wettable by molten steel with contact angles higher than 90 degree. Therefore, molten steel cannot infiltrate into the pores of the porous bricks without external force. Assuming that the pores are simple cylindrical shape, the external force $P$ can be written using the Washburn equation [2], with the surface tension of the molten steel $\gamma$, the contact angle between the molten steel and the refractory material $\theta$, and the maximum pore diameter $D$ without molten steel infiltration as follows:

$$P = -\frac{4\gamma}{D}\cos\theta \qquad (1)$$

Since the head pressure of the molten steel acts as an external force in the actual ladle, the external force $P$ can be also written as:

$$P = \rho g h \qquad (2)$$

Where $\rho$ is the density of the molten steel, $g$ is the gravitational acceleration, and $h$ is the height of the molten steel level in the ladle.

Thus, from equations (1) and (2):

$$D = -\frac{4\gamma}{\rho g h}\cos\theta \qquad (3)$$

is found to be the relation between $D$ and $h$. Applying the $\rho$ and $\gamma$ for the molten steel as 7000 $kg \cdot m^{-3}$ and 1.8 $N \cdot m^{-1}$, respectively [3], together with the value of $\theta$ for the molten steel against refractory material (ex. $Al_2O_3$) as 110 degree [4] and $g$ as 9.8 $m \cdot s^{-2}$, the relation between the $h$ and the $D$ is shown as an asymtotic curve in Fig. 1. In the figure, the quadrant area expressed by the $h$ and the $D$ is divided by the curve into the infiltration and the non-infiltration areas for upper and lower of the curve, respectively.

In general, to ensure the gas flow rate required for refining, the average pore diameter of the porous bricks is often larger than 100 μm, while the molten steel level of the steel ladle in the actual operation (shown as zone in Fig. 1) is often higher than 1 m, depending on the ladle capacity. Therefore, it is difficult to inhibit completely the infiltration of molten steel by reducing the pore size of the brick.

On the basis of the knowledge thus obtained we consider rate of infiltration. Although the infiltration phenomenon is a passing phase itself actually, for simplicity we assume a Hagen-Poiseuille flow for it. In this case, from the Hagen-Poiseuille equation,

$$\Delta P = \frac{32\mu l u}{D^2} \qquad (4)$$

where $\Delta P$ is the pressure difference, $\mu$ is the viscosity of the molten steel, $l$ and $u$ are the depth and the rate of the infiltration, respectively. Since $l$ and $u$ are both time-dependent quantities, they are denoted hereafter as $l(t)$ and $u(t)$, respectively. Then, the pressure difference $\Delta P$, at both ends of pores can be expressed by the static pressure of molten steel $P_h$, the pressures caused by gas bubbling $P_g$ and wetting $P_c$, respectively, as follows;

$$\Delta P = P_h - P_g - P_c \qquad (5)$$

Now, for the sake of simplicity, we assume a state that the gas bubbling is completely stopped as $P_g = 0$. Thus, from the equations (1) and (2) it can be written as:

*Fig. 1: Relationship between the height of the molten steel level and the diameter of the pore through which the molten steel can infiltrate into the pore.*

$$\Delta P = \rho g\big(h - l(t)\big) + \frac{4\gamma}{D}\cos\theta \qquad (6)$$

and from the equations (4) and (6),

$$u(t) = \frac{D^2}{32\mu l(t)}\left[\rho g\big(h - l(t)\big) + \frac{4\gamma}{D}\cos\theta\right] \qquad (7)$$

is held. In general, since $h \gg l(t)$, we can simplify as $\rho g\big(h - l(t)\big) \cong \rho g h$, therefore,

$$u(t) = \frac{D^2}{32\mu l(t)}\left(\rho g h + \frac{4\gamma}{D}\cos\theta\right) \qquad (8)$$

is held. Now, the $u(t)$ is also expressed by the following equation:

$$u(t) = \frac{dl(t)}{dt} \qquad (9)$$

and from the equations (8) and (9), we can express $l(t)$ as follows;

$$l(t) = \frac{D}{4}\sqrt{\frac{\rho g h + \frac{4\gamma}{D}\cos\theta}{\mu}} \cdot \sqrt{t} \qquad (10)$$

The equation (10) shows that under this assumption, the infiltration depth is expressed as $l(t) \propto \sqrt{t}$. Figure 2 (a) and (b) shows examples of the calculated infiltration profiles with the time for the heights of the molten steel levels, $h = 2$ and $4$ m respectively, for the pore diameters $D = 50, 100, 150, 200$ and $250$ μm respectively.

The results of these calculations show that the amount of infiltration is about 10 mm even at the time of about 0.05 s for the condition of $h = 2$ m and $D = 50$ μm, where infiltration is difficult to occur. Matsushita et al. have conducted the experiments that molten steel, silver, and mercury were infiltrated into the porous bricks by pressurizing [5], and observed in situ the infiltration by X-ray radiography images. They introduced the labyrinth coefficient $\xi$ for the infiltration rate to correct the structure difference in the porous brick, and proposed the following modified equation:

$$u(t) = \frac{D^2}{32\mu l(t)}\left[\left(\rho g h + \frac{4\gamma}{D}\cos\theta\right)\xi - \rho g l(t)\right] \qquad (11)$$

Note that the term $\rho g l(t)$ has a negative sign because the direction of infiltration in their experiment is opposite to gravity. Now, as same as the former case, assuming that $h \gg l(t)$ and the term $\rho g l(t)$ is negligibly small,

$$u(t) = \frac{D^2}{32\mu l(t)}\left(\rho g h + \frac{4\gamma}{D}\cos\theta\right)\xi \qquad (12)$$

is held, and $u(t)$ is $\xi$ times that in equation (8). In addition, they have expressed $\xi$ as a function of porosity $\varepsilon$ [6]:

$$\xi = 0.04 + 0.238\varepsilon \qquad (13)$$

The equation (13) agreed with the experimental results for silver, but did not with those for both steel and mercury. Because the size and the morphology of the pore have also a significant influence on the infiltration, the equation (13) is insufficient to explain the effect of the structure of refractories on the infiltration. In their experiment, the applied pressure was about 0.01-0.06 MPa, which is 0.15-0.88 m in terms of molten steel head, which is too small to compare to the heights for the molten steel level in the actual ladle. Therefore, $h \gg l(t)$ does not necessarily to hold, and the term $\rho g l(t)$ is not negligible. Thus, they attempted to estimate the labyrinth coefficient $\xi$ by experimentally measuring $l(\infty)$, the height at which the infiltration rate $u$ becomes zero and the infiltration stops [5][7]. In their experiment, applied pressure is defined as $\Delta P_o$ and the infiltration height $l(0) = 0$ at the time of $t = 0$, from the equation (11),

$$l(\infty) = \frac{\Delta P_o}{\rho g} + \frac{4\gamma\cos\theta}{\rho g D_{\max}}\xi \qquad (14)$$

where $D_{\max}$ is the maximum pore diameter. Furthermore, they determined as $\xi = 1$ when the path through which the molten metal can infiltrate due to the applied pressure $\Delta P_o$ are connected from one end of the specimen to the other, the infiltration behavior is the same as the simple cylindrical shape pores with the narrowest channel diameter in that path. However, in the actual use of the porous bricks, the infiltration occurs downward, the gravity never stop infiltration, and the hydrostatic pressure on the bricks is about one order of magnitude higher than the pressure in their experiment. As shown in Fig. 2, the infiltration rate is considered to be very high. Therefore, a kinetic discussion of the process of the infiltration is important.

Yamada et al. have also conducted the experiment in which porous bricks shown in Table 1 were immersed in the molten steel and infiltration depth was only about 20mm under the vacuum evacuation with the pressure difference equivalent to molten steel head $h = 1.5$ m [8]. If $\xi = 1$, the result shows the lower infiltration depth compared to the calculation in Fig. 2.

Therefore, in order to discuss a kinetics on the molten steel infiltration phenomenon in porous bricks with considering the effect of the structure of the bricks, we have analysed numerically by the FVM to simulate the infiltration of molten steel into the three-dimensional structure of the actual porous bricks by X-ray CT.

## NUMERICAL CALCULATION

The calculations were carried out using the porous brick samples 1 to 4 shown in Table 1 with same porosity data determined both by experiment and image analysis using the X-ray CT. Figure 3 shows the schematic diagram of the X-ray CT measurements system.

The radiography image measured by the X-ray CT was reconstructed into a three-dimensional tomographic image. An example of the tomogram is shown in Fig. 4 (a). The tomogram was binarized by the brightness value to distinguish the pores from refractory materials (Fig. 4 (b), (c)). The resulting 3D pore structures are shown in Fig. 5 for samples 1 to 4, respectively. As described previously, Table 1 showed the calculated porosity by image analysis based on the X-ray CT data which agreed well to the measured apparent porosity by the Archimedes method. Therefore, the structure obtained by the X-ray CT is considered to be a representative of the entire structure.

The numerical calculation was performed with OpenFOAM 4.x [9] using the Volume of Fluid (VOF) method. The density and kinematic viscosity of the air are set to $1 \ \mathrm{kg \cdot m^{-3}}$ and $14.8 \ \mathrm{mm^2 \cdot s^{-1}}$, respectively, while the density $\rho$, surface tension $\gamma$ and kinematic viscosity $\mu/\rho$ of the molten steel are set to $7000 \ \mathrm{kg \cdot m^{-3}}$, $1.8 \ \mathrm{N \cdot m^{-1}}$ and $1.0 \ \mathrm{mm^2 \cdot s^{-1}}$, respectively, and contact angle $\theta$ between molten steel and refractory material is set to 110°, and the gravity is not considered. The boundary conditions are shown in Fig. 6. The molten steel was infiltrated from the left side of the figure by applying a pressure difference of 0.1 MPa (equivalent to the molten steel head height of 1.5 m) to an air-filled pore. The sides and the contact area with the refractory were assumed to be non-slip walls. The non-steady state analysis was performed with the computation time of 1 ms.

## RESULTS AND DISCUSSION

The simulation results of molten steel infiltration by fluid analysis are shown in Fig. 7, as the state of the infiltration after 1 ms.

The infiltration morphology into the pores and the rate of infiltration seems different from sample to sample. For example, in the sample 1 infiltration proceeds in the selective pores with heterogeneous front where as in the sample 3 the infiltration proceeds rather uniformly. Figure 8 shows the analytical data on the relation between the apparent depth of the infiltration and time for each material obtained by the present simulation. Where the apparent depth of the infiltration is defined as the value of the deepest infiltration. As shown in the figure, the rate of infiltration is same for all samples up to 0.1 ms, but exceeding the time, the rate differs for each sample, with the order of the samples 4-1-3-2. In Fig. 9, the calculated infiltration rates at 1 ms were plotted against mean pore size determined by the 3D-CT image analysis for each sample, showing some correlation between the infiltration rate and the pore diameter. The orange dotted line in the figure is the infiltration rate determined by the flow equation (8) (Hagen-Poiseuille) for a simple cylindrical shape pore. Comparing the plots with the line, the infiltration rate by numerical simulation with the 3D-CT is roughly 1/3 of the infiltration rate for the simple cylindrical shape pore. Now, the labyrinth coefficient $\xi$ is also determined for comparison with equation (13). For simplicity, since the molten steel head height $h$ is

*Fig.9: Relationship between calculated infiltration rate and mean pore diameter for each sample comparing calculated results by equation (8).*

equivalent to 1.5 m, the equation (12) holds with negligibly small effect of the $\rho gl(t)$ term. In this case, since the rate calculated by the equation (12) is $\xi$ times of that calculated by the equation (10), the labyrinth coefficient $\xi$ for each sample is calculated as shown in Table 2. From Table 2, the labyrinth coefficients calculated in the present work were about 0.34-0.45 times higher than those by the equation (13) [6]. In the model of Matsushita et al. in which the coefficient $\xi$ was calculated from the height at which infiltration stops due to gravity, $\xi = 1$ when the sample was applied the pressure

*Tab. 2: Calculated labyrinth coefficient $\xi$ for each sample*

| | Sample | 1 | 2 | 3 | 4 |
|---|---|---|---|---|---|
| Infiltration rate at 1 ms / m·s⁻¹ | Simulation with 3D-CT | 1.75 | 1.24 | 1.56 | 1.93 |
| | Eq. (8) | 4.70 | 3.65 | 3.50 | 5.12 |
| Labyrinth coefficient, $\xi$ / - | Present work | 0.37 | 0.34 | 0.45 | 0.38 |
| | Eq. (13) | 0.54 | 0.77 | 0.79 | 0.72 |

difference that can infiltrate from one end to the other, but in the present work, the $\xi$ calculated by the infiltration rate obtained by the numerical simulation results in different values. In addition, the magnification factor is about half of that obtained by using equation (13). The present method is considered to be simulated more closely to the actual molten steel infiltration phenomenon because the calculations are performed using the more realistic structures of the refractory materials obtained by the 3D-CT method. The validity of numerical analysis deployed in the present work, however, has not yet been fully verified, and further extended study will be required for more quantitative discussions.

## CONCLUSIONS

In order to discuss kinetically the effect of structure of the porous bricks on the infiltration of the molten steel into the pores of the bricks, the infiltration in the case of pores of a simple cylindrical shape was analyzed at first using both Washburn's and Hagen-Poiseuille's equations. Then, the finite volume method (FVM) was applied to simulate the infiltration of the molten steel into the porous bricks using a three-dimensional (3D) pore structure obtained by the X-ray computed tomography (CT). The results of the simulation were compared to those of analysis using the simplified model of pores.

The rate of infiltration obtained by the simulation correlated more intensively to the mean pore size determined by the 3D-CT image analysis than the other parameters of both porosity and the maximum pore size. Values of both infiltration rate and labyrinth coefficient determined in the simulation were respectively about one-third (34 to 45%) and about half of those in the anaysis using the simplified pore shape.

A realistic structure of the porous bricks determined by the X-ray CT has highly contributed to obtain more accurate simulation results for the infiltration of molten steel into the bricks superior to the results obtained in the conventional analytical works carried out previously in this field. There are, however, still susceptible to further improvements for validation of the numerical analysis deployed in the present work.

# CAO ATTACK ON REFRACTORY MATERIALS OF THE SYSTEM SIO$_2$–AL$_2$O$_3$

S. Uhlendorf, K. Weber*, X. Ritter, H. Wirsing, H.-J. Klischat
Refratechnik Cement GmbH, Goettingen, Germany

## ABSTRACT

The thermochemical attack of CaO-rich kiln feed on refractory materials of the system SiO$_2$-Al$_2$O$_3$ is a major cause of wear in e. g. cement clinker and lime kilns, and often limits the use of these refractories. Nevertheless, refractory materials of this system could gain in importance compared to basic products due to their lower CO$_2$ footprint, lower thermal conductivity, and their potential for lower firing temperature products, e.g. belite cement. Results are reported on reaction tests between CaO and SiO$_2$-Al$_2$O$_3$-based refractory material to contribute to the understanding of the thermochemical CaO attack. Bauxite and tabular alumina based mixtures with SiC addition were chosen, representing state of the art refractory products with increased alkali resistance.

The reaction tests showed that while corundum remains comparatively stable, the component most reactive to CaO is the matrix phase consisting of a finely grained mixture of mullite and glass phase/cristobalite. The susceptibility of the matrix phase to corrosion results from the high diffusion rates of Ca$^{2+}$ ions and their high potential of forming eutectic melting phases, as soon as CaO is added to SiO$_2$-Al$_2$O$_3$.

The findings support further development of enhanced high alumina and SiC-enriched high alumina refractory products with increased CaO and alkali resistance.

## INTRODUCTION

One of the major shares of well-known refractory materials is built on the system SiO$_2$-Al$_2$O$_3$ and includes fireclay, andalusite, mullite, bauxite, or corundum products. Technical data sheets often list excellent refractoriness (refractoriness under load) of the high alumina refractories (defined as Al$_2$O$_3$ > 45 % by mass) in the range of 1500-1800 °C, which would be sufficient for most industrial processes. However, in reality, increased thermal wear begins at much lower temperatures and is the result of the kiln feed and volatile components attacking the refractory material. In cement clinker kilns, the thermal application limit of SiO$_2$-Al$_2$O$_3$ refractory materials is often given as approximately 1300-1350 °C, which coincides with the occurrence of the first cement clinker melts. In most cement clinker rotary kilns, this is the case in the upper transition zone. Similar observations were made in lime kilns, in waste burning kilns, hot gas generators, steel treatment aggregates in contact with slags, etc. By visual inspection, smooth, wavy, or concave eroded hot surfaces are visible and indicate a softening and erosion of the hot face of the refractory lining (figure 1). In most cases, only a thin reaction layer is visible at the eroded hot face surface. The structural cut usually reveals no melt infiltration (figure 2).
*Fig. 1: Thermally eroded alumina lining in the safety zone of a cement clinker rotary kiln. Smoothly and wavy eroded brick surfaces can be observed in the foreground. Transition to the basic lining in outlet direction is marked with a dashed line.*

*Fig. 2: Bauxite-based high alumina bricks subjected to thermal erosion after usage in a lime rotary kiln. The concavely eroded surface is covered with a very thin reaction layer. Thermochemical alteration is limited to the uppermost hot face horizon.*

After analysing such reaction layers mineralogically in many case studies, the minerals anorthite (CAS$_2$) and gehlenite (C$_2$AS) were pointed out as main reaction products between kiln feed/slag/ashes and non-basic refractory material. In the case of silica-rich refractory material, wollastonite (CS) was found, too. In the case of corundum-based material, calcium aluminates such as hibonite (CA$_6$) and grossite (CA$_2$) were detected. These findings indicate that calcium is mainly responsible for the thermal/thermochemical wear of the SiO$_2$-Al$_2$O$_3$ refractory materials. While the fundamental principle of the chemical reaction of basic components, such as CaO, with non-basic refractory components (SiO$_2$-Al$_2$O$_3$) is relatively easy to understand, little is published on the details of the reaction mechanism and the kinetics. This paper shall contribute to the understanding of the CaO attack on refractory materials of the system SiO$_2$-Al$_2$O$_3$, as this attack defines the thermal application limit of the non-basic refractory lining in most cases.

The typical measure to prevent CaO attack is the use of a basic refractory lining based on magnesia, magnesia-spinel, or magnesia-carbon, as a similar basicity of refractory material and CaO reduces the chemical reaction potential. However, basic refractories may carry a higher CO$_2$ footprint due to their higher thermal conductivity and their composition if produced from magnesite.

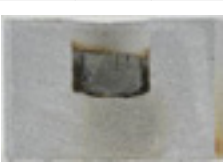
Therefore, an expansion of the application limits of SiO$_2$-Al$_2$O$_3$ refractories by optimisation of their CaO resistance can be seen as one forward-looking measure to reduce the carbon footprint of the processes, especially when a similar or even longer refractory service life can be achieved as well.

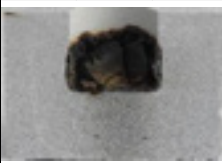
## EXPERIMENTAL

To characterize the reaction mechanism between CaO and refractory material, a crucible test was performed as described in DIN CEN/TS 15418. Bauxite and tabular alumina-based refractory mixtures with 10 % SiC and 5 % bonding clay were chosen since they represent state of the art refractory materials for high temperature applications with enhanced alkali resistance thanks to the SiC (table 1). The mixtures were formed in moulds and fired at 1460 °C. The main mineralogical difference between both mixtures after firing is that mullite is the main phase in the bauxite mixture, while in the tabular alumina mixture corundum is the main phase and mullite is only formed in the matrix due to the presence of bonding clay (tables 2-3). Crucibles were cut out from both mixtures for reaction tests with a sulphate-resistant cement clinker (SRC clinker) as reactant (table 1). When compared to ordinary Portland cement clinker, the SRC clinker has a higher iron oxide content and forms a more reactive, low-viscosity clinker melt above 1300 °C. The crucible tests were carried out in an electric laboratory furnace with a

heating rate of 5 K/min, a dwell time of 5 hours at test temperature and free cooling. Test temperatures were 1300 °C, 1350 °C, 1400 °C, 1450 °C, and 1550 °C.

The mineral phase composition of the refractory material, the cement clinker, and the reaction zone at each testing temperature was obtained by X-ray powder diffraction using a PANalytical X´Pert Pro diffractometer (Cu-Kα-radiation, step size: 0,017°, time per step: 20 s; tables 2-3) and analysed using the X´Pert HighScorePlus software. The reaction zone was analysed by reflected light microscopy on polished sections (figures 3-4). The element distribution was determined using a µ-XRF Tornado M4 from Bruker Corporation (figures 5-12).

Tab. 1: Chemical composition (XRF, fused bead) of the refractory mixtures after firing and the SRC clinker as reactant.




| | Al₂O₃ | SiO₂ | SiC | CaO | Fe₂O₃ | K₂O |
|---|---|---|---|---|---|---|
| Bauxite mixture (85 % bauxite, 10 % SiC, 5 % bonding clay) | 66,7 % | 20,8 % | 6,5 % | 0,6 % | 1,5 % | 0,4 % |
| Tab.alumina mixture (85 % tab.alumina, 10 % SiC, 5 % bonding clay) | 86,3 % | 5,8 % | 7,3 % | 0,1 % | 0,1 % | 0,0 % |
| Sulphate-resistant cement clinker (SRC clinker) | 4,2 % | 21,1 % | - | 65,2 % | 7,3 % | 0,4 % |

The crucibles tests with the SRC clinker showed a reaction layer that formed between the refractory material and the clinker. The reaction layer is slag-like and thus indicates the presence of a liquid phase. The thickness of the reaction layer increased with the test temperature, while the clinker filling is consumed. The refractory material in the contact area was subsequently dissolved and became part of the reaction

layer. At 1450 °C and above, most of the clinker has already reacted and melted. The crucible filling became more homogenous with increasing temperature due to melting and approaching equilibrium conditions. At 1550 °C, the molten reaction product partially infiltrated the texture of the unreacted crucible in the case of the tabular alumina material. In the case of the bauxite material, no infiltration beyond the reaction layer in the contact zone was observed. Gehlenite ($C_2AS$) was determined by XRD as first reaction phase at 1300 °C test temperature in both refractory material mixtures. At 1350 °C and 1400 °C, anorthite ($CAS_2$) was found as well.

The contact reaction was significantly more intense in the bauxite + SiC mixture, where hibonite ($CA_6$) was additionally detected as reaction phase at 1400 °C. At 1450°C, the clinker almost fully reacted with the bauxite + SiC mixture, no clinker phases remained at this temperature. The mullite was completely consumed by the reaction, while SiC and considerable corundum contents survived. Anorthite was the main reaction phase at 1550 °C. This already leads to the assumption that mullite is the weaker phase in bauxite regarding CaO attack, compared to corundum.

In the case of the tabular alumina mixture, the reaction with clinker is slower so that clinker phases still exist at 1450 °C. The reason for slower reaction is most likely the limited amount of mullite here. Main reaction products are still gehlenite and anorthite at 1450 °C, while grossite ($CA_2$) and hibonite appear as well. The calcium aluminates indicate that corundum also starts corroding at higher temperatures. At 1550 °C, gehlenite is the main reaction phase beside significant amounts of anorthite, grossite, and hibonite. Mullite was consumed by the reaction, while SiC and considerable corundum contents remained in the contact area.

The microscopic investigation confirms the advancing melting processes in the reaction layer. It was also confirmed that corundum and SiC partially resist the corrosion and melting process in the reaction zone. Bauxite is more affected by disintegration than tabular alumina as the mullite phase reacts entirely. Tabular alumina grains exhibit a higher resistance to the corrosion and melting process. Since the matrix contains also mullite due to the bonding clay, the melt phase proceeds through the matrix. Finally, mainly intact tabular alumina grains were incorporated into the melt phase as a whole as soon as they are surrounded by the melt.
*Fig. 3-4: Reflected light micrographs of the contact area in the crucibles after reaction with SRC clinker at 1450 °C, bauxite + SiC mixture (left), tabular alumina + SiC mixture (right). A melt phase formed and propagated through the refractory matrix, which is thereby densified. The approximate front line of the reaction zone is marked with the dashed line. The bauxite grains (1) essentially consist of corundum crystals embedded in a mullite matrix. This mineral assembly was dissolved by the advancing melt phase, the corundum crystals partially survived. SiC (2) also partially survived in the reaction layer. In the case of the tabular alumina (3), the grains remained mainly intact but were subsequently incorporated into the melt phase as soon as they were surrounded by melt.*

*Fig. 5-12: Reflected light micrographs and element mappings (μ-XRF) of the contact area in the crucibles after reaction with SRC clinker at 1450 °C, bauxite + SiC mixture (top), tabular alumina + SiC mixture (bottom). The approximate position of the microscopically visible melting front is marked with the dashed magenta line. Fe is a typical constituent of eutectic cement clinker melt but not present in the reaction front area. The Ca content decreases gradually in direction of the refractory material. K from the SRC clinker and the bonding clay is significantly enriched in the reaction zone. Map data: Rh- Kα-radiation, 20 μm pixel size, 500 ms time per pixel.*

Element mappings by μ-XRF of the contact area revealed that the proceeding melt phase in the reaction zone does not contain significant amounts of iron. Hence, this melt phase cannot be referred to as a eutectic cement clinker melt, which would be enriched in iron(oxide). This

is of special interest since the melt phase may otherwise be misinterpreted as an infiltrating clinker melt. The calcium content decreased gradually in the reaction zone in direction of the refractory material. This gradual transition indicates a diffusion-driven migration process of calcium ions. It can also be stated that the $Ca^{2+}$ diffusion front is closely ahead of the melting. Despite the low potassium content in the SRC clinker of 0.4 %, a strong enrichment of potassium took place in the reaction area. Potassium, along with calcium, will have contributed significantly to melt formation.

## CONCLUSIONS

The results of laboratory reaction tests showed a good consistency when compared with the results of post-mortem analyses of used refractory materials subjected to CaO-containing kiln feed or slags at high temperatures. It was confirmed that CaO is mainly responsible for the liquid phase formation in the contact area. The results indicate that the CaO attack can be characterized by a diffusion process of $Ca^{2+}$ ions into the refractory material. High diffusion coefficients of $Ca^{2+}$ were determined by other authors in cement clinker systems before [1]. The diffusion of $Ca^{2+}$ into the refractory material leads to melt formation if a certain level of Ca is reached and the temperatures are high enough. The mineralogically determined reaction phases finally crystallize out of the melt phase. The liquid phase formation is furthermore enhanced by the presence of $K^+$, which is known to act as a flux in refractories.

Mullite or a mixture of mullite, cristobalite, and glass phase were found to be attacked first. The higher degree of structural disorder in these phases favours the diffusion of $Ca^{2+}$ and other ions. The mullitised bonding clay itself is therefore prone for CaO attack and a refractory matrix-containing bonding clay acts as a pathway for the diffusion processes and melt propagation. Diffusion of $Ca^{2+}$ into the refractory material of the binary phase system $Al_2O_3$-$SiO_2$ necessitates consideration of the ternary system CaO-$Al_2O_3$-$SiO_2$ for further description of the processes in more detail (fig. 13)

fig. 13: Ternary system CaO-$Al_2O_3$-$SiO_2$ [2] with plotted composition of the used materials and a typical clinker melt composition at 1450 °C [3] (circles). First reactions were assumed and observed between the refractory matrix (red circle) and CaO coming from the eutectic clinker melt, which is formed in every clinker [3] (light blue circle). Considering a diffusion of $Ca^{2+}$, all compositions between the tie lines (yellow dashed) of both materials exist at the same time. These coexistent compositions in the reaction zone plot in the systems belite-calcium aluminates-gehlenite (blue area), gehlenite-anorthite (purple area) and anorthite-mullite-cristobalite/glass (red area). Relevant eutectics of the locally formed composition are in the range of 1270 - 1350 °C (purple arrows).

843

With the theoretical approach, the constantly determined formation of gehlenite and anorthite as first reaction phases is understandable since these minerals are in the tie line between the composition of the reactive refractory matrix and the composition of clinker melt or pure CaO. Relevant eutectic points are between 1270 °C and 1350 °C and hence agree with the determined occurrence of first liquid phases and the formation of the characteristic reaction minerals around 1300 - 1350 °C.

It can be concluded that the temperatures that are necessary for a significant $Ca^{2+}$ diffusion into the refractory matrix are in the same range as the eutectic melting temperatures. Melting of the refractory material therefore takes place closely behind the diffusion front. This mechanism is apparently the reason why in practice only a thin reaction layer and no deeper infiltration is observed. The melt formation itself further accelerates the diffusion of $Ca^{2+}$, which is a positive feedback reaction. Alkalis, like potassium or sodium, enrich in the reaction zone and most likely worsen the situation by increased glass phase formation, lowering the melting points and increased diffusivity.

## PROSPECTS

With reference to the results of numerous post-mortem analyses, the here described reaction mechanisms between $SiO_2$-$Al_2O_3$ refractory materials and CaO is similar over a wide product range from acidic fireclay to corundum-based bricks or concretes. There will be no magic bullet that can overcome the chemical reaction potential between both media. However, with the aid of understanding the corrosion processes in detail, new refractory products of the system $SiO_2$-$Al_2O_3$ and $SiO_2$-$Al_2O_3$-SiC with a higher buffer for thermochemical resistance have been developed, which currently prove themselves in the application and already led to significantly prolonged service life such as an entire additional campaign. It should be highlighted that a prolonged refractory service life is a very efficient way to reduce cost and $CO_2$ emissions. A substitution of a basic with a non-basic refractory lining is locally possible after a careful revision of the still limiting thermal loads and corrosion by process melts. Positive effects of replacing a basic lining include a lower thermal conductivity, higher resistance to sulphur attack, nearly unlimited shelf life, resistance to hydration, lower expansion coefficient, a more predictable wear pattern, and a lower product carbon footprint.

# IMPACT OF HYDROGEN ON CARBON MONOXIDE DISINTEGRATION OF REFRACTORIES

Joeri Liefhebber, Rinus Siebring
Tata Steel, IJmuiden, The Netherlands

**ABSTRACT**
In many critical installations for the steel industry, refractory materials are (locally) exposed to carbon monoxide (CO) gas. The reaction of CO gas to solid carbon and carbon dioxide ($CO_2$), the Boudouard reaction, has been studied by many authors over the past decades. The reaction results in the deterioration of refractory materials, which can influence the lifetime and availability of production installations. To evaluate the resistance of materials to CO disintegration, the standard test method uses a 100% CO atmosphere. However, various studies have shown that the use of a few percent $H_2$ together with the CO gas significantly increases the reaction rate. Current process gases (like in the Blast Furnace) already contain 2 - 8 vol% $H_2$ and this influences the reaction rates. In future processes, to reduce greenhouse gas emissions, this will further increase when more hydrogen containing gases, like $H_2/CH_4$, are used. Also, from a testing perspective it makes more sense to include hydrogen as faster reaction kinetics are observed to enhance the relative differences between materials' resistance. Tata Steel uses an inhouse testing method for the evaluation of the resistance of refractory materials to CO disintegration. Clear differences are observed when comparing the same samples, which are tested with and without H2 in the gas mix. This approach and method is being discussed with refractory suppliers and used by both sides for the selection of refractory materials where appropriate for the application.

**INTRODUCTION**
When refractories are exposed to carbon monoxide gas for a long period of time this could lead to the disintegration of the material structure, damaging the integrity of the refractory lining.
The reaction of carbon monoxide to solid carbon and carbon dioxide (1) is known as the Boudouard reaction. This reaction has been studied for many years over the past decades [1][2][3].

$$2CO_{(g)} \leftrightharpoons CO_{2(g)} + C_{(s)} \tag{1}$$

The reaction is catalysed by the presence of cementite particles formed from metallic iron and iron oxide particles in reaction with CO gas. These particles are introduced in the refractory products as impurities of the raw materials that are used for its production. The temperature range at which the reaction occurs is between 400 and 900ºC, the maximum rate of carbon deposition is around 500 to 700ºC, depending on the gas composition [2][3].
The resistance to CO gas is usually controlled by selection of low iron raw materials for the refractories production and/or sufficiently high firing temperature. Especially in alumina-silicate refractories the higher firing temperature leads to the formation of iron-silicate phases (like fayalite), which are stable in contact with CO gas. In other refractory materials, like carbon blocks for the Blast Furnace (BF) hearth, a higher firing temperature does not contribute to a better CO resistance. Recent work reveals that sulphur, in the solid and gaseous states, is an efficient inhibitor to limit the carbon formation [5][6].
There are many studies of carbon deposition in a 100% CO atmosphere, but it has been demonstrated that the rate of carbon deposition is strongly influenced by the presence of hydrogen ($H_2$) [2][3][4]. In ironmaking installations where the resistance against CO is relevant, $H_2$ is often present in the gas atmosphere. But the current test methods for determination of resistance of refractory materials to carbon monoxide are done with a 100% CO gas atmosphere (ISO 12676 and ASTM C288). For many materials, especially those with limited carbon deposition during the test, the standard test suffers from poor reproducibility. Even samples cut from the same piece show different results [7].
The role of hydrogen ($H_2$) in the test atmosphere is not fully understood, but it is seen as an accelerator for carbon deposition [3]. For many years Tata Steel has worked with an internal test method, that includes $H_2$ in the gas mixture, to compare the relative resistance of refractory materials against CO gas and select the most suitable materials for the application. More recently this method is discussed with refractory suppliers and used for quality control purposes.
With increasing levels of hydrogen in existing processes, like the Blast Furnace, but also in Direct Reduction Plants (DRP) one should not ignore its effect on carbon monoxide disintegration of refractories. For the selection of refractory materials that are resistant to CO, the inclusion of hydrogen in the test is required.

**CO DISINTEGRATION IN PRACTICE**
Also at Tata Steel in IJmuiden, multiple cases exist of refractory materials that have been damaged by decomposition of carbon monoxide. One of these examples is the torpedo safety lining. The torpedoes are used to transport hot metal from the blast furnaces to the steel plant. The lining consist of an insulation board against the shell, a chamotte (alumina-silicate) safety lining and a carbon bonded ASC (Alumina-SiC-C) wear lining. The gas atmosphere behind the carbon containing wear lining is reducing and CO gas can attack the lining. Figure 1 shows the internal structure (picture taken on a broken brick surface) of the safety lining with many black spots that were identified as deposited carbon in the matrix porosity. The carbon deposition causes the brick to fracture and weakens the structure. It results in damage to the safety lining and more frequent repairs.

*Fig. 1: Broken surface of a safety lining refractory brick in the torpedo. Black spots of deposited carbon have formed (see also red arrows).*

Another installation where CO disintegration of the refractories is observed is the blast furnace hearth. Samples of the carbon and graphite blocks in the hearth have shown crack formation, microstructural evaluation confirmed that the cracks were generated by local growth of carbon in the matrix (figure 2). Once a nucleation site (iron particle) is present and the conditions for the Boudouard reaction are there, the process of carbon deposition continues and creates sufficient forces to break the refractory.
Fig. 2: cross section of the hot face of a carbon block from the blast furnace hearth, showing cracks generated by carbon deposition.

## TEST METHOD
### Historic development
At Tata Steel in IJmuiden, internal reports date back to the 1970's (at that time the company was called Koninklijke Hoogovens) where the CO resistance of refractory materials was tested using gas mixtures that not only consist of 100% CO. Initially trials were set up to resemble a gas composition close to process gases. Samples were ground to powder and heated under inert gas atmosphere to 600ºC, then the sample was exposed to a gas mixture of 65% $N_2$, 33% CO and 2% $H_2$ for a duration of 5 hours. The off gas was analysed to determine how much $CO_2$ formed during the test. At that time there was already information from literature describing the effect of $H_2$ on the decomposition of CO gas [2][3].

In the 1990's the test was adapted and the use of the inert gas ($N_2$) was eliminated and instead of powdered samples fixed rectangular samples were used. Based on several experiments the gas composition was set at 95% CO and 5%. This corresponds to the observation of Turkdogan et al. [2] that a small addition of hydrogen has a considerable effect on the rate of decomposition of carbon monoxide. The addition of a few percent increases the rate drastically but further increase of hydrogen has not much more effect. The temperature was set at 700ºC and the duration of the test was extended to 96 hours.

For many years this has been the internal test method for evaluating refractory materials for their carbon monoxide resistance.

### Current method
The test equipment consists of an electrically heated furnace with 4 horizontal gastight tubes through which the test gas is lead. Samples have a dimension of 15 x 15 x 50 mm and are weighed before the test on a balance with 0.01 gram accuracy. For each tube one sample is placed on a ceramic tray and pushed in the hot zone after which the tube ends are closed gas tight. One end with the gas entry the other for the gas outlet. A gas mixing facility provides the gases (N2, CO and/or H2) in the right quantities. The gas flow is controlled by mass flow controllers.

After placement of the samples the gas flow is switched on with 100% $N_2$ at 5 litre/hr for each tube. The furnace is heated to 700 ºC with 4 ºC/min, after this temperature is reached the gas is switched to a gas mixture of 95% CO and 5% $H_2$, again with a flow of 5 litre/hr per tube.

The test duration is 96 hours (4 days) after which the gas is switched to $N_2$ and the furnace heating is stopped for natural cooling of the furnace. The tube ends are opened when the temperature dropped below 100ºC after which the samples are extracted .

Fig. 3: horizontal tube furnace with gas mixing facilities

### Sample evaluation after the test
After extraction from the furnace the sample is weighed again to determine the weight change. However, most attention is paid to the visual appearance of the samples. Similar to the ASTM C288 standard, the most affected face(s) of the samples are photographed and the extend of the degree of disintegration is described according to the following classifications:

- Unaffected, no particles spall and no cracking occurs. Some degree of discoloration can be observed.
- Affected – surface popouts, popout of small refractory pieces (less then 13 mm) or growth of carbon on the surface.
- Affected – cracked, when sample is cracked and/or larger pieces (more than 13mm) are popped out.
- Destructive, sample breaks is several pieces apart.

Samples that are affected sometimes show very little weight change (mainly in case of popouts), which can be even less than samples that are unaffected. Therefore, weight change is not seen as the determining factor in this test.

## COMPARISON RESULTS WITH AND WITHOUT $H_2$
It has been demonstrated before that the formation of carbon by the reverse Boudouad reaction becomes much more efficient when hydrogen ($H_2$) is present. In the absence of $H_2$ the amount of carbon deposited at a given time is proportional to the amount of catalyst present. On the other hand in a $H_2$-CO atmosphere carbon deposition increases to a lesser extend with an increasing amount of catalyst [2]. Nolan et al. have shown significant effect of $H_2$ present in a CO atmosphere on the formation of carbon [7]. The type of structure appears to be an essential point that leads to the weakening and destruction of refractory materials [2][4][9]. As was also observed in the carbon block of the BF hearth (fig. 2) the build-up of carbon concretions eventually results in the formation of cracks. The presence of $H_2$ in the gas influences how the size of the Fe-catalyst evolves over time and is a key point for the growth and the morphology of the resulting carbon.

In a mixture of CO and $H_2$ gas there are different reactions taking place, such as (1) the reduction of iron oxides by either CO or $H_2$ (2) carbon deposition and (3) water and carbon formation via the reverse water-gas reaction.

In the presence of $H_2$ the catalyst particles are fragmented into much smaller pieces, each being able to form their own filament. In the absence of $H_2$ the catalyst particle is being encapsulated in carbon, which may slow down the reaction and forms less carbon.
*Sample of chamotte fireclay brick after test (100% CO)*

*Sample of chamotte fireclay brick after test (95% CO an 5% H₂)*

*Sample of micropore carbon after test (100% CO)*

*Sample of micropore carbon after test (95% CO an 5% H₂)*

*Fig. 4: Result of CO resistance test on a fireclay brick and micropore carbon brick. The test was performed under a 100% CO atmosphere and a gas mixture of 95% CO and 5% H₂.*

Studies are often done on well-defined/pure catalyst particles to eliminate side effects.

At Tata Steel we use our internally developed method on commercially available refractory materials. Tests that were done to compare the influence of $H_2$ on the test result reveal clear differences. In fig. 4 the result of two different brick types that can be exposed to reducing gases in practice are shown, a) a chamotte based fireclay brick and b) a micropore carbon block. On the left side the result after the test under a 100% CO atmosphere is shown and on the right the result after exposure to a gas mixture of 95% CO and 5% $H_2$. There is a clear difference in visual appearance of samples from the same brick that are exposed to the different atmospheres. The samples exposed to a 100% CO atmosphere are judged as unaffected. The samples that are exposed to a mixture of CO and $H_2$ on the other hand are affected, at various locations across the samples carbon has deposited and accumulated. This results in popouts from the samples, likely the catalyst particles are fragmented which allows more abundant growth of carbon.

**Increasing H₂ level**

Tests have also been done with different CO/$H_2$ ratios by increasing the level of $H_2$ in the gas mix to test the impact on the test result. Fig. 5 shows the result of 4 different test conditions ranging from 100% CO to 85% CO with 15% $H_2$. With changes in the equipment setup higher levels of $H_2$ could be possible in the future. For this test an andalusite brick (60% $Al_2O_3$) was selected of which it was known to be not resistant to CO in our internal test. Again it is seen that with 100% CO there is no significant effect detected in terms of carbon deposition. When $H_2$ is present in the gas mix, popouts are observed on the sample surface. There is no visual difference in the test with 5 or 10 % $H_2$, both showing black dots and surface popouts. With 15% $H_2$ one could argue that the surface looks to have more black spots, but in terms of surface popouts there is not much difference.

**APPROACH IN MATERIAL SELECTION**

At Tata Steel in IJmuiden it has been the protocol for a long time to use a different method for testing the CO resistance of refractory materials than the ISO 12676 and ASTM C288. The lack of $H_2$ in these test methods makes it much more difficult to distinguish between the relative CO resistance of similar products. For selection of new products (especially for the BF lining) the internal test method of Tata Steel with 95% CO and 5% $H_2$ is used.

When a suitable material is found, it is important to guarantee similar resistance to CO in future deliveries. Most commonly, the iron content gets a guaranteed upper limit on the product definition. More recently we have discussed the test method for CO resistance with refractory suppliers for materials for the BF, such that they understand the approach. Some are also setting up own equipment in order to run the CO resistance test in an CO/$H_2$ atmosphere themselves. Ultimately, Tata Steel in IJmuiden is requesting the resistance to CO according to this method to be guaranteed on the product definition. In some cases this has been proven to be successful.

Not many companies (refractory producers and users) have their own facilities to perform such tests, but there are also third party labs in Europe that can perform these tests when necessary.

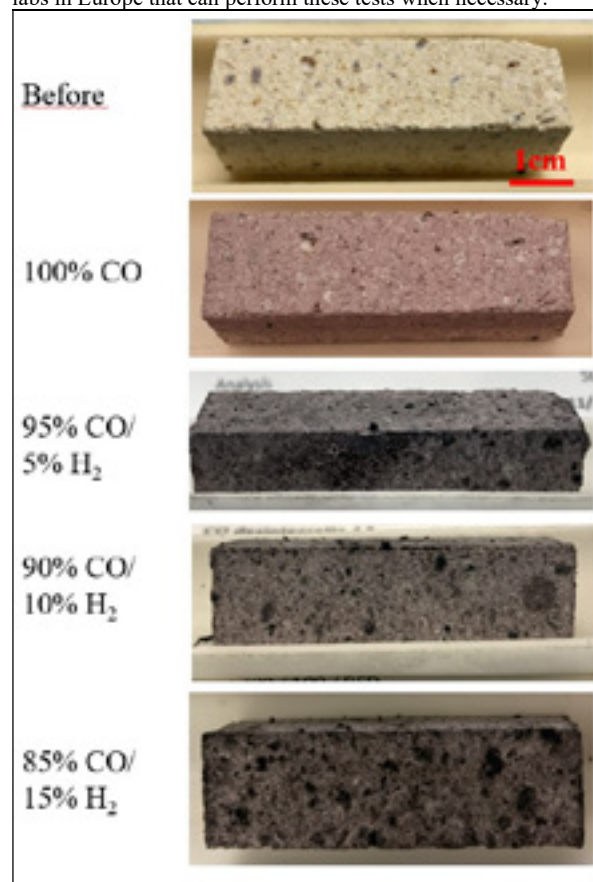

*Fig. 5: Result of CO resistance test with increasing level of H₂ in the gas mix*

## IMPLICATION FOR (FUTURE) IRON- AND STEELMAKING PROCESSES

One of the important installations where the mechanism of CO disintegration can damage the refractories is the Blast Furnace. Even though the trend for future ironmaking is to phase out Blast Furnaces and replace it by other processes, there will still be many blast furnaces in operation in the coming years. There are many trials (ongoing and planned) to increase hydrogen in the blast furnace process. Effects on refractory wear should be carefully monitored, if accelerated wear is observed the role of hydrogen in the decomposition of CO and subsequent deterioration of the refractories shouldn't be underestimated.

In the torpedoes (used for hot metal transport) it has been shown that CO disintegration can play a role in the deterioration of the refractory permanent/safety lining. However, the role of hydrogen here is very small or even not there. The only time when hydrogen is present is directly after repairs (from castables and mortars) or after a cold standby (moisture from air or rain). Of course CO disintegration can still take place, but without the contribution of hydrogen.

Various projects worldwide are underway to eliminate $CO_2$ emissions from the traditional BF-BOF route [10]. One of the trends for future ironmaking is the development of hydrogen based DRI production followed by melting the DRI. The existing way of DRI production is based on natural gas, for future DRI production this will then gradually be replaced by $H_2$. This is dependent on the availability of green hydrogen. In any case the reductant gases will be a combination of CO and $H_2$ until the process would run on 100% $H_2$. CO disintegration under the presence of hydrogen can potentially contribute to the wear of the refractories. Evaluating the suitability of refractory materials for this process would therefore be most relevant in the presence of hydrogen during the test.

Depending on the selected process route the hydrogen based DRI can be further used in an EAF or a reducing melting furnace. The EAF is an oxidising environment where CO disintegration is expected not to play an important role in the wear mechanism in the refractories. For melting DRI under reducing conditions it is expected that CO disintegration can play role in the deterioration of the refractories. However, the influence of $H_2$ is probably very limited again. There is no active source of $H_2$ (as gas or water vapour) in these processes that can influence the Boudouard reaction.

## CONCLUSIONS

The current standard test methods for determination of resistance of refractory materials to carbon monoxide use a 100% CO gas atmosphere (ISO 12676 and ASTM C288). It has been demonstrated before that the formation of carbon by the reverse Boudouad reaction becomes much more efficient when hydrogen ($H_2$) is present.

For many years Tata Steel has worked with an internal test method, that includes $H_2$ in the gas mixture, to compare the relative resistance of refractory materials against CO gas and select the most suitable materials for the application. More recently this method is now also discussed with refractory suppliers and used for quality control purposes.

## ABSTRACT

Carbon nanotubes (CNT) are graphene sheets in cylindric structure and have exceptionally qualities. The single-walled CNT, for example, depict excellent thermal and electrical properties. Whereby multi-walled CNT present extraordinary mechanical qualities and a high aspect ratio. On the other hand, it is well known that carbon nanotubes build a remarkable tabular structure which expands enormously during formation in refractory castables. Hence, the CNT are an unwanted and well documented by-product in refractory materials by exposure in CO atmosphere at intermediate temperatures. Solutions for CO resistance for refractory materials and, consequently, a better understanding of the decomposition and production process is desired and inevitable.

In this paper the knowledge of the development and destruction of the microstructure of refractory castables due to carbon deposition is given. For the first time an imaging method for the deposition of carbon in the microstructure of castables is presented. By varying the number of impurities in the refractory castables under CO atmosphere the progression of the carbon deposition was analyzed and displays the influence of crack formation, built by the carbon nanotubes. The results were gathered by using a Field Emission Scanning Electron Microscope (FESEM).

## INTROCUTION

The mechanism of carbon monoxide decomposition in refractory castables is a well-known issue by the refractory industry, whereas the microstructural process and mechanism is not fully understood till today.

So far two main mechanisms are analyzed and known to be the cause for the CO decomposition. The availability of a catalytic reactive phase in liquid form is required, which promotes the so-called vapor-liquid-solid (VLS) mechanism [1]. The vaporous phase, here CO, dissolves on the liquid catalyst, often iron, and generates fusible cementite ($Fe_3C$) until an oversaturation is reached. The result is the precipitation of the pure, whisker-shaped carbon. The other inevitable process is a shift of the Boudouard equilibrium ($2\ CO \leftrightarrows C + CO_2$) [2] to the reactant at around 500 – 600 °C, providing the necessary free carbon for the dissolution on the catalyst. In refractory products the crucial catalytical substances are Fe and $Fe_2O_3$, which are present as impurities in the (refractory) raw materials [3, 4].

The carbon generated in the process precipitates in $sp^2$ hybridization as carbon nanotubes or similar structures which lead to an enormous volume expansion with a crystallization pressure of 63 kbar. This leads to drastic destruction in the refractory products [5].

The standard corrosion test for CO bursting delineated in ISO 12676 and ASTM C 288 and is not reproducible and leads to divergent results which is confirmed by several studies [1, 3, 6]. Therefore, a proper testing method is aspired. In 2022 a newly designed furnace including a thermogravimetric test stand was presented after the conclusion of IGF project 21408N [7]. During the heating under CO-atmosphere the weight of a cylindric specimen is constantly measured, resulting in a time-depending weight gain analysis. The benefits are tremendous, because the evaluation of carbon deposition in the refractory materials during the heating process is now based on actual data. In comparison the corrosion test ISO 12676 is a superficial assessment of the treated samples categorizing them into groups of "A" to "D". The new, quantitative and reliable testing method was verified using scanning electron microscopy (SEM) in which the generated carbon species and their amount were determined. The new test method opens up new possibilities for testing the influence of different factors such as the number of catalysts, the gas flow rate and the permeability. The previously established relationship between a higher number of impurities (catalyst) and increased carbon deposition in the refractory material was confirmed by both thermogravimetric and SEM analysis [3, 5, 7, 8]. However, the dependency of the gas flow rate and carbon deposition in Krause and Pötschke was refuted with both analysis methods. In addition to the standard gas flow rate of 60 l/h, four different gas flow rates (10, 20, 30 and 40 l/h) were examined and yielded no weight gain or rising amount of carbon nanotubes with increasing gas flow rate. However, the porosity of the refractory castables affects the carbon deposition. Even a 1.5 % increase in open porosity doubles the weight gain of the cylindrical refractories [9]. The influence in open porosity goes along with the development of the microstructure, in particular the formation of cracks and the ingress of CO gas, which is inevitable for the formation of carbon nanotubes in the core and back of samples of refractory applications in the industry.

## METHOD

A model refractory castable was designed for the in-situ analysis in the newly designed furnace and ex-situ studies by other analytical methods. It primarily consists of CA-bonded alumina and has been spiked with varying amounts of hematite ($Fe_2O_3$) ranging from 0.1 to 0.3 wt.-% (table 1), provided by Thyssenkrupp Steel Europe AG with a purity level > 99,5 % iron oxide. The samples were manufactured in accordance with the standard procedure described in DIN EN ISO 12676. After mixing, the cylindrical castables were placed in a climate chamber for 24 h, followed by 24 h drying at 110 °C. The cylinders were then preheated for 5 h at 540°C in an oxidizing atmosphere in accordance with DIN EN ISO 12676. The pretreated samples were cut in half to form cylinders of 50 mm diameter and height. Afterwards, they were heated for 25 h in the newly constructed CO furnace, except for the sample V1 which was heated for 50 h.

Tab. 1: Compositions of the refractory material with various concentrations of iron oxide in wt.-%.

| Component wt.% | V1 | V2 | V3 | V4 | V5 |
|---|---|---|---|---|---|
| Tabular Alumina | | | | | |
| 1.0-3.0 mm | 25 | 25 | 25 | 25 | 25 |
| 0.5-1.0 mm | 21 | 21 | 21 | 21 | 21 |
| 0.2-0.6 mm | 11 | 11 | 11 | 11 | 11 |
| 0.0-0.2 mm | 12 | 12 | 12 | 12 | 12 |
| 0.0-0.045 mm | 9 | 9 | 9 | 9 | 9 |
| Calcined alumina | 10 | 10 | 10 | 10 | 10 |
| Reactive alumina | 7 | 7 | 7 | 7 | 7 |
| Dispersing agent (PCE) | 0.15 | 0.15 | 0.15 | 0.15 | 0.15 |
| CA cement | 5 | 5 | 5 | 5 | 5 |

| Fibers | - | - | - | 0.01 | - |
| Water | 4.5 | 4.5 | 5 | 4.5 | 5 |

For understanding the microstructural texture and their influence on the carbon deposition microscopical analyses were conducted. Therefore, polished sections, fragments and sawn discs of the cylindric samples were prepared. The analyses for the distribution of the iron oxides and carbon depositions occurred using a Digital Microscope VXH 7000 from Keyence. SEM images of the specimen microstructure were taken at 10 kV using a JEOL JSM 7200F field emission scanning electron microscope. It was necessary to have a conductive surface for which reason the samples were coated with differing layers of iridium in a range of 0.5 – 2 nm. The analyses were conducted at the center and edge of the samples. In addition, the sawn discs provided information about how deep the reaction infiltrated the samples. For this reason, the reacted edge of the sample was related to the lesser affected center of the samples.

## RESULTS AND DISCUSSION
### Textural results
In a reduced atmosphere, the stress on the refractory materials is intensive. The more the refractory material is contaminated, the more carbon is deposited on the iron oxide particles and the more stress is placed on the material. [3, 5, 8]. The homogeneous distribution of the hematite in the cylinders produced ensures good accessibility for the CO gas and the subsequent carbon dissolution (figure 1a), resulting in good research conditions. In industry, the distribution of the impurities is more localized and not as dispersed as in the cylinder produced.

As shown in figure 1b the entire matrix of the castables discolors into different shades of gray, due to the precipitation of carbon. The darker an area the more carbon was deposited. The progression of the amount of carbon formed decreases from the edge to the core, respectively to the accessibility of the iron particles. Naturally with high amounts of hematite the amount of carbon deposited rises. The more affected edge of the cylinder presents the penetration depth of the CO gas. The comparison of affected edge to core is measured and presented in table 2. Once again, the dependency of the available iron oxide for the carbon disposition becomes apparent and gives a new approach to determine the CO resistance.

Fig. 1: a) Homogenous distribution of the hematite in the preheated cylinder. b) Cut disk of a heated cylinder of V2 (highest iron oxide content) in CO atmosphere. The edge of the sample is highly attacked presenting a high carbon deposition compared to the inner zone.

Tab. 2: Relation of the more CO-affected edge toward the center of the samples V1-5.

| Sample | Edge [mm] | Center [mm] | Ratio | Percent [%] | Iron oxide [wt.-%] |
|---|---|---|---|---|---|
| V1 | 7.2±0.3 | 17.8±0.3 | 2.5 : 1 | 29.0 | 0.2 |
| V2 | 10.2±0,3 | 14.8±0.3 | 1.5 : 1 | 40.8 | 0.3 |
| V3 | 6.7±0.4 | 18.3±0.4 | 2.7 : 1 | 26.8 | 0.2 |
| V4 | 2.9±0.2 | 26.9±0.2 | 7.5 : 1 | 11.8 | 0.1 |
| V5 | 23.0±0.2 | 22.0±0.3 | 7.4 : 1 | 12.0 | 0.1 |

V4 and V5 were spiked with as little as 0.1 wt.-% of hematite and have the smallest of the more affected zones with less than 2.5 mm. By increasing the iron content to 0.2 wt.% (V1 and V3) the affected zone rises to 6.2 – 9.6 mm. At last, in the castable with 0.3 wt.-%

hematite (V2), a highly carbon precipitated zone of more than 10 mm is produced.

On closer examination the integration of the particles in the matrix has changed after the heating in CO atmosphere. Depending on the hematite content, many particles broke out of the matrix and are not interlocked anymore, as depicted in figure 2a. In addition, circular cracks appear around the particles in the samples. Both are typical indicators of an enormous volumetric expansion. The crack evolution is shown in figure 2b and displays a gradient from outside inwards. During the heating, these cracks facilitate the CO gas to reach the inner iron oxide particles and precipitate more carbon. As a result, the volumetric expansion continues to increase, providing a constant space for the CO gas to infiltrate the refractory castables, which corresponds to an increase in permeability.

Fig. 2: a) Incoherent Particles in carbon rich matrix of the refractory castable V3 containing the highest amount of iron oxide (0.3 wt.-%). b) crack evolution from the outside inwards in the same sample.

### Microscopic results
SEM analysis of the heated samples gave a further, deeper impression of the interlocking of the carbon allotropes, in this case mostly represented by CNT, in the matrix of the castables. Depending on the amount of hematite the cylinders were already destroyed after 15 h of CO exposure with a gas flow rate of 10 lh$^{-1}$, as for example the cylinder of the castable of V2 containing 0.3 wt.-% of iron oxide. In figure 3 the fragment of the specimen V3 is displayed with an enormous amount of CNT interlocking in the matrix of the castable. Consistently, the amount of hematite affects the number of produced CNT, as the comparison of figure 3 and 4 illustrates.

Fig. 3: SEM image of a fragment of the specimen V3. The CNT are present in a large quantity in the matrix. There are many different shapes of the CNT – plain and curly with variable length and thickness.

Although, the number of CNT is lower with less hematite, the increase in volume, which facilitates the circular cracks around the alumina particles, is apparent in the SEM images (figure 4). The
849

*Fig. 4: SEM image of a fragment of the specimen V5. The amount of the CNT is locally elevated. In addition, the CNT, as in the other specimen, are interlocked in the matrix and have a variety of different shapes.*

SEM examinations of edge and core fragments from one specimen confirm the before stated relation of more affected zones of the CO gas. In the fragments of the outer rim more CNT were detected than in the fragments of the core of the cylinders. Generally, the CNT were scattered in the matrix and regularly occurred in clusters. Compared to this, the centered CNT seem to form more often in clusters of varying sizes (figure 5).

Besides the CNT and hydrate phases as binding elements, calcite was found every now and then in various fragments and polished sections. As shown in figure 6, the calcite is predominant in its rhomboedric shape. In one specimen a rather scarce examples of full-grown calcite crystals as trapezohedrons were detected. The $CaCO_3$ polymorph originated from relictic cement phases, which were formed during the preheating phase at 540 °C in oxide atmosphere. As visible in figure 6, sparse CNT are in between the calcite crystals. This appears in other specimens (V5) in the opposite way, so that seldom calcite crystals are present at CNT clusters and in matrix phases or pores.

However, there is no correlation between CNT formation, iron content and calcite formation, as calcite was found in each specimen independent of the iron oxide content.

*Fig. 6: SEM image of a polished section of the specimen V4. The typical rhombohedron of calcite appear in a bulk within the matrix.*

*Fig. 5: SEM image of a CNT cluster in an edge fragment of the sample V4. This is a fairly large example of a CNT cluster, given the hematite content of only 0.1 wt.-%.*

**CONCLUSIONS**

The analysis of the microstructure sheds light on the intensity of the carbon infiltration and its influence on the refractory castables. It is possible to correlate the destruction of a refractory castable to impurities and duration of heating in CO atmosphere. As a result, the higher the level of impurity is, in our case hematite, the greater the area of refractory castables affected and the greater the degree of destruction. The same assumption applies for the heating time in CO atmosphere.

Cracking during heating is a fatal process as the CO gas can infiltrate further into the sample, leading to more carbon deposition. On the one hand, the observed cracks leading from outside inward, promote this process. On the other hand, the second type of cracks detected (circular around the particles) is typical of an increase in the volume expansion of the matrix. This is the result of the built carbon nanotubes, which are known for their high volumetric expansion in refractory castables, causing a large increase in porosity and permeability. Whereby, the refractory castable loses consistency until its complete destruction. The formation of scattered CNT in the matrix as well as clusters could be confirmed using the generated SEM and microscopical images. The variation of length and diameter of the CNT is keen. The number of CNT depends mostly on the content of impurity and duration of firing in CO atmosphere. Additionally, other fullerene as well as calcite were found in the varying specimens.

This approach offers a good opportunity to determine the penetration of carbon deposition; however, more data is needed to verify the work done so far and to ensure reproducibility and consistency. Furthermore, the next steps will be to analyze different refractory castables with varying open porosity and subsequently permeability using imaging methods (e.g. SEM).

## ABSTRACT

The disintegration of refractory materials in CO containing atmospheres, due to the deposition of carbon in the microstructure in the presence of reducible iron phases, is a relevant issue for both refractory manufacturers and users.

With a new testing method, developed previously by Forschungsgemeinschaft Feuerfest e. V., reproducible and quantifiable in situ information on the reaction kinetics of this destruction process in unshaped refractory materials can be determined. With this method, the reaction kinetics of the carbon deposition was investigated in dependency of the pore structure of the refractory material by measuring the open porosity together with thermogravimetrical analysis to collect data on reaction kinetics of the carbon deposition in CO containing atmospheres.

The results of these investigations are helpful to develop new CO resistant refractory materials and to optimize already existing material systems for the application in reducing conditions.

## INTRODUCTION

The Boudouard reaction ($2CO \leftrightarrow CO_2 + C_{(solid)}$) and the accompanied carbon deposition due to the catalytic effect of iron and iron containing phases has been investigated for a long time [1]. In the relevant temperature range of 500 to 600 °C, the Boudouard reaction is thermodynamically shifted towards $C + CO_2$. However, the deposition of carbon is kinetically inhibited without the presence of catalytically active particles like iron oxide, nickel oxide or manganese oxide [2]. Since refractory materials often contain iron of metallic or oxidic nature, they are particularly affected by this effect when they are being used in reducing, carbon monoxide containing atmospheres. The damaging process of refractories can be summarized by [3]:

1. Diffusion of CO into the open pores of the refractory structure
2. Reduction of iron oxides into metallic iron (Fe)
3. Conversion of Fe into $Fe_3C$ as a result of saturation with carbon
4. Growth of elemental carbon in the material with a crystallisation pressure of 64 kbar
5. Formation of cracks and complete disintegration of the refractory material over time

The iron containing phases are either brought in via natural impurities from refractory raw materials or through mechanical processing. Earlier work was able to show that hematite ($Fe_2O_3$), as an iron containing phase, shows the highest catalytic effect in the deposition of elemental carbon in refractory materials. Under CO atmosphere, hematite is converted to magnetite with a decrease in density and an increase in surface area due to crack formation because of volume expansion through recrystallization [4]. As a result, the remaining hematite is converted more rapidly, leading to a cascading increase in surface area of the catalyst material. The reactions occurring during the conversion of iron containing phases under CO atmosphere can be summarized as:

$$3Fe_2O_3 + CO = 2Fe_3O_4 + CO_2 \quad (1)$$

$$Fe_3O_4 + 4CO = 2Fe + 4CO_2 \quad (2)$$

$$3Fe + 2CO = Fe_3C + CO_2 \quad (3)$$
The resulting cementite ($Fe_3C$) is then supersaturated with elemental carbon from the atmosphere and further separated carbon is deposited on the cementite surface in the form of graphite. This leads to the instability of the cementite which decomposes according to:

$$Fe_3C \rightarrow 3Fe + C \quad (4)$$
The graphite growing in the cementite during this process acts as an adhesion surface for additional carbon atoms, which in turn act as a catalyst for further carbon deposition. The carbon deposition can be qualitatively described as [5]:

$$Fe_3C \rightarrow C_{(graphite)} + \text{oversaturated solution } (Fe + C) \quad (5)$$
As the carbon deposition within the Boudouard reaction requires liquid iron or carbide droplets, shaped refractory materials are usually pre-treated at higher temperatures to increase the resistance of the material against destruction in carbon monoxide atmospheres. As a result, existing iron is bound in silicate form and no longer has a catalytic effect in the relevant temperature range between 500 and 600 °C. Since unshaped refractories are not pre-treated at sufficiently high temperatures, they are particularly susceptible to CO bursting – the destruction caused by the deposition of elementary carbon.

Previous work suggests that the CO bursting is a diffusion-controlled process that depends heavily on the open porosity and the associated gas permeability of the material [4]. The reason for this assumption is an observed re-increase in the carbon deposition rate after initial crack formation on the surface of the material. This results in new diffusion paths for CO gas and previously unreachable catalytically reactive particles are reduced and thus promote the further deposition of carbon in the refractory material.

To further understand this process, the influence of open porosity and thus the gas permeability of refractory materials on the carbon deposition by the Boudouard reaction using $Fe_2O_3$ catalyst and a CO atmosphere at 500 °C was investigated. The open porosity was varied by increasing the water content during preparation of unshaped refractory samples, by the addition of organic fibres and by changes in pore size distribution. The carbon deposition was investigated using a new test stand using thermogravimetrical analysis.

## METHODS AND MATERIALS
### Model materials

In order to investigate the influence of open porosity on carbon deposition, a reference refractory castable was developed and specifically contaminated with hematite as the catalytically active phase. Since the proportion of catalytically active material also plays a significant role for carbon deposition, this was also varied for two selected materials (V1 and V3) [7].

This reference material was a high-alumina based (all aluminas were provided by Almatis), CA-cement bonded (CAC was provided by Imerys Aluminates) refractory castable (table 1).

Based on this reference material, the open porosity was varied by adding organic fibres that are burnt out before testing (V2), increasing the water content of the mixture (V3) and changing the pore size distribution by increasing the proportion of coarse grains (V4). In addition, three materials were produced in which the proportions

of reactive alumina particles and the finest proportion of tabular alumina were varied (V5, V6 and V7).

Using the recipes shown in table 1, cylindrical test samples with a height and diameter of 50 mm were produced and thermally pretreated according to DIN EN ISO 12676 (5 hours at 540 °C under oxidizing conditions) For each material, four cylindrical samples were produced. Three of these samples were used to determine the open porosity, while one sample was subjected to thermogravimetric analysis and scanning electron microscopy after exposing the material to CO.

*Tab. 1: Composition of the high-alumina and CA-cement bonded refractory castables (all data given in wt.-%), TA = tabular alumina, RA = reactive alumina, CAC = calcium aluminate cement. Digits highlighted in red mark the differences compared to the reference material V1.*

**Measuring the open porosity**

The open porosity of the refractory castables was measured according to DIN EN 993-1 (Archimedean principle in water). Therefore, three samples from each batch were measured in order to ensure the uniformity of the measurements.

**Determining the carbon deposition**

The time dependent carbon deposition was measured with the help of a new test stand that was developed at Forschungsgemeinschaft Feuerfest e. V. [7]. This test stand is based on thermogravimetrical analysis and measures the mass gain of refractory materials due to carbon deposition under a constant flow of carbon monoxide gas (figure 1). This test stand was designed with the help of fluid dynamic simulations to ensure uniform and homogeneous flow conditions around the samples and thus provides a high reproducibility of the tests [6].

For each test, a cylindrical sample (height and diameter of 50 mm) is being placed on an alumina sample plate and is then heated up to 500 °C at a rate of 5 °C min$^{-1}$ under 60 l h$^{-1}$ of nitrogen inert gas to eliminate remaining oxygen in the reaction chamber and thus to prevent oxidation reactions. After holding the sample temperature at 500 °C for 1 h under a constant flow of nitrogen to allow thermal influences on the weighing signal and the associated apparent changes in mass to subside, the sample is exposed to CO gas for either 50 h (samples with 0.25 wt.-% hematite) or 25 h (samples with 0.1 wt.-% hematite) at a constant flow rate (10 l h$^{-1}$).

## RESULTS

### Open porosity of the model materials

Table 2 shows the results of the investigations on the open porosity and bulk density of the materials. The deviations from average for both material parameters are also shown. Both the material with an increased water content (V3) and the one doped with fibres (V2) showed the highest open porosities of the materials measured (V3 with an open porosity of 15.1 vol.-% and V2 with an open porosity of 13.8 vol.-%). The material with an increased proportion of coarse grain and a lower water content showed the lowest open porosity of all materials of 11.5 vol.-%. All the other materials, including the reference material (V1a/b) and the comparison materials with differing finest fractions, showed very similar open porosities between 13.0 and 13.4 vol.-%.

*Tab. 2: Overview of the measured open porosities and bulk densities of the refractory castables.*

| Material | Bulk density in g cm$^{-3}$ | Deviation from average | Open porosity in vol.-% | Deviation from average |
|---|---|---|---|---|
| V1a/b | 3.136 | 0.002 | 13.1 | 0.6 |
| V2 | 3.107 | 0.005 | 13.8 | 0.7 |
| V3a/b | 3.141 | 0.003 | 15.1 | 0.1 |
| V4 | 3.137 | 0.011 | 11.5 | 0.7 |
| V5 | 3.151 | 0.004 | 13.0 | 0.3 |
| V6 | 3.127 | 0.002 | 13.4 | 0.4 |
| V7 | 3.131 | 0.003 | 13.3 | 0.4 |

### Thermogravimetrical analysis

The results from the thermogravimetric measurements with the reference material, a hematite content of 0.25 wt.-% and differing open porosities (V1b and V3b) are shown in figure 2. The samples were exposed for 50 hours in a CO atmosphere with a constant supply of CO gas (10 l h$^{-1}$) at 500 °C. The material with a higher open porosity is shown in red (V3b), the material with lower open porosity in blue (V1b). The rate of carbon deposition of V3b (open porosity of 15.1 vol.-%) was found to be significantly higher than the deposition rate of V1b (open porosity of 13.1 vol.-%). Both materials showed an initial strong weight gain due to carbon deposition, followed by a continuous decrease in the carbon deposition rate until an almost linear course of carbon deposition set in. Aside from that, both materials showed a re-increase of the carbon deposition rate after several hours of linear progression. However, the two materials differed significantly in terms of the point in time where the re-increase began. While V1b showed a re-increase in the carbon deposition rate after an exposure time of around 40 hours, the re-increase occurred after an exposure time of around 20 hours

for V3b. Due to the overall higher carbon deposition rate of V3b, after 50 hours of exposing the material to CO, the material showed an increase of 1.74 wt.-% due to carbon deposition, while V1b showed an increase of only 0.98 wt.-%. Since the samples no longer had structural stability after CO treatment and were therefore unsuitable for microscopic structural investigations, all further investigations were carried out on materials with a reduced hematite content of 0.1 wt.-% and a reduced exposition time of 25 h.

*Figure 2: Overview of the carbon deposition in high alumina refractory castables with different open porosities (V1b: 13.1 vol.-%, V3b: 15.1 vol.-%) and a hematite content of 0.25 wt.-%. The tests were carried out for 50 h at 500 °C and a CO flow rate of 10 l h$^{-1}$.*

Figure 3 shows the results of the thermogravimetric measurements with the reference and comparison material, 0.1 wt.-% hematite and differing porosities. The samples were exposed for 25 h in CO atmosphere with a constant supply of CO gas (10 l h$^{-1}$) at 500 °C. Right at the beginning of the exposition in CO, all the materials showed the same strong increase in mass. All the samples examined as part of these measurements showed a steady decrease in the carbon deposition rate after the first strong increase in mass. This was followed by the transition into an almost linear progression of carbon deposition from a test duration of about 10 h onwards. It is noticeable that V3a (highest open porosity of 15.1 vol.-%) showed a significantly higher carbon deposition rate after one hour of exposition to CO in comparison to all other materials. This trend continued for V3a until the end of the test duration and resulted in the highest mass increase of 0.41 wt.-%. In addition to V3a, V2 (open porosity of 13.8 vol.-%) also clearly stood out from the other materials regarding the carbon deposition rate after about 5 h of testing time. As a result, V3a and V2 showed the highest mass gains after 25 h of exposing them to CO. The increase in mass was 0.41 wt.-% for V3a and 0.39 wt.-% for V2. The lowest carbon deposition rate and thus the lowest mass increase with 0.33 wt.-% after 25 h in CO atmosphere was observed for the material with an increased proportion of coarse grain and a lower water content (V4, open porosity of 11.5 vol.-%). Both the reference material (V1a, open porosity of 13.1 vol.-%) and the materials with modified finest fraction (V5, V6 and V7, open porosities between 13.0 and 13.4 vol.-%) showed very similar final mass gains after testing. V1a and V6 showed a mass gain of 0.36 wt.-%. For V5 the mass gain was 0.33 wt.-% and for V7 0.35 wt.-%.

*Figure 3: Overview of the carbon deposition in high alumina refractory castables with different open porosities and a hematite content of 0.1 wt.-%. The tests were carried out for 25 h at 500 °C and a CO flow rate of 10 l h$^{-1}$. The enlarged area shows a more legible view of the differences of the studied materials in terms of their mass gain due to carbon deposition.*

**Correlation of open porosity and carbon deposition**

The data of open porosity and carbon deposition of the examined refractory castables are compared in table 3 and visually presented in figure 4. The refractory castable with an increased water content and the highest measured open porosity of 15.1 vol.-% (V3a) also shows the highest mass gain after exposing it to CO (0.41 wt.-%), followed by V2, the refractory castable with organic fibre material and the second highest values for open porosity (13.8 vol.-%) and mass gain due to carbon deposition (0.39 wt.-%). The materials V1a, V5, V6 and V7 (reference material and materials with variations in finest fraction) differ only slightly in terms of their open porosity (in a range between 13.0 and 13.4 vol.-%) and carbon deposition (in a range between 0.33 and 0.36 wt.-%). V4, the material with an increased proportion of coarse grains and reduced water content, shows both the lowest open porosity and the lowest mass gain with 11.5 vol.-% and 0.33 wt.-%. In general, it should be noted that the measurement of the open porosity of refractory castables has an error that is not negligible. Within the measurements carried out, this error is up to 0.7 vol.-% (deviation from average according to table 2). A determined deviation from average of max. 5 % (related to the mass gain in wt.-%) applies to the carbon deposition [8]. Under consideration of the possible errors for both measurement methods, a linear correlation between the open porosity and the tendency to carbon deposition of refractory castables can be assumed for the test results obtained so far.

*Table 3: Overview of the mass gain in refractory materials after exposition in CO for 25 h at 500 °C and the open porosities of the respective materials after thermal pre-treatment at 540 °C and prior to the exposition to CO.*

|  | V1a | V2 | V3a | V4 | V5 | V6 | V7 |
|---|---|---|---|---|---|---|---|
| Mass gain in wt.-% | 0.36 | 0.39 | 0.41 | 0.33 | 0.33 | 0.36 | 0.35 |
| Open porosity in vol.% | 13.1 | 13.8 | 15.1 | 11.5 | 13.0 | 13.4 | 13.3 |

*Figure 4: Correlation of the thermogravimetric data for the final carbon deposition in all comparison materials after 25 h in a CO atmosphere at 500 °C and the open porosity of the materials after thermal pre-treatment and before the exposition in the CO test stand. The error indicators for the open porosity correspond to the deviation from average from table 2, the error indicators for the carbon deposition correspond to the maximum error from repeatability tests with the test stand [8].*

## CONCLUSIONS

Experimental results on the open porosity of refractory castables (after thermal pre-treatment) and the carbon deposition (after exposing the material to a CO atmosphere at 500 °C) are reported and correlated with each other. The refractory castables used in the test series were specifically contaminated with hematite to promote the carbon deposition within the Boudouard reaction.

For refractory castables with an increased degree of contamination (in this case 0.25 wt.-% hematite), increasing the open porosity by 2 vol.-% (due to an increased water content) led to a significant change in the reaction kinetics of the carbon deposition. While the carbon deposition rate of the refractory castable with a porosity of 13.0 vol.-% did not start to re-increase again until after 40 hours of exposition in a CO atmosphere, the rate of carbon deposition of the comparative material with a porosity of 15 vol.-% already started to re-increase after 20 hours. As a result, the increase in open porosity leads to a shortening of the time until the structural destruction of the refractory material due to cracking begins.

In a direct comparison of the open porosity of thermally pre-treated refractory castables with a reduced hematite content (0.1 wt.-%) and their mass increase due to carbon deposition after exposition in CO atmosphere, an almost linear correlation was observed. However, when assuming this linear correlation, the comparatively large measurement error of the open porosity measurement must be considered.

In summary, the results so far indicate a clear influence of the open porosity and thus the permeability of the material on its carbon deposition in CO containing atmospheres. The trend here is that materials with higher open porosities tend to have a much higher carbon deposition than those with lower open porosities. However, the assumption of a linear correlation between open porosity and carbon deposition needs to be investigated more intensively.

## OUTLOOK

Due to the promising results and the clear influence of the open porosity of refractory castables on carbon deposition, these investigations will be extended in the future. This includes the further adaption of the test materials in order to be able to map a larger area of the open porosity and to be able to describe the correlation with the mass increase due to carbon deposition more precisely.

# EXCEPTIONAL "HIGHLIGHTS" OF EXTREME WEAR OF REFRACTORIES

Jasper Neese, Thomas Schemmel, Bertram Kesselheim, Steffen Rollmann
Refratechnik Steel GmbH, Duesseldorf, Germany

## ABSTRACT

It is hard to imagine modern industrial high temperature processes without refractories. All of these processes cause a high load on the wear materials. The typical edges of the wear triangle are erosion, thermomechanical wear and corrosion. Various groups of refractories can be found in the industrial field depending on the profile of requirements of the particular process. For example, MgO-C bricks in steel making, Magnesia-Chromite bricks in non-ferrous metal making and so forth. Thermal stability, corrosion resistance, erosion resistance as well as thermal shock resistance are necessary properties. Each industry, each process and each furnace have their own requirements concerning the material properties. The present work points out some "highlights" of extreme refractory wear that we have collected during the last years. The given cases derive from different industrial processes and represent various failure modes that may occur in modern industrial high temperature processes.

## INTRODUCTION

In the steel and non-ferrous industry different refractory materials are used. In the most common cases a wear lining of refractory materials is produced, which reacts directly with melt, slag, process materials or gases. Therefore, a resulting wear is no surprise, the objective is to keep the wear as low as possible. In order to understand the wear mechanisms, post-mortem tests on heavily used bricks or components are useful. In this way, a broad knowledge can be generated, which subsequently helps in the most suitable material selection. The range of refractory materials is versatile - the following examples include products with different raw materials and different bond types. From the steel industry, a wear case from the steel ladle is shown using the example of $Al_2O_3$-MgO-Carbon (short "AMC") bricks. Common challenges have their origin in modern steel making practice: e.g. very high process temperatures, aggressive slags, intensive treatment and strong thermal cycling [1]. In the copper industry, fired magnesia chrome bricks (short "Mg-Cr") are often used, here an example from the copper recycling process is presented. In the case of castables, in addition to wear in use, installation and heating are also critical points. Therefore, a large-scale test is shown, which demonstrates the explosion potential during heating. Finally, a look into the future follows - laboratory tests on the attack of andalusite bricks by hydrogen-containing atmospheres are presented. Wear caused by gas attack is already frequently the cause of damage, for example due to CO gas. Hydrogen is already present in today's plants, but the concentration will increase significantly soon.

## WEAR MECHANISM OF REFRACTORIES

Typically, every type of wear found in practice can be attributed to three general mechanisms: corrosion and oxidation, abrasion and erosion and thermomechanical wear. In general, wear is always a combination in various portions of these basic mechanisms (Fig. 1) [2]. In the rarest of cases, only one factor is responsible for the wear. Figure 2 therefore shows the approximate areas in which the following examples are based. The areas of corrosion and oxidation and thermomechanical wear are dealt with in detail below. The shown examples are mainly from this area of the wear triangle.

### Corrosion and Oxidation

This mechanism is based on a result of chemical reactions. The reaction potential between slag and refractory material (based on the chemical composition) determines whether a reaction takes place. The reaction grade is driven by the total number and concentration of components, reaction space, reaction time, oxygen activity and temperature. To show the reaction potential commonly the c/s-ratio is used. Between CaO (basic) and $SiO_2$ (acidic) a high reaction potential is known for example. The complete calculation is shown in eq. 1 [3]. However, simplified forms also exist (CaO/$SiO_2$) and are often used.

$$c/s = ([CaO]+[MgO]/([SiO_2]+[Al_2O_3]+[TiO_2]+[Fe_2O_3])) \quad (1)$$

Temperature is a decisive factor in all reactions. In addition to the influence on the reaction kinetics, there are also process-related problems that lead to higher stress. An increase in temperature reduces the viscosity of the slag, which makes it more difficult to build up a protective layer on the refractory. This significantly increases corrosion, since fresh reactants can be added more and more. Kinetically accelerated oxidation leads to carbon burn-off by air oxygen and FeO.

The first example is a classic case of oxidation with subsequent thermomechanical wear. This mechanism is especially critical for carbon-bonded and carbon-containing products. In a steel casting ladle, AMC bricks were used as wear lining in the wall area. After only a few heats, a massive layer formed on the bricks. In figure 3, the layer on the AMC bricks can be clearly seen. This had to be removed at great expense after cooling down the ladle.

Fig. 1: General wear triangle

Fig. 2: Wear triangle. Examples are located inside the triangle.

*Fig. 3: Detail of hot build-up on AMC bricks in the side wall of a steel ladle*

*Fig. 4: Microscopic examination of the AMC brick. Slightly attacked original AMC structure at the bottom, decarburized structure in the middle and slag deposit on the upper side*

In this case, a good impression of the wear progress could be obtained from the microscopic examination (figure 4). The original structure of the AMC brick was damaged by oxidation of the carbon. This phenomenon is often evident when the ladle has been pre-heated for a long time at high temperatures before its first use or in the case of oxidative wear during the process. The damaged and porous structure allows the calcium-aluminate slag to penetrate the brick while tapping and has a large surface area for chemical attack. Formation of new phases also occur (e.g. spinel). The reacted zone shows completely different hot properties such as melting behaviour and thermal expansion compared to the original material. The infiltrated layer therefore remained as a separate material and had to be removed manually.

**Thermomechanical Wear**

All types of damage that are caused by a temperature related increase in volume are summarized under the generic term of thermomechanical wear. One of the most important material properties in high-temperature processes is thermal expansion. The thermal expansion is a combination of the reversible thermal

expansion coefficient and irreversible expansion by physical-chemical reactions (after-contraction/after-expansion) [4]. Thermal expansion leads to stresses due to the increasing load in the ring network or if temperature inside the refractory is inhomogeneous or if material reactions result in a changed expansion behaviour (e.g. filled pores or chemical reactions). Also, the temperature gradient, the volume of the refractory and the ability to balance stresses without degradation determine the level of wear. Furthermore, all damages through mechanical strain (impacts, flexural stress, pressure) are important for thermomechanical wear.

The second example is a combination of corrosive and thermomechanical wear. The Peirce Smith Converter is a melting unit from the copper recycling process. The lining is made with magnesia-chrome bricks, for example. In this case the brick was attacked by an acidic fayalite slag. The proportion of sintered magnesia (approx. 50%) in the brick was strongly attacked by the acidic slag. Mixed spinels $(Mg,Fe,Cu)O*(Fe,Cr,Al)_2O_3$, monticellite and olivine were formed as a product from brick and slag. These mineral phases have changed melting and expansion behaviour, which has led to premature wear of the lining. During operation, the front layer is densified due to the lowering of the melting point and when the temperature changes, the infiltrated areas spall off due to the changed thermal expansion.

The increase in the $SiO_2$ proportion can be made visible in the bricks cross-section using µ-XRF. From the cold side (below) to the hot side (above), the proportion of $SiO_2$ increases significantly (figure 5). Deep penetration into the brick matrix takes place especially with such aggressive and low-viscosity slags. The reaction mechanism can be understood in the microscopy image in figure 6. The adherend slag on the hot side can be seen in the upper part of the picture. The fayalite slag has decomposed into magnetite and $SiO_2$ glass under oxidizing conditions. The acidic $SiO_2$ glass attacks the basic components, especially the magnesia. The relic of a partially dissolved DBM grain can be seen on the left. The chrome is incorporated into the slag without being dissolved.

857

*Fig. 5: Investigation of Mg-Cr bricks cross section with µ-XRF. Enrichment of $SiO_2$ towards the hot face (above), due to infiltration of aggressive acidic slag.*
*Fig. 6: Microscopic view on Mg-Cr hot face (above). Adhering slag on the hot side, it has decomposed into magnetite and SiO₂ glass under oxidizing conditions. The relic of a partially dissolved DBM grain can be seen on the left. The chrome is incorporated into the slag without being dissolved.*

In addition to this frequent combination of mechanisms, there are also phenomena that are more clearly based on just one of the two wear mechanisms presented. In this case, heating damage to a castable pre-shape component is considered. Since it is a case of spalling caused by volume expansion under the influence of temperature, one can speak of thermomechanical wear in the broadest sense. Even if no process medium such as steel or slag was involved. The increase in volume of the chemically bound water in the component alone leads to explosive destruction of the refractory material if it is heated up too quickly. In a large-scale trial, two pre-shaped components, each weighing one ton, were placed in a furnace operated at 800 °C. The sudden increase in volume of the water builds up an enormous pressure. If the structure cannot dissipate the water vapor and withstand the pressure, the component abruptly fails. The result of such damage is shown in figure 7. A cement-free castable with high strength can cope with the high heating rate, while the reference material cannot withstand the pressure increase.

*Fig. 7: Result of a large-scale fast heating test with different pre-shaped castable to 800 °C. Increasing steam pressure led to a total collapse of the sample on the right side.*

## OUTLOOK

One last highly discussed example in the field of corrosion is the attack of hydrogen gas at high temperatures. In the course of decarburization in the steel industry, the use of large amounts of hydrogen at temperatures > 900 °C is being increasingly examined. When hydrogen is burned, the $H_2$ content in the atmosphere is still low, in the case of direct reduction processes with hydrogen, the doses can be very high. A critical refractory oxide is $SiO_2$. It reacts with hydrogen even at relatively low temperatures according to equation 2.

$$SiO_{2(s)} + 2\ H_{2(g)} = Si_{(s,l)} + 2\ H_2O_{(g)}$$
That this is not just theory is confirmed by exposure tests in a 100% hydrogen atmosphere. In this example, a fired CO-resistant andalusite brick was subjected to corrosive attack by hydrogen at 1400°C for 200 hours. In addition to the measured weight loss, the chemical analysis of the sample is interesting. Figure 8 shows μ-XRF recordings of the sample cross-section. A significant reduction in $SiO_2$ was determined in the edge area. This leads to a complete change in the structure. Thus, in use, thermomechanical or abrasion wear would have to be expected in the next step. Corrosion of gases is not a new topic but is becoming an intense subject for the future due to the use of high amounts of hydrogen.

*Fig. 8: Laboratory trial with Andalusite brick in pure hydrogen atmosphere at 1400 °C. μ-XRF measurements are showing the strong reduction of SiO₂ in the edges.*

## CONCLUSIONS

The cases presented in this publication are intended to show how diverse the corrosion mechanisms on refractory products can be. Almost all refractory products are subject to wear over their lifetime. Basically, the mechanisms can be found in the corrosion triangle. However, the areas of application for refractory products

are exactly where other materials do not have sufficient properties. Many processes and industries depend on refractory products. In times with a focus on efficiency and sustainability, the longest possible service life of refractory linings should be striven for. This requires a detailed understanding of how corrosion mechanisms work and what the critical factors are. This means that there are special requirements for each application which must be understood in order to be able to carry out the optimal lining.

# DEGRADATION BEHAVIOR OF MGO−C REFRACTORY BY AR BLOWING IN CONTACT WITH LIQUID STEEL

Jaewoo Myung, Hana Lee, Byoungkwon Choi, Yongsug Chung[*]
Tech University of Korea, Siheung, Korea

## ABSTRACT

Degradation behavior of a MgO-15wt%C refractory by Ar blowing in contact with liquid steel was studied using a high frequency induction furnace at a temperature range between 1550 and 1650℃. When Ar was blown through the refractory, surface degradation was observed over 1600℃ compared to the no degradation without blowing. Internal degradation was observed in all specimens even though without blowing. It progressed from the interface between liquid steel and refractory to the inside of the refractory. Ar blowing and increasing temperature increased degradation of specimen. The degradation can be thought to be the carbothermic reduction reaction of MgO. The carbon content in the liquid steel increased with time by immersion of MgO-C, and it increased continuously with Ar blowing. The Mg content did not change significantly with time. It seems that Mg was consumed during the formation of the MgO layer and inclusions.

## Introduction

MgO-C materials are being considered for the purging plugs in EAFs [1], converters [2,3]. MgO-C gives strong stirring by injecting gas directly into the liquid steel through stainless pipes inserted inside the refractory. MgO-C is an appropriate material when cold gas is injected through it into liquid steel because of its excellent thermal shock resistance due to the carbon.

However, when MgO-C is in contact with liquid steel, chemical reactions occur. The MgO-C is degraded, which generates Mg and CO vapors by carbothermic reduction of MgO above 1400℃ [4]. The degraded MgO-C is easily damaged by liquid steel. Mg and CO vapors generated by degradation of MgO-C can be dissolved into liquid steel and affect the composition of the liquid steel. Carbon content in the liquid steel can be increased by the reaction between MgO-C and liquid steel [5,6]. Dissolved Mg can react with oxygen in liquid steel to form MgO layer and/or inclusions [7]. In particular, this contributed to formation of spinel inclusions in the case of Al killed steel [8].

In this study, for the case when Ar gas is passes through MgO-15wt%C into liquid steel, we conducted a fundamental study based on the degradation of MgO-C, interfacial reaction between MgO-C and liquid steel at a temperature range between 1550 and 1650℃.

## Experimental procedure

Experiments were carried out using a high-frequency induction furnace. Pure steel (99.97% in purity) and commercial MgO-15wt%C brick were used in this experiment. Tables 1 and 2 show the compositions of the MgO-C and steel, respectively. High purity Ar gas (99.999%) was used for gas injection into liquid steel. When the MgO-C specimen was immersed into the liquid steel, Ar gas was uniformly injected into the liquid steel at a flow rate of 1 NL/min by a Mass Flow Controller for 4 hr after immersion time of 20 min. After the experiment, the specimen was removed from the liquid steel and cooled. The steel samples were collected at the main experiment times (0, 5, 10, 15, 20, 30, and 80 min) without and with Ar blowing at 1600℃ to analyze the changes in the content in the liquid steel.

## Results and discussion
### Degradation of MgO-C in contact with liquid steel without/with Ar blowing

Fig. 1 shows the appearance, vertical cross-section, X-ray CT images of MgO-C specimen after the experiment at the condition of 1550℃ and Ar blowing. In the case without blowing, there was no surface degradation of the MgO-C. However, in the case with Ar blowing, the surface of the MgO-C slightly burst at 1600℃, and more severely at 1650℃. As seen in eq. 1, the surface degradation ratio was calculated as the degraded surface area ($A_d^s$) among the immersed area ($A_0^s$) in the liquid steel. The surface degradation ratios with Ar blowing were 9 and 29% at 1600 and 1650℃, respectively.

$$\text{Surface degradation ratio} = A_d^s/A_0^s \qquad (1)$$

As seen in Fig. 1 (c), density distribution inside the MgO-C was determined from 3D reconstructed X-ray CT scanning images based on differences in density; the grey phase of high density and the black & white phase of low density. As seen in Fig. 1 (a) and (b), even though no surface degradation was observed, difference in density was observed by this technique as seen in Fig. 1 (c). It was also seen in all MgO-C specimens without blowing where no

*Fig. 1. Analysis images of MgO-C specimen after the experiment at the condition of 1550℃ and Ar blowing (a) appearance, (b) optical image of vertical cross-section (c) X-ray CT image*

Tab. 1: Chemical composition of MgO-C

| Element | MgO | Carbon | Antioxidant(Al) | Others (CaO, SiO$_2$,etc) |
|---|---|---|---|---|
| Pct in Weight | 78.2 | 15.5 | 3.6 | 2.7 |

Tab. 2: Chemical composition of pure steel

| Element | C | Si | S | P | Mn | Ni | Al | O | etc | Fe |
|---|---|---|---|---|---|---|---|---|---|---|
| Pct in ppm | < 20 | < 10 | 10 | 12 | < 25 | < 5 | < 5 | 145 | < 10 | Bal. |

surface degradation was observed. As seen in eq. 2, the internal degradation ratio was calculated as the black & white phase area ($A_d^I$) from the X-ray CT image among the total area ($A_0^I$) of the cross-section of the specimen. In the case without blowing, the internal degradation ratios were 8, 31, and 58% at 1550, 1600, and 1650℃, respectively. In the case with Ar blowing, the internal degradation ratios were 47, 100, and 100% at 1550, 1600, and 1650℃, respectively. At the same temperature, the internal degradation always increased with Ar blowing.

$$\text{Internal degradation ratio} = A_d^I/A_0^I \tag{2}$$

It is well known that MgO and carbon react at temperatures above 1400℃, which forms Mg and CO vapor [4]. It can be explained by chain reactions of carbothermic reduction reaction of MgO by eq. 3 of the solid-solid reaction (direct reaction) and eqs. 2 and 3 of the solid-gas reaction (indirect reaction) [9,10].

$$MgO_{(s)} + C_{(s)} = Mg_{(g)} + CO_{(g)} \tag{3}$$
$$MgO_{(s)} + CO_{(g)} = Mg_{(g)} + CO_{2(g)} \tag{4}$$
$$C_{(s)} + CO_{2(g)} = 2CO_{(g)} \tag{5}$$
Several studies have been conducted on the degradation mechanism of MgO-C in an inert atmosphere. As seen in Fig. 2, Lee et al.[10] reported that the degradation mechanism of MgO-C. In their observation by X-ray CT, the degraded matrix of MgO-C was generated at the outside of the surface and progressed inward. Compared to their X-ray CT results, the degradation behavior of present study was similar in this study.

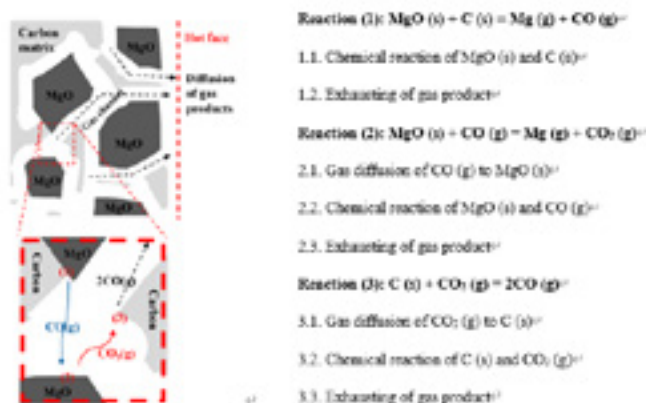

*Fig. 2. Kinetic steps of degradation of MgO-C [10]*

**Interfacial reaction between MgO-C and liquid steel without/with Ar blowing**

The composition changes in liquid steel were analyzed as a function of time. As seen in eqs. 6 and 7, CO and Mg vapors generated from MgO-C can be dissolved into liquid steel [11].

$$CO_{(g)} = C_{(in\ Fe)} + O_{(in\ Fe)} \tag{6}$$
$$Mg_{(g)} = Mg_{(in\ Fe)} \tag{7}$$
In the case without blowing, carbon content increased from about 20 ppm to about 120 ppm at 20 min and then it remained unchanged until 80 min. In the case with Ar blowing, carbon content increased from about 20 ppm to about 45 ppm at 20 min before Ar blowing, and then continuously increased until about 340 ppm after 80 min during Ar blowing. An increase in carbon content during Ar blowing can be reasonably explained by C-O deoxidation equilibrium in liquid steel as seen in eq. 8 [11]. The oxygen content was 12 ppm at 80 min with Ar blowing. The $P_{CO}$ was obtained 0.11 atm based on equation 1 at 1600℃. The equilibrium carbon content was calculated to be 0.18%. It can be though that carbon content was increased by the CO vapor.

$$K = ([\%C][ppmO])/(P_{CO}(atm)) = 20 \tag{8}$$

The Mg content did not changed without/with Ar blowing, which can be explained by Mg-O deoxidation equilibrium in liquid steel as seen in eq. 9 [12].

$$Mg_{(in\ Fe)} + O_{(in\ Fe)} = MgO_{(s)} \tag{9}$$

Brabie reported the formation of a MgO-based oxide layer at the interface between MgO-C and liquid steel [7]. As seen in Fig. 3, MgO layer was formed at the interface between MgO-C and liquid steel. The thickness increased with an increasing temperature and Ar blowing. However, there was no MgO layer with Ar blowing at 1650℃, which was due to the bursting of the specimen.

*Fig. 3. FE-SEM/EDS mapping images of the interface at 1600℃ without blowing*

**Conclusion**

We studied the degradation behavior of a MgO-15%C by Ar blowing in contact with liquid in experiments using a high frequency induction furnace for 4 hr at a temperature range between 1550 and 1650℃. The results are as follows.

1. No surface degradation of MgO-C was observed without blowing at the experimental temperatures, but it was observed with Ar blowing over 1600℃. The surface degradation ratios with Ar blowing were 9 and 29% at 1600 and 1650℃, respectively.

2. Internal degradation of MgO-C was observed using X-ray CT. In the case without blowing, the internal degradation ratios were 8, 31, and 58% at 1550, 1600, and 1650℃, respectively. In the case with Ar blowing, the internal degradation ratios were 47, 100, and 100% at 1550, 1600, and 1650℃, respectively.

3. The degradation reaction can be though to be the chain reactions of carbothermic reduction reaction of MgO.

4. The carbon content in the liquid steel increased with time. Ar blowing continuous increased the carbon content. The Mg content in the liquid steel did not change significantly with time regardless of Ar blowing, as a MgO layer was formed at the interface.

# HYDROGEN: AN ISSUE AND A NEW CHALLENGE FOR THE DURABILITY OF REFRACTORIES

**Jacques Poirier, CEMHTI-CNRS / University of Orléans, France**

## ABSTRACT

To achieve the objectives of the energy transition, green and renewable hydrogen could contribute to decarbonizing many industrial sectors: steel, glass, cement, ceramic industry.

However, the deployment of hydrogen technologies requires removing of barriers concerning the durability and corrosion of refractory materials.

Refractory industrial issues for decarbonated steelmaking, new energies (production of bio syngas), hydrogen enrichment of the atmosphere of furnaces will be approached with an innovative perspective. Approaches combining experimental methods and digital tools and making it possible to provide industrial solutions will be detailed in this paper:

- "Post-mortem" observations
- Thermodynamic calculations
- Experiments (corrosion tests) and high temperature characterizations (Raman, HT-DRX, HR-TEM, SEM) on a laboratory scale to identify key parameters and deduce reaction kinetics
- Evolution of microstructures at the micro and nanometric scale

Examples concerning the durability and corrosion of refractories will illustrate this approach.

- Volatilization, reduction, or fusion of refractory oxides ($SiO_2$, $Fe_2O_3$, alkaline)
- Boudouard reaction under $CO/H_2$
- Degradation by $H_2O$
- Other effects (Marangoni effect, ….)

## CONTEXT

Global greenhouse gas emissions produced by industry represent respectively 21% in 2010 and 18% in 2022 of total emissions. Table 1 shows the quantities of $CO_2$ produced to manufacture one ton of steel, glass, cement, or aluminum.

Tab. 1: $CO_2$ produced per ton of materials.

| Aluminum | Steel | Cement | Glass (packaging) |
|----------|-------|--------|-------------------|
| 8,6 t | 1,85 t | 0,86 t | 0,9 t |

The use of green hydrogen is a major challenge to decarbonize the high temperature industry:
- Supply carbon-free energy to industrial units
- Contribute to the decarbonization of high-temperature processes to replace the fossil fuels currently used.

The reduction of iron ores by green hydrogen for steelmaking is the most emblematic example.

Consequently, hydrogen is an issue and a new challenge for the durability of refractories.

The objectives of this research are:
- Understand the effect of $H_2$ on the damage of refractory ceramics at high temperature
- Provide recommendations to increase their durability in use
- Present the example of hydrogen for steel making.

## MECHANISMS OF REFRACTORY DAMAGE BY $H_2$

In contact with hydrogen, 5 main corrosion/damage reactions can occur (Figure 1).

Fig. 1: Main mechanisms of damage by $H_2$ [1]

## FUSION OF REFRACTORY OXIDES

Under $H_2$, a refractory such as a fire clay brick with <1% $Fe_2O_3$ can melt locally (Figure 2). This degradation, which occurs at high temperatures > 1000°C, is explained by the reduction of iron oxides by hydrogen :

$$Fe_2O_3(s) + H_2(g) = 2FeO(s,l) + H_2O(g)$$
$$FeO(s,l) + H_2(g) = 2Fe(s,l) + H_2O(g)$$
$Fe_2O_3$ particles are present in the refractories as impurities in raw materials and by attrition of the mixing devices while blending the refractory formulation.

Fig. 2: Partial fusion of $Al_2O_3$-$SiO_2$ refractory due to hydrogen [1]

The phase diagrams $Al_2O_3$-$SiO_2$-$Fe_2O_3$ and $Al_2O_3$-$SiO_2$-$FeO$ confirm this hypothesis and show that temperatures of the liquidus fall under reducing conditions.

Refractory performance can be improved by the selection of raw materials with a low content of iron particles and by raising the refractory sintering temperature.

## VOLATILIZATION OF REFRACTORY OXIDES

Figure 3 shows the effect of hydrogen containing 5 ppm $H_2O$ at 1300°C for 500h on the microstructure of a high alumina refractory. After testing, the EDS mapping of the silicon shows the partial disappearance of the silica in the matrix. The open porosity increases, and the vitreous phase is corroded.

There is a reduction of the oxides by $H_2$ and the volatilization of $SiO(g)$ according to the reactions:

$$SiO_2(s) + H_2(g) = SiO(g) + H_2O(g)$$

$$3Al_2O_3-2SiO_2(s) + 2H_2(g) = 3Al_2O_3(s) + 2SiO(g) + 2H_2O$$

Fig. 3: Evolution of the microstructure of a high alumina refractory after 500h at 1300°C under $H_2$ containing 5 ppm $H_2O$.

The reduction by $H_2$ concerns the oxides which are thermodynamically the least stables: $SiO_2$, $Fe_xO_y$, alkali.

The partial pressure of $H_2O$ plays a major role. As an example, the Ellingham diagram (Fig. 4) shows that, at 1300°C, $SiO_2$ is reduced by $H_2$ if $P(H_2)/P(H_2O) > 10^5$.

Practical recommendations can be proposed:

- Increasing the partial pressure $P(H_2O)$ inhibits the reducing effect of $H_2$
- Avoid "free" silica for T > 1000°C. Mullite $3Al_2O_3$ -$2SiO_2$ is less sensitive to $H_2$
- Favor stable oxides $Al_2O_3$, $ZrO_2$, $MgO$
- Optimize microstructures.
Fig. 4: Determination of silica reduction conditions using the Ellingham diagram.

**BOUDOUARD REACTION UNDER CO/$H_2$**

The mechanism of carbon monoxide decomposition: $2CO(g) \rightarrow CO_2(g) + C(s)$ results in the deposition of solid carbon. It causes premature degradation of refractories (Fig.5). This reaction occurs at temperature ranging between 400 to 900°C with a maximum intensity around 600 °C and is highly favored by the presence of catalytic particles such as iron and iron oxides [2].

Fig. 5: Degradation of refractories by Boudouard reaction

When refractories are subjected to CO and $H_2$ reducing atmospheres (Biomass and Coal Gasification, Steam Methane Reformers, Direct Reduction shafts.....), the Boudouard reaction becomes more efficient. $H_2$ favours the nucleation and growth of carbon filaments on the iron-carbide particles.

Raman spectroscopy is an ideal technique to characterize in situ $sp^2$ carbon materials. It is the most sensitive to explore the full range of the structural states from perfectly crystalline to amorphous [3].

The typical Raman spectrum of "$sp^2$ carbon" is reported in Fig. 6 and shows three prominent features. The so-called G band located at approximately 1580 $cm^{-1}$ and corresponds to the in-plane bond stretching of carbon atoms ($E_{2g}$ symmetry). When defects are present, the crystal symmetry breaks down and additional bands appear at specific frequencies depending on the excitation energy used. These bands are called the defect bands: D ($\approx$1250-1400 cm-1) and D' ($\approx$1600-1630 cm-1). At relatively low defect density, the intensity ratio of the defect-induced D band and the symmetry-allowed G band increases with disorder.

Pure iron and iron oxides powders were submitted for 30 minutes at 600°C under reducing atmosphere: 100% CO and CO+$H_2$ mixture (industrial gas).

Fig. 6 summarizes the results obtained using Raman spectroscopy and TEM. Raman spectra of the carbon formed in the two types of gas are totally different. G band is observed in the carbon formed under 100% CO and D and G bands are observed when the gas is a mixture of CO and $H_2$.

Fig. 6: Schematic representation of the interaction of the Raman excitation laser and the carbon particles in shell around catalyst particles in 100% CO and in nano-fibers in CO + $H_2$ atmosphere. TEM micrographs of nano-carbon shells and filaments formed à 600°C in a- 100%CO and b- 70.0% CO, 3.0% $CO_2$, 10.0% $H_2$ and 17.0% $N_2$ from $Fe_2O_3$ nanometer size catalyst.

In CO atmosphere, well organized sp² carbon is formed around the catalyst particles and the defect-induced D bands are not observed. Only chemical reduction of the catalyst particle occurs without significant size reduction. Therefore, poly-aromatic layers are formed around the catalyst particles in the form of encapsulating shells. These layers are sufficiently large with regards to the laser diameter which explains the no activation of the defect-induced D band in the corresponding Raman spectrum [4]. In CO + H₂ atmosphere, the corresponding Raman spectrum exhibits the defect induced D band suggesting disordered carbon. Catalyst particles are chemically reduced and highly fragmented. Therefore, small-sized carbon nanofibers are formed exhibiting a large amount of poly-aromatic boundaries. This eventually leads to the activation of the defect induced D band without the local structural order being necessarily disturbed [5].

Figure 7 reports the different steps of the formation of carbon nanofibers by the Boudouard reaction in CO-H₂ atmosphere:

- Step 1: Fragmentation of iron oxides to nanometer-sized grains and reduction by H₂ with formation of suboxides of iron (Fe₂O₃ ➔ FeO ➔ Fe)

- Step 2: Formation of Fe₃C nanoparticles

- Step 3: grow of polyaromatic carbon nanofibers.

Fig. 7: Mechanism of carbon nanofibers formation by the reverse Boudouard reaction in CO-H₂ atmosphere

Sulphur is an efficient inhibitor to limit the carbon formation [6]. From 100 ppm of $SO_2(g)$, the carbon growth rate decreases by a factor of 70 compared to an experiment without inhibitor. In a CO/H2 atmosphere at 600 °C, iron oxide particles are chemically reduced to $Fe_3C$ and their sizes decrease. With the addition of sulphur such as 100 to 1000 ppm of $SO_2(g)$, the size of iron oxide particles ($Fe_2O_3$) decreases to a lesser extent but are still reduced to cementite ($Fe_3C$) and to Hägg iron carbide ($Fe_5C_2$). The sulphur intake has contributed to the formation of a very thin FeS layer (0.5–1 nm) around the iron carbide particles, preventing the catalytic effect of the Boudouard reaction (Fig. 8).

Fig.8: SEM micrograph of iron sulphides at the surface of catalytic iron particles.

Sulfur stabilizes iron carbides so that it can be heated above 600°C without decomposition.

Sulfur does not prevent the reduction of $Fe_2O_3$ by $H_2$ and the fragmentation of the $Fe_2O_3$ grains. Nevertheless, it prevents the formation of sp2 carbon. Sulfur diffuses into the crystallite structure or through the grain boundaries. Moreover, it is not necessary to transform all the iron into iron sulphides to inhibit the reverse Boudouard reaction. Figure 9 reports the mechanism of carbon inhibition in CO-H₂ atmosphere.

To sum up, lab experimentations show

- In the presence of pure CO gas, a carbon with a high structural organization and an important coherent domain diameter is produced in the form of shells around the catalyst particles.
- In the presence of a CO and H₂ mixture, a carbon with a nanofiber morphology is favored.
- In the presence of CO and H₂ mixture with an addition of S, the catalytic effect of the iron oxide particles is prevented.

Fig. 9 Inhibition of carbon formation by S in CO-H₂ atmosphere.

### ATTACK BY H₂O IN LIQUID OR VAPOR PHASE

The combustion of hydrogen produces $H_2O(g)$ which can corrode the refractories.

Silica (in the presence of NaOH, HBO₂, SO2 vapors) forms hydroxides at a temperature T> 1000 – 1200°C.

- $SiO_2(s) + H_2O(g)$ ➔ $SiO(OH)_2(g)$
- $SiO_2(s) + 2 H_2O(g)$ ➔ $SiO(OH)_4(g)$
- $SiO_2(s) + 3 H_2O(g)$ ➔ $SiO(OH)_6(g)$
- $SiO_2(s) + 0,5 H_2O(g)$ ➔ $SiO(OH)(g)+ 0,25 O2(g)$

Silicon carbide is protected by a surface layer of silica which is vulnerable to H₂O and at high temperatures (Fig. 10)
865

*Fig.10 Damage to the projective silica layer in a hydrogenated atmosphere in the presence of alkali chloride vapors*

Sulphur combines with water vapor to form acidic compounds. These acidic compounds condense at low temperatures (<600°C) and attack the ceramic fibers (Fig. 11)

*Fig.11. Alteration of ceramic fibres by sulphuric acid after 3 months*

## OTHER EFFECTS

Corrosion mechanisms at the triple point – refractory/bath/ atmosphere (Marangoni effect) can be modified due to a modification of the surface tension in presence of a hydrogen atmosphere.

## AN EMBLEMATIC EXAMPLE OF THE FUTURE USE OF $H_2$: THE STEEL MAKING

Hydrogen is of great interest, replacing the fossil fuels currently used, to supply industrial units with carbon-free energy and contribute to the decarbonization of processes. The most emblematic example is the manufacture of steel: why not reduce iron ores with green hydrogen?
The basics of iron and steel are based on two chemical reactions: the oxidation of carbon by oxygen which produces CO and the reduction of iron oxides by carbon monoxide to form iron with a little carbon, with the production of $CO_2$.

$2 C(s) + O_2 \rightarrow 2 CO$
$Fe_2O_3 + 3 CO \rightarrow 2 Fe_{(l)} + 3 CO_2$
For one ton of steel, 1.8 tons of $CO_2$ are produced, and in 2022 the world steel industry produced 2.6 billion tons of $CO_2$, i.e. between 7 and 9% of global emissions, which is colossal.

The future challenge is a 30% reduction in the $CO_2$ produced by 2030 to achieve carbon neutrality by 2050, thanks to "green" steel.
Instead of reducing the iron oxides by carbon monoxide, a reduction by hydrogen is used:
$Fe_2O_3 + 3 H_2 \rightarrow 2 Fe(s) + 3 H_2O$
The steel plant will be then totally transformed, without blast furnaces and BOF convertors, but industrial units called the direct reduction and electric furnaces associated with a hydrogen production unit. The hydrogen is introduced into a preheater and sent to the reactor, the temperature of which is between 500 and 1200°C. Iron ore is introduced and pre-reduced iron ores, known as DRI
(Direct Reduction Iron), are obtained through the hydrogen reduction of iron oxide.
These new processes will impact the refractories, in particular the corrosion of refractories by hydrogen occurs (Fig.13). $H_2$ reduces silica. The $H_2$ corrosion will be associated with attacks by acids, abrasion, and thermomechanical stresses [7].

*Fig.12 Solicitations of refractories for DRI technology (direct reduction*

## CONCLUSIONS

Green hydrogen is a promising avenue for the energy transition. A wide field of scientific and technological progress remains to be made for the optimal choice of refractories and lead to mature and competitive high temperature processes.

# STATUS AND CHALLENGES OF HYDROGEN CONTAINING FUELS ON POROUS CERAMIC MATERIALS AND PROTECTIVE SYSTEMS IN THE ENERGY INDUSTRY

Holger Grote[1]; Reiner Anton[1]; Arturo Flores Renteria[2]; Christian Nikasch[1]; Ivo Krausz[2]

[1]Siemens Energy, Ceramic and Coatings, Mülheim an der Ruhr, Germany; [2]Siemens Energy, Ceramic and Coatings, Berlin, Germany

As the world continues to move forward with ambitious decarbonization targets, the European Union has set goals to cut $CO_2$ emissions by 55% by 2030.

One opportunity to achieve this goal is blending green hydrogen with natural gas as fuel for power generation.

However, there is no siginificant contribution of hydrogen to the electricity generation as of today.

Siemens Energy is leading the way by providing the world's first proof of concept for hydrogen co-firing and hydrogen fireing in gas turbines in combined cycle application. The presentation highlights challenges and possible solutions for the use of porous ceramic protection systems in power plants. Furthermore, we will address alternative applications in the future of the hydrogen and energy industry.

# H₂-CHANGE: REFRACTORIES UNDER ATTACK OF CHALLENGING ATMOSPHERES DURING TRANSFORMATION PROCESS

## INTRODUCTION

Our modern industrialised society is focussing on a new challenge regarding our own living environment. Therefore a change in mind and a change in economy is unavoidable. We can call this a global green deal as a basis for a sustainable economy.

To reach this aim the emissions of greenhouse gases have to be reduced. Only one part but of very high importance. Consequently a lot of transformation of industrial processes is needed. Caused by a long existing alternative process and therefore a high possible decrease of emissions the steel industry gets into this focus of transformation. Namely the direct reduction process will be one of the major production routes for iron and steel in the future.

In this paper common and advanced lining materials for gas driven DRI shaft furnaces are discussed. Based on more than 15 years of experience STEULER Linings shows some examples of lining solutions for the different major processes. Based on reformed natural gas as a standard we will take a closer look to the transformation route via hydrogen boosted coke oven gas in an integrated steel plant up to the pure hydrogen use in a pilot plant.

Especially by using different gases such as hydrogen, methane, carbon monoxide and water vapour and mixtures of these gases as attacking agent. Therefore we are will show the first result of tests made in a STA equipment where we are able to use these different gases under different pressures up to app. 72 psi and temperatures up to 2550 F. Whereas the transformation process with different gas compositions will be the real challenge we will focus in the first step on the hydrogen attack of standard and advanced brick material.

In another part of the paper the usual wear of lining materials for DRI shaft furnaces will be discussed. This will be done for both gas driven DRI processes.

## LINING CONCEPTS

### Improvement of gas inlet area

In this paper we will focus on the two major gas driven processes. One in a non-pressurised and the second one in a pressurised vessel. Both types of DRI shaft furnaces were lining with more or less a comparable refractory material. Most critical lining areas are the lower and upper shaft lining and especially the gas inlet area. The lining of this area in a non-pressurized reactor was always done with some special shaped so called port blocks. This area in a pressurized vessel were originally done by using small-format special shapes with small-size interlocking. Due to high mechanical loads, damage often occurs in this area because the "noses" break off and the brickwork loses stability. On the following pages we show the steps of improvement during a time frame of 5 years starting with the insufficient original lining design.

During a certain time of design review and inspections of old and new lining design we finally installing nowadays only the below mentioned lining design shown in pictures 4 to 6.

Very impressive to see was the behaviour of the old design after app. 18 month of operation. The brick arrangement in the gas inlet area was shifted by around 2 inch inside the reactor. Usually not possible but indeed it happened. On the other side it can be seen that the brick material itself shows fortunately more or less no wear. Anyway we came to the conclusion to provide a new design for the repair work based on special shaped bricks in a double layer design corresponding to the usual lining

concept of a pressurized vessel. Installation was done in 2016 and the inspection after 2 years in 2018 showed no issues regarding the design and the material used for this modification.

Picture 1. Design gas inlet area 2013

Picture 2. Gas inlet area 2013 during installation

Picture 3. Gas inlet area 2014 shifting of the lining

Picture 4. Gas inlet area redesign 2016

Table 1. Properties of different types of lining material for DRI shaft furnaces

| | Unit | Fireclay brick | Mullite fireclay brick | Mullite/Corundum brick |
|---|---|---|---|---|
| Chemical Analysis | | | | |
| $Al_2O_3$ | [wt%] | 45 - 55 | 60 – 75 | 88 – 92 |
| $SiO_2$ | [wt%] | 40 – 50 | 20 – 35 | 9 – 11 |
| $TiO_2$ | [wt%] | 1.5 - 2 | 0.5 – 1.5 | 0 – 0.1 |
| $Fe_2O_3$ | [wt%] | 1 – 1.5 | 0.6 – 1.2 | 0 – 0.2 |
| $P_2O_5$ | [wt%] | 0 - 4 | 0 - 4 | < 0.05 |
| Physical Properties | | | | |
| Bulk Density | [g/cm³] | 2.35 – 2.45 | 2.55 – 2.75 | 2.95 – 3.03 |
| Apparent Porosity | [vol. %] | 14 – 18 | 14 – 18 | 14 - 18 |
| Cold Crushing Strength | [MPa] | 45 – 65 | 60 - 100 | 80 - 100 |
| Youngs' Modulus | [MPa] | 20,000 – 30,000 | 15,000 – 25,000 | 15,000 – 20,000 |
| Thermal Expansion Coefficient | $[*10^{-6}/K]$ | 5.5 – 6.5 | 5.8 – 6.5 | 5.8 – 6.2 |

The original brick material was a kind of Mullite fireclay brick whereas the special shaped gas inlet bricks of the new design were made as high fired Mullite/Corundum brick.

**Expansion joint and support rings**

Picture 7. 3D Visualization of temperature distribution at expansion joint and steel support ring

Due to the thermal conductivity of the support ring made of steel we see a higher temperature on the steel shell outside. The areas with an increased risk for hotspots are clearly visible. Detailed adjustments to the lining concept of these areas can

be implemented and evaluated on the 3D model in order to minimize these hotspot areas.

**Reducing gas transfer line inlet**

Picture 8. Transfer line connection to vessel upper half with a higher shell temperature

Due to the inlet hot gas stream the temperature on the upper half of the transfer line inlet increases. Therefore the installation of the inside refractory material has to be done very carefully to get a lining with sufficient tightness. Experience shown in the last paper let to the best solution by implementing a ring of special shaped bricks for the connection of transfer line and ring channel of the reactor.

## TYPICAL WEAR OF LINING

**Wear of shaft lining**

On the following pictures 9-10 we see the typical wear of a shaft lining based on mullite-fireclay bricks. Sometimes this happens when a chemical reaction of the pellets and or the coating of the pellets lead to a sticking of the feed to the lining material. Usually only in areas where there is a minor movement of the pellet bed accompanied with a possible temperature excursion. In the area with the highest gas velocity and therefore most turbulence this usually does not occur. So at least the area of the gas inlet nozzle bricks and app. half a meter below we don't see an impact.

Picture 9. Shaft lining with rough surface
Picture 10. Closer look to the brick surface
Picture 11. Shaft lining with open joint/expansion joint after shutdown, filled with pellets

Above picture 11 shows a possible situation after a shutdown for maintenance issues. Before restart it is necessary to clean up these joints and remove the pellets. If this happens some measures have to be obtained to avoid a refilling with pellets during the restart operation.

**Mechanical impact**

Another impact may occur if thermal expansion of the lining is not calculated in the right way. Due to uncompensated expansion of the lining the thermal stress can induce a spalling effect on the top surface of the brick lining. On the following picture 12 we see beside this effect above the gas inlet area. And of course above this spalled area we see also an advanced wear of the joints. To avoid such an impact the alignment of mortar and brick material has to be done in a proper way.
Picture 12. Gas inlet area (old design) with spalled area above and advanced wear of the joints in the upper part

## POST MORTEM ANALYSIS

### Analysis of upper shaft material

The samples for the analysis were taken out of the upper shaft lining above the gas inlet area. In this case the lining was done with a usual blast furnace brick based on fireclay (super duty). The following pictures 13-15 show the pieces for the analysis get out of partially spalled material which was already attached to the brick surface. Beside the brick material we see also a lot of metallic material attached to the brick surface.

Picture 13. Spalled brick sample – Lab No. 6705-18

Picture 14. Big flake, metallic – Lab No. 6708-18

Picture 15. Small flake, metallic – Lab No. 6709-18

Picture 16. View into the upper shaft

Based on the chemical analysis in table 2 below we are able to state that there is no real chemical impact on the upper shaft lining due to the process and due to the possible occurring reduction gases in this area. Analysis of Lab No. 6705-18 compared to the mean value of this brand out of production are more or less the same. Definitely the difference in the major components based on alumina and silica show more or less no deviation. Therefore we can be very sure that there is no real attack by the reducing gases like carbon monoxide or hydrogen. Remaining reducing gases should also occur in this area, nevertheless they should reacted in the reducing part of the shaft which is in a lower part of the vessel. Seen from the point of chemical analysis the iron content of the spalled piece is slightly higher which is not really surprisingly.

On the other side we see very interesting analysis of the metallic flakes. It was not possible to separate the metal completely from the remaining brick material and therefore we got also alumina and silica in the analysis. The proportion of alumina and silica is contrary to the proportion in the brick. This may be related to the forming of iron silicates which will be attached in a very small amount to the metallic flakes. This may explain the small difference in alumina and silica analysis between the mean value of production and the spalled brick part out of the reactor.

Furthermore we have to accept a temperature excursion in this area with the effect of creating molten metal flakes. There is still no idea how this could happen in this area but it is a fact. Seen from the point of molten metal the temperature should have reached a level close to 2350 °F which is far away from a supposed temperature of app. 1900-1950 °F in the gas inlet area which is several meters below the investigated area.

Additionally the chemical analysis of the metallic flakes shows especially also a higher content of lime (CaO) and magnesia (MgO) which can be lead back to the use of cement as coating material for the pellets.

Table 2. Chemical analysis of the above mentioned samples

| | Unit | Lab No. 6705-18 fireclay brick | Mean value production fireclay brick | | Lab No. 6708-18 Big flake, metallic | Lab No. 6709-18 Small flake, metallic |
|---|---|---|---|---|---|---|
| Chemical Analysis (XRF) | | | | | | |

**STARTING NEW INVESTGATIONS**

Picture 17. New STA-equipment at Steuler-Lab

Picture 18. Example of online measured

**STA analysis in different atmospheres**

The testing of raw materials and refractory material in atmospheres containing hydrogen, carbon monoxide, methane and water vapour needs a fully new equipment which we have already installed this year. Additionally to the possibility for testing in different atmospheres it is also possible to apply different pressures up to 72 psi. The system is able to run at temperatures up to 2550 F and flexible heating up rates and holding ramps. During the first testing period we tested only in 100 % hydrogen atmosphere at atmospheric pressure to get a first impression on the effectiveness of the new equipment. An example of a measurement given as TG analysis is shown in the picture 19 below.

Picture 19. TG diagram of a mullite fireclay material

The above mentioned diagram shows the graphs of the measurement of a mullite fireclay brick. The brick material was milled and then fractionized. 2000 mg of this powder was given into the TG-crucible. The graphs show from up to down the pressure, the temperature, the weight difference and the hydrogen throughput in cm³ per minute. Additionally it is also possible to run a DSC analysis of such a sample. Between 1740 and 1830 F we see a weight increase of app. 0.01 wt.%, whereas afterwards up to 2550 F we are determining a slight weight loss of app. 0.2 wt.%. Currently we have no idea regarding the first effect, but maybe we see more after DSC running. The second effect shows a minor affected material. This slight effect is not really surprisingly cause this material is currently used in a lot of DRI plants and is obviously a suitable material for this kind of application.

**CONCLUSION**

This paper shows the importance of a careful consideration of the refractory engineering and design. Calculations of thermal stresses etc. are very helpful for getting a suitable lining concept. Combined with the experience of the use of especially developed refractory material for this kind of application we see currently no difficulties in the built up of DRI plants for the hydrogen case. Common systems based on reformed natural gas are running with more or less the same lining material and design.

For the transformation process with a lot of different possible gas atmospheres we are now able to run specialized tests. And one of the most important components in this field could be the addition of water vapour. Due to current knowledge this could change the measured attack in the lab. With pure hydrogen we see a minor effect but pure hydrogen will never go to the DRI-shaft. Also some water will be in the gas due to the heating up of the reducing gas. But we will also take this challenge.

# SWITCHING TO HYDROGEN BASED FUELS AND THEIR EFFECT ON REFRACTORY LININGS AND PROCESSES

Philip Walls

Hitech Materials Pty Ltd, Wollongong, Australia

## ABSTRACT

As we transition from carbon to hydrogen-based fuels to reduce carbon dioxide emissions to stem climate change. Many of the materials contained in the products we use every day at some stage during their manufacture rely on high temperature processes which are in turn directly reliant on "refractory" materials.

This paper summarises the main properties of hydrogen compared to natural gas fuels. It looks at the effect of hydrogen on refractory lining materials and provides some comment on the steps that need to be taken to ensure the transition to a reduced carbon economy proceeds as rapidly as possible.

## INTRODUCTION

Protective refractory linings are required to attain high process temperatures and when hydrogen-based fuels are used in place of natural gas, the refractories must be able to withstand the modified atmosphere and process conditions.

Such atmospheric modification must also be considered with respect to the affect they have on the material being processed in the plant.

Thoughtful refractory material selection and lining design, and/or development of "modified" refractory materials will be required to ensure lining durability and extended plant operation as this fuel transition progresses.

The shift from a "carbon" to a 'hydrogen" based fuel can affect burner design / material selection and alteration of hot zone position, the heat distribution within the process vessel and heat transmitted through the refractory lining. These all affect the durability of the refractories used.

As a reducing agent, at temperatures more than 1000°C, hydrogen attacks normally stable refractory oxides, causing them to decompose by release of volatile species. Such corrosion has a deleterious effect on lining strength and durability, creating headaches for plant managers.

Fortunately, refractories engineers are already on notice and significant research is being conducted to help mitigate potential issues.

Finally, the effect of additional steam generation during the combustion of hydrogen fuels needs to be accounted for. If this is not accommodated by process modifications, condensation in cooler regions can lead to corrosion of metallic components.

## HYDROGEN VERSUS NATURAL GAS FUELS

When comparing hydrogen ($H_2$) as a fuel source, to natural gas (~90% $CH_4$), various factors arising from the difference in their properties need to be considered [1]. These are briefly outlined below and include.

– *Flammability Limit*
  The amount of fuel required for the fuel air mixture to ignite. This is between 4 - 75% for hydrogen, and 7 - 20% for natural gas. This means that hydrogen has a much larger range of fuel/air mixtures that can combust compared to natural gas making hydrogen firing more difficult to control.

– *Flame Temperature*
  For natural gas this is approximately 1950°C and for hydrogen it is 2097°C, almost a 150°C hotter for the hydrogen flame, see (figure 1) below.

Fig. 1: Higher burning temperature for hydrogen.

– *Flame Speed*
  The speed at which a flame travels through an unburnt fuel air mixture. For hydrogen this is about 0.3 m/s about 7 times higher than for natural gas at 0.04 m/s. This makes control of where combustion occurs within the process vessel upstream when using hydrogen compared to natural gas fuels. This directly affects refractory lining, design, and material choice.

– *Energy Density*
  Hydrogen an energy density ~2.5 times that of natural gas, however as its density is lower, for the same amount of energy ~3 times the volume of hydrogen to natural gas is required.

– *Fuel flow rate*
  Because more hydrogen is required due to its low volumetric density, the flow rate for hydrogen fuels is significantly higher than for natural gas.

The comparisons above show there to be significant differences in the combustion behaviour of hydrogen over natural gas. This would require design changes to some existing process vessels if hydrogen is to be used as a replacement fuel.

## MICROSTRUCTURE OF REFRACTORY MATERIALS

Refractory materials for high temperature applications come in two forms, either as pressed bricks (or other shapes), or as monolithic refractory concretes. The latter are either preformed, dried and fired, or are installed in-situ by casting, gunning or ramming processes.

In both shaped and monolithic refractories, the main components include.

– Refractory aggregate grains of various size and/or composition, either straight from the mine or processed to control size, shape

and composition. Aggregates often contain finer particles and phases bonded either chemically or by an amorphous phase.

– A bond phase, which is initially cementitious in nature, before conversion to amorphous or crystalline grain boundary phases at operating temperatures. These are mainly silicate, aluminosilicate, or phosphate in composition.

There are therefore several potential sites where hydrogen can attack the surface of the refractory. These include the primary aggregate particles, the bond phase in general and the grain boundary phases between and within the primary aggregate particles.

These sites will have different compositions and so will be affected by hydrogen attack in different ways.

Now to look at the refractory phases in more detail.

## HYDROGEN CORROSION OF SILICATE AND ALUMINOSILICATE CONTAINING REFRACTORIES

Numerous studies [1-6] have shown that silica, silicate, and aluminosilicate glass phases are attacked by hydrogen via a reduction/corrosion process. Above 1000°C the sub-oxide of silica, SiO is generated in gaseous form together with the generation of water vapour. This is shown by equation (1) below.

$$SiO_2 \text{ (s)} + H_2 \text{ (g)} \rightarrow SiO \text{ (g)} + H_2O \text{ (g)} \tag{1}$$
The silica component of aluminosilicate grain boundary phases and aggregates (such as mullite [7]) are also attacked by hydrogen as shown by equation (2).

$$Al_2Si_2O_{13} \text{ (s)} + 2H_2 \text{ (g)} \rightarrow 3Al_2O_3 \text{ (s)} + 2SiO\text{(g)} + 2H_2O \text{ (g)} \tag{2}$$
The SiO extracted from the refractory lining then either re-deposits further down the process line where the temperature is cooler causing build-up and eventual clogging of components or can interact with other refractory material or the material being processed.

Elimination or reduction of silica containing material in the refractories is necessary to assist hydrogen combustion.

## ALTERNATIVE COMPONENTS FOR REFRACTORIES

Work by Misra [8] on the chemical stability of ceramic materials, showed the upper temperature limits for different ceramics in pure hydrogen (figure 2), as well as in hydrogen/water environments (figure 3).

This work suggested that lime (CaO), alumina, yttria and zirconia were the most stable oxide materials and titanium diboride and carbide were the best performing non-oxides.

Interestingly both silicon carbide and silicon nitride did not perform well in Misra's evaluation. This is most likely due to the presence of a silica surface layer on these ceramics. They therefore would not be recommended to include in a hydrogen resistant refractory material.

Fig. 2: Upper temperature limits for different ceramic materials in pure hydrogen.

Fig. 3: Upper temperature limits for different ceramic materials in $H_2 / H_2O$ environments.

## CONCLUSIONS

At temperatures exceeding 1000°C, hydrogen attacks silica, silicate and aluminosilicate components of refractory materials as well as other refractory oxides to lesser degrees. Hydrogen also appears to attack the thin silica surface coating present on silicon nitride and carbides.

Alumina is stable in hydrogen and hydrogen water environments up to approximately 1340°C.

Zirconia and yttria are the most resistant to hydrogen attack and so yttria stabilised zirconia can be used at temperatures up to ~2000°C.

Titanium boride and carbide are also stable to approximately 1550°C in pure hydrogen.

Both silicon, carbide, and silicon nitride should be avoided as the thin silica layer on their surface, can be attacked by hydrogen in a similar way to silicates and aluminosilicates.

I also note in conclusion that there is little mention of the performance of phosphate bonded refractories. A phosphate rather than a silicate bond may well be beneficial regarding hydrogen attack resistance.

The complex microstructure of refractory materials containing multiple crystalline and amorphous phases, both complicates assessment of their stability in hydrogen containing atmospheres and offers possibilities for tailoring their composition and microstructure to improve their resistance to attack by hydrogen.

A recent review by Hemrick [9] highlighted that *"significant resources and attention are being devoted to the use of hydrogen as an alternative fuel source to fossil fuels…. (but) less information is available regarding the effects of hydrogen firing on processes and process vessels."*

If the transition from carbon to hydrogen-based fuels is to be successful in the timeframe stipulated by the United Nations Framework Convention on Climate Change. Then significant resources are needed to both develop refractory materials and convert existing process vessels to enable this change.

Further, during development of new refractory materials for hydrogen fired processes, it is necessary to develop new standards for assessing the durability of refractories in hydrogen atmospheres.

Such standards will hopefully be developed under the guidance of the ISO/TC 33 technical committee on refractories.

## ABSTRACT

In the transition to a $CO_2$-neutral industry, traditional carbon fuel-based systems must be replaced by sustainable fuel systems such as hydrogen. This change implies a different atmosphere during the operation at high temperature, which is a big challenge for refractory lining materials. This study focuses on four different phosphate-bonded refractories, which are generally characterised by fast drying times, adequate refractoriness, and excellent abrasion and slag resistances. Two phosphate-bonded industrial refractory masses, one based on corundum and the other on fireclay, are tested under corrosive conditions. Two model systems are considered to provide a fundamental view of the behaviour. These focus on smaller grain sizes, reduced silica content and proportionally contain higher amounts of different phosphate-based binders. The first model system contains mainly magnesia and is bound by sodium polyphosphate. The other consists of alumina and is bonded with monoaluminium phosphate. All materials are exposed in a dilute, $9Ar\ 1H_2$, hydrogen atmosphere at various temperatures and holding times.

Corrosion experiments up to 1500 °C have been carried out using a tube furnace with the above conditions. The microstructure, and in particular the binder phase, was characterized by SEM and EDS. Microstructural components undergoing reaction or loss will be identified and their behaviour and movement in the system will be considered. Particular attention is paid to the phosphorus components, their possible reduction and their influence on the binder phase.

## INTRODUCTION

Society, our life standards and the exponential growth of population require a considerable increase of energy consumption and raw materials. Briefly, this has some consequences such as global warming and $CO_2$ contamination, among others. Particular attention is being paid to the steel industry, as it accounts for the largest share of greenhouse gas emissions (around 30 % of the total $CO_2$ emissions) compared to other sectors and 6 % of total emissions in Germany. As a result, low-$CO_2$ and long-term climate-neutral process technology is a key area within the industry. [1] For example, the use of hydrogen in industry, which has a low $CO_2$ footprint depending on the source, can help to reduce substantially the carbon footprint of steel products by minimising the need for carbon-based reducing agents. [2] In addition, the non-ferrous industry is also exploring the potential of hydrogen to reduce greenhouse gas emissions in this sector. One current application is the deoxidation of copper melts in the anode furnace. [3] These changes in turn affect the process enablers, such as refractory materials. These must demonstrate their ability to withstand the changed process conditions, such as increased gas flow and higher levels of hydrogen and water vapour in the reactor atmosphere.

## EXPERIMENTAL PART

Four types of samples were processed and tested in this study. The first two, designated RM1 and RM2, are refractory masses bonded with phosphates. Sample RM1 is mainly based on fireclay and corundum as raw materials, while sample RM2 is mainly composed of corundum. Both samples have a maximum grain size of up to 6 mm. Prior to the tests, the samples were fired at 1500 °C for 8 h to minimise temperature related effects on the samples.

The other two sample types, labelled M1 and M2, are model systems designed to highlight specific effects within the matrix. The grain size distribution of these samples is limited to 1 mm and the amount of binder is significantly increased. Sample M1 is based on sintered magnesia grains with a maximum diameter of 1 mm, 5 wt.-% sodium polyphosphate binder and 1 wt.-% microsilica to prevent brucite formation. Sample M2, on the other hand, consists of a mixture of tabular alumina with a maximum grain size of 1 mm, bound with 8 wt.-% monoaluminium phosphate. Both model materials were sintered at 1100 °C. While the first two samples give an insight into the behaviour of commercial refractories, the latter two materials emphasise the effects within the matrix to a greater extent.

While the first two types of samples give an insight into the behaviour of commercial refractories, the two model systems were chosen to focus on more isolated effects. Sodium polyphosphates can be used as binders for basic refractory materials such as magnesia and as additives for cementitious castings. Their behaviour is observed in the first model system, M1. The second model system, M2, is used to observe the reaction of monoaluminium phosphate binders in more detail. The use of tabular alumina reduces the amount of impurities, which, combined with a low silica content, allows the binder to react with less interference from competing reactions. A tube furnace, Figure 3a, was used to expose the samples to a defined atmosphere at specific temperatures.

The tests were carried out at two temperatures: 1100 °C, representing the upper end of direct reduction technology for iron extraction, and 1500 °C to facilitate corrosive mechanisms. Two different time periods were chosen to assess the effects at the given temperatures and gaseous atmosphere. The gas used in all tests was a hydrogen-argon mixture (1:9 ratio). Control runs were performed to understand the behaviour of the samples in an oxidising atmosphere.

## RESULTS AND DISCUSSION

The behaviour at high temperature of the four different compositions was firstly determined by the mass balance, weighing the samples before and after each test. In addition, to the temperature, the position within the tubular furnace also plays a determinant role. Figure 1 shows the mass changes of all material systems and their respective samples. The first observation is the difference in the magnitude of the mass losses of the material systems RM1 and RM2 on the one hand and M1 and M2 on the other. The losses reach maximum values of 1.2% to 1.6% for the two refractory masses, whereas the two model systems show losses of up to 6%. This seems to correspond very well with the increased binder content of the model systems of 5 wt% for M1 and 8 wt% for M2.

Another notable result for all materials is that the mass losses generally increase at higher temperatures, i.e. from 1100 °C to 1500 °C. The two masses RM1 and RM2 only lose a maximum of about 0.4% at 1100°C and up to 1.6% at 1500°C. This shows the enhanced effect of increased activation energies and kinetics as well as the shifted equilibrium towards a higher proportion of gaseous species. The influence of increased holding time is of minor consequence.

Another aspect which is evident for all samples is that the mass loss of the sample exposed to air at 1500°C for 72 h is consistently lower than that of the samples at comparable temperature conditions from the corrosion tests. This generally demonstrates the influence of the corrosive conditions of the applied testing atmosphere. When looking at the positions of the individual samples and their respective mass

losses, it can be seen that the mass losses of the last sample in the test setup, i.e. the outlet sample, viewed from the direction of gas flow, are the lowest. In contrast, the first two samples, inlet and middle, show a comparably high mass loss. The middle samples of RM2, Figure 1b, show a slightly higher loss than the corresponding inlet samples in all tests. Similar behaviour occurs with M1, Figure 1c, where only the test at 1500 °C for 24 h results in a higher mass loss of the gas inlet sample than the middle sample.

In principle, it would be expected that the mass loss of the inlet samples should be the highest as the introduced reaction gas has not yet reacted at this point and therefore the hydrogen partial pressure is significantly higher in relation to the oxygen content. This should result in a correspondingly significant reduction and therefore mass loss of the inlet samples. The equilibrium should then shift away from the reducing conditions, resulting in less severe corrosion conditions for the intermediate and outlet samples.

*Figure 1: Mass changes of the different materials in dependence of the test conditions and sample positions*

The reason for the deviating behaviour may be explained by the design of the tube furnace. An insufficiently developed homogeneous heating zone of the furnace could lead to a shifted temperature field. This would result in a higher temperature in the centre, i.e. for the middle sample, compared to the inlet and outlet samples. This in turn would cause a shift in the equilibrium, resulting in a higher proportion of gas phase for the middle sample due to the higher temperature.

The reason why the outlet sample has the lowest mass loss is due to the composition of the reduction gas. It can be assumed that the gas is already enriched with products from reactions with the other two samples, resulting in a less pronounced reduction for the outlet sample. However, this would not explain the mass increase observed for M1 at 1100 °C for 72 h Figure 1c. It is known that silicon monoxide is formed from silica under reducing conditions. In this case, this reaction is already happening at the inlet and the middle sample. This gas can then act as a reducing gas for oxides with less affinity for oxygen, such as disodium oxides or phosphorus trioxide. As a result, silica is deposited on the last sample, while more volatile components pass into the gas phase and are removed with the stream. Another aspect that could explain the different mass behaviour of the outlet sample and favour the previously described back reaction of products from the other two samples on the outlet sample is a possible lower sample temperature. As already described, this could be due to the temperature field of the furnace, which would then favour condensation of the gas phase on the samples.

In the case of M2, Figure 1d, particularly in contrast to RM1 and RM2, an increased mass loss can be observed for the inlet and middle sample in the test at 1100 °C for 72 hours. At just under 5 %, the losses here already reach the level of the two tests at 1500 °C of 5.5 %. This indicates that the phosphorus oxides are reduced, transferred to the gas phase and removed in the 1100 °C temperature range as long as there are only minor competitive reactions.

# HYDROGEN CORROSION OF REFRACTORY MINERALS AND THE IMPACT OF SIO-GAS

J. Astoveza, E. Frier, R.M. Mineau, L. Thomas, C. Wöhrmeyer

Imerys S.A., Paris, France

## ABSTRACT

In this study, the resistance of andalusite, mullite, tabular alumina, and stabilized zirconia against hydrogen attack was tested for 240 h in a laboratory furnace. At 900°C, no evidence of reaction was detected for all the minerals. This was not the case at 1400°C where significant mass losses were measured in direct proportion to the silica content. Microstructural analysis highlighted the influence of the unique morphology of mullite and andalusite to their corrosion resistance. A progressive conversion of mullite and glass phase into α-alumina was observed on the sample surface, where silica was preferentially consumed from the glass phase over the silica structurally-bonded in mullite. On the other hand, mullitized andalusite characterized by the dense, ordered capillary network of mullite and glass phase could potentially hinder hydrogen infiltration. Beside hydrogen itself, the effect of the by-product SiO-gas revealed that cross-reactions can be triggered in the presence of calcium resulting in the formation of a calcium silicate phase and subsequently leading to the destabilization of the calcia-stabilized zirconia at 1400 °C, while yttria-stabilized zirconia remained stable.

## INTRODUCTION

The major European steelmakers are on a race towards the green steel transition propelling paramount technological investments prompted by government subsidies to cut their industrial emissions. A target reduction by at least 55 % by 2030 was established under the European Green Deal to align with the 1.5 °C warming mark trajectory [1]. This has driven unprecedented technological disruptions in iron and steel-making, including the substitution of coal by hydrogen as the main reductant and energy source in blast- and direct reduction (DRI) furnaces. As expected, principal stakeholders including the refractory industry are faced with the challenge of identifying and addressing the impact of this technological shift to the market.

Theoretically, it is known that hydrogen at elevated temperatures reacts with free silica, or silicates in refractory linings to produce gaseous SiO and water, depicted primarily by the equation below:

$$SiO_2(s) + H_2(g) \rightleftharpoons SiO(g) + H_2O(g) \qquad (1)$$
The gaseous products can be carried off in the process stream. When temperatures decrease downstream, the reaction reverses and silica is deposited as a solid. The result can be heat-exchanger fouling and product contamination [2]. Although limited in number, recent studies [3, 4, 5] demonstrated the resistance of conventional alumino-silicates and high alumina refractories at conditions pertinent to green steel processes.

This study aims to explore the fundamental mechanism of hydrogen attack on refractory minerals under pure hydrogen atmosphere at temperatures up to 1400°C. A cross-reaction effect by the SiO gas originating from the reduction of the silicate-rich phases and its impact to the stabilization of zirconia is also highlighted.

## METHODOLOGY

Pressed cylindrical samples as shown in figure 1 were obtained using a 3R hydraulic press applying 80 kN of force for 20 s on 100 g of pure refractory minerals. The raw materials were selected within the product portfolio of Imerys including Mulcoa®, Durandal™, Kerphalite™ KA and Zionic™, except the Tabular Alumina T60 from Almatis. Size distributions were obtained following the Andreasen packing model with the distribution (q) modulus of 0.35. Conpac500 superplasticizer and Solvitose FP7 starch were added to aid the dispersion and bond. Pre-firing at 1400 °C for 6 hours proved to be necessary to aid the compaction before subjecting the samples to the corrosion test.

*Fig. 1: Photos of pressed refractory samples before the corrosion test. The arrangement of samples inside the furnace is shown in (c).*

The codes along with the properties of the pressed samples measured after pre-firing are presented in table 1. Five duplicates were prepared per formulation with the following representation: a sample before pre-firing; one after pre-firing; and the other three were subjected to the corrosion test. All the samples were loaded together in a single batch as shown in figure 1 (c).

*Tab. 1: Sample codes and general characteristics including alumina content, aggregate type, apparent porosity (AP), and bulk density measured after pressing and pre-firing at 1400 °C.*

| Code | Al₂O₃ (%) | Aggregate Type | AP (%) | ρ (g/cm3) |
|---|---|---|---|---|
| Mul-47 | 47 | Mullite | 24 | 2.17 |
| Mul-60 | 60 | Mullite | 25 | 2.31 |
| And-60 | 60 | Andalusite | 19 | 2.45 |
| TA-99 | 99 | Tabular Alumina | 24 | 2.38 |
| YSZ | Zirconia – 8% Y₂O₃ | | 29 | 4.21 |
| CSZ | Zirconia – 4% CaO | | 26 | 4.46 |
| 900-sample code | subjected to corrosion test at 900 °C | | | |
| 1400-sample code | subjected to corrosion test at 1400 °C | | | |

The corrosion tests were performed in a muffle-type laboratory furnace under 100 % hydrogen atmosphere both at 900 °C and 1400 °C, respectively, for a total duration of 240 h divided into three 80-h segments. Pure hydrogen gas was injected at a constant flow rate of 200 l/h throughout the tests. At each 80-h interval, a duplicate sample was taken out for weighing and further analysis.

To evaluate the impact of SiO gas, 230 g of CSZ fines (<325 mesh) was subjected to thermal treatment at 1400°C under pure hydrogen atmosphere using the Setsys™ TGA device. The focus on this paper is given to the XRD-Rietveld analysis of the end product and not to the details of the thermogravimetric study.

## RESULTS AND DISCUSSION

### Physical observations

Photos of the cross-sections of the pressed samples obtained using an optical microscope are shown in figure 2. Note that the sections were taken from the mid-region of the cylinders such that only their outer rims were directly exposed to hydrogen. A layer of reacted zone, 1-3 mm thick, is visible on the surfaces of mullite and andalusite after the test at 1400 °C. Polished sections were prepared for Scanning Electron Microscopy (SEM) with scan areas marked in red (figure 2). At this scale, no physical change was discernible for the other minerals tested at 1400 °C. No reaction zone was detected for all the formulations tested at 900 °C.
*Fig. 2: Cross-sections of samples after 240 h of hydrogen corrosion test at 1400 °C. SEM scan areas are marked in red.*

**Weight changes**

Consistent with the physical observations, all samples tested at 900 °C did not exhibit weight change beyond 0-0.50 %. On the other hand, a weight loss proportional to the silicate content was obtained at 1400°C, as shown in figure 3. Additionally, the calcia-stabilized-zirconia gained 1.15% of mass after 240 h. While a stable weight in some of the samples could already be an indication of their resistance against hydrogen attack, mineralogical verification is needed as weight re-gain due to oxidation during cooling, transfer of ions from the gaseous state, and the formation of new phases could counter-balance the weight loss from hydrogen reduction [2, 5].

*Fig. 3: Weight changes measured every 80 h*

**Microstructure**

This section is focused on the results obtained from the 1400 °C test, where notable changes in physical properties were observed. The association of mineralogy to the microstructures presented here is supported by the results of energy dispersive X-ray spectroscopy (EDS) analyses.

*Mullite*

Having obtained the highest weight loss, a clear reaction zone with significantly lower Si content is visible on the exposed surface of 1400-Mul-47, as shown in its micro-XRF scan in figure 4.

*Fig. 4: Cross-section and chemical analysis by area of the mullite sample obtained using micro-XRF*

A closer look at the morphology of the altered zone in figure 5 (a-d) reveals the complete absence of Si in the outermost regions. Instead, only hexagonal plates of α-alumina remained on the surface (a). The conversion of mullite + glass phase into mullite + degraded matrix[1] (d), then subsequently into α-alumina becomes more evident in the transition zones (b, c). It is therefore proposed that the silica from the

grain-boundary liquid phase was preferentially consumed over the silica structurally-bonded in mullite. This mechanism is consistent with that previously reported [6] in mullite test bars subjected to dry hydrogen atmospheres at 1050°C and 1250°C for 500 h. The same study also reported a reduction in the mechanical strength (up to 53% reduction at higher temperatures) attributed to the removal of the glassy matrix.

*Fig. 5: SEM-BSE images of the mullite samples after the corrosion test at 1400 °C. Shown here are areas from the reacted surface.*

*Andalusite*

The SEM images of the andalusite in figure 6 demonstrate how its dense, homogeneous single-crystal structure can somehow constrain the infiltration of hydrogen. It can be seen that the altered zones were deeper in regions of the fine-aggregate matrix, while the attack on the denser crystals were more concentrated along the borders and cracks.

*Fig. 6: SEM images of mullitized andalusite after corrosion test at 1400 °C. Highlighted are areas with visible reaction.*

The total weight loss for 1400-And-60 is noted to be slightly lower than that of 1400-Mul-60 (figure 3) despite its slightly higher silicates content: 38 % $SiO_2$ for And-60 vs. 35 % for Mul-60 estimated using XRD-Rietveld analysis. The unique microstructure of mullitized andalusite reflected in its significantly lower apparent porosity (table 1) is postulated to contribute to an improved resistance against hydrogen attack. Evidence of corrosion appear to be concentrated along the cracks and the prismatic cleavages of andalusite in figure 6. It is important to note that after pre-firing at 1400°C, only 51 % of the andalusite has been converted into mullite and glass phase based on Rietveld analysis. Once mullitization is complete, the cracks are expected to close potentially eliminating the problem of hydrogen infiltration in these localized zones.

---

[1] where the glass phase is either partially or completely depleted due to the volatilization of silicates

*Tabular Alumina*

The SEM images of tabular alumina in figure 7 after the test at 1400 °C demonstrate its excellent resistance to hydrogen attack. The microstructure remained intact displaying no altered zone unlike the other refractory minerals tested. A magnified image (b) with its Fe map (c) marks a thin layer of reduced Fe in the outermost regions, signifying that hydrogen has anyway penetrated through, displacing Fe towards the surface – a phenomenon previously observed in bauxite samples subjected to hydrogen attack (90% Argon - 10% $H_2$) at 1500 °C for 72 h [5]. In their study, agglomerates of reduced Fe, Ti and P oxides were detected in castable surfaces.

*Fig. 7: SEM-BSE images (a,b) of tabular alumina and Fe chemical map (c) of (b) after the corrosion test at 1400 °C.*

Even in the 900 °C test, the migration of reduced impurities notably Fe and P to the surface was evident in figure 8. This marks the importance of the level and type of impurities even in high-alumina aggregates and even at lower temperatures under hydrogen-rich atmosphere. A question is raised whether other alumina-rich alternatives such as fused alumina with larger crystals and less inter-crystal boundaries [7] could better resist the infiltration of hydrogen. Furthermore, sintered alumina is known to have networks of closed micro pores while its fused counterpart has rather local clusters of big pores, where impurities are likely concentrated in some clusters rather than homogenously distributed.

*Fig. 8: SEM-BSE image of tabular alumina (a) and its Fe and P chemical maps, after the 900 °C test.*

*Stabilized Zirconia*

Yttria-stabilized zirconia (YSZ) displayed excellent resistance to hydrogen attack characterized by its stable weight (figure 3), intact microstructure (figure 9 a-b), and unaltered mineralogy (figure 10 a). On the contrary, the stabilization of zirconia with CaO proved to be ineffective under the test conditions. The globular microstructure characteristic to monoclinic zirconia (figure 9 c-d; figure 10 a) has been broadly detected even within the innermost regions of the samples indicating destabilization. This is further supported by the Rietveld estimations for 1400-CSZ in figure 10 b.

**The impact of SiO gas**

EDS analysis on the destabilized CSZ after the test at 1400 °C points to a cross-reaction with the $SiO_{(gas)}$ resulting in the uptake of Si in CSZ. Even with the 200 l/h constant hydrogen flow assumed to provide sufficient gas replenishment, cross-contamination among the samples was not prevented.

*Fig. 9: SEM-BSE images of stabilized zirconia after the corrosion test at 1400 °C. The globular morphology of monoclinic zirconia was largely observed for CSZ signaling destabilization.*

*Fig. 10: Compositions estimated using XRD-Rietveld analysis*

The formation of a calcium silicate phase (figure 11 b) was detected on various zones with the following molar composition: 10-20 % Ca; 5-16 % Si; 5-7% Zr; 60% O. XRD analysis was not able to establish the exact identity of the new phase, having no distinct contribution to the X-ray diffraction patterns. Furthermore, it could be inferred that the volumetric instability, notably shrinkage, expected due to the transformation of the tetragonal and cubic zirconia into its monoclinic structure may have facilitated the infiltration of hydrogen reaching the innermost regions of the sample.

*Fig. 11: SEM-BSE images of CSZ for which destabilization was demonstrated by the extensive conversion to monoclinic zirconia (a) and the formation of a new calcium silicate phase (b).*

To verify whether the destabilization of CSZ was triggered by the $SiO_{(gas)}$ rather than by the corrosion due to hydrogen attack at 1400°C, thermogravimetric analysis on CSZ fines was performed. This time, no other refractory minerals were co-loaded and only raw powder was used. After the 5.5 h of thermal treatment with isotherms at 950 °C and 1400 °C under pure hydrogen atmosphere, the composition of the end product was estimated using Rietveld analysis and compared to previous results in figure 12.

The result shows that CSZ remained stable in the absence of $SiO_{(gas)}$. No significant change in the proportion of monoclinic, tetragonal and cubic zirconia was observed, unlike in the presence of $SiO_{(gas)}$ for the pressed samples. One important implication of this result could be that calcium has a role to play in triggering corrosion by hydrogen in these conditions. This finding, if validated with further tests, would

883

influence the selection of stabilizer for zirconia in applications involving hydrogen-rich atmospheres at very high temperatures.

*Fig. 12: Composition based on XRD-Rietveld estimation of 1400-CSZ (with SiO) and CSZ fines (no SiO) from the thermogravimetric analysis.*

## Perspectives

In the end, it is important to underline that the test conditions used in this study may not even correspond to those in the actual application, notably to the industrial hydrogen-reduced iron processes. For instance, direct reduction using the Midrex® or the Tenova HYL® technologies is expected to be operated at temperatures below 1050 °C and with a pressure between 2-5 bars [3]. The practicality of easing the transition with mixed-gas atmospheres (natural gas, CO and hydrogen) would be taken advantage of. In any case, the atmosphere could theoretically not be purely hydrogen given the co-generation of steam and potentially of other by-product gases. More importantly, the role of the binder in minimizing the porosity to limit hydrogen infiltration is an indispensable factor unaccounted for in this study.

Nonetheless, the fundamental mechanism of corrosion demonstrated in this study contributes to a better understanding of the resistance of common refractory minerals against hydrogen. The excellent resistance of all the samples tested at 900 °C is already a promising prelude for DRI application. Trials involving a wider selection of refractory minerals incorporated in bricks and monolithics are on the way. Investigations on multi-component models based on standard industrial formulations is expected to bring results closer to those anticipated in actual applications as the effects of the binder-matrix systems, porosity distribution, gas permeability and impurity levels are factored in. In the end, all these efforts are directed towards predicting and achieving a well-balanced techno-economic and sustainable refractory solution to enable the green steel transition.

## CONCLUSIONS

This study validates the excellent resistance of common refractory phases against hydrogen attack at 900 °C. When the temperature is increased to 1400 °C, the mechanism of corrosion can be demonstrated:

– Silica volatilization in alumino-silicate minerals is manifested as weight loss and degradation of the sample surface. For mullite and andalusite, the total depletion of Si on the exposed surface resulted in complete transformation into α-alumina. This process was progressive with the preferential consumption of Si from the glass phase over the silica structurally-bonded in mullite.

– The unique microstructure of mullitized andalusite characterized by the dense, ordered capillary network of mullite and glass phase could potentially hinder hydrogen infiltration.

– The cross-reaction triggered by the SiO by-product gas in the presence of calcium resulted in the formation of a calcium silicate phase and led to the destabilization of the calcia-stabilized zirconia.

– Yttria-stabilized zirconia showed excellent resistance against hydrogen, kept a high degree of cubic/tetragonal stabilization and was not impacted by any cross-creation with SiO-gas.

## ABSTRACT
This study aims to provide the basic knowledge for furnace refractory design by investigating refractory property changes occurred in hydrogen atmosphere. Since refractory bricks are thermodynamically stable in hydrogen atmosphere at 1100°C, we tried to find out the minute changes. In this experiment, refractory brick is prepared by andalusite, mullite chamotte, and clay as raw materials and heated to 1100°C in 100% hydrogen atmosphere for 72 hours. In this experiment we found out the brick's strength was decreased and the color was changed into black by the reduction of impurities.

## INTRODUCTION
In order to achieve carbon neutrality, research is being conducted to convert the existing coke reduction iron method to hydrogen reduction iron[1]. Accordingly, the research is required to identify changes of refractories used in hydrogen atmosphere and the factors that cause the change. A lot of researches have reported that when refractories are exposed to hydrogen atmosphere at a high temperature, silica is reduced by hydrogen and decomposed into $SiO(g)$, reducing the strength of refractories[2,3,4,5]. Our research reports phase changes, weight changes, color changes, and physical properties shown when refractory bricks are exposed to hydrogen atmosphere at around 1,100°C. And further reports the effect of components that cause changes in the state of refractories based on thermodynamic theoretical calculations. We expect that this study is to be used as basic data to design refractories for hydrogen reduction steelmaking.

## PREDICTION OF THERMODYNAMIC REACTIONS IN HYDROGEN ATMOSPHERE

*Fig. 1: Ellingham diagram*

HSC Chemistry 10 was used to predict the thermodynamic reaction of refractories in hydrogen atmosphere. As a result, the Ellingham diagram is shown in Figure 1. In the case of pure hydrogen atmosphere ($100(H_2)$), an oxygen potential was calculated by the partial pressure of hydrogen and water vapor. Among the oxide raw materials, $SiO_2$, $Na_2O$, $K_2O$, $Fe_2O_3$ and $TiO_2$ are predicted to be reduced at 1100°C.

## CHANGES OF REFRACTORY BRICK IN HYDROGEN ATMOSPHERE

### Refractory brick specimen preparation
As a specimen, we use a refractory brick which is composed of Andalusite, Mullite chamotte, and Clay as raw materials. After kneading raw materials with binder in a mixer, the mixture is molded with a uniaxial pressing press, dried at 110°C for 24 hours, and heat treated at 1,350°C for 6 hours in the air atmosphere. Table 1 shows the compositions of refractory brick.

Tab.1: The raw materials & composition of refractory brick

| Raw material (particle size, mm) | Composition (wt%) |
|---|---|
| Andalusite (1~0.3) | 30 |
| Mullite chamotte (3~0.3) | 60 |
| Clay (1) | 10 |

### Heat treatment conditions
A refractory brick fired in the air atmosphere was prepared in a size of 20×20×70mm. And the specimen brick is charged into an alumina tube which is capable of controlling the atmosphere, and heat-treated at 1100°C for 72 hours while injecting hydrogen and argon gas at a flow rate of 200cc/min. The heating rate was 5°C/min, and the pressure in the furnace was about 1 bar. Table 2 shows the heat treatment conditions of the specimen.

Tab.2: The heat treatment conditions of the specimen

| Specimen | A | B | C | D | E |
|---|---|---|---|---|---|
| 1st | Fired at 1350°C*6hrs (Air atmosphere) | | | | |
| 2nd | - | Heat-treated at 1100°C*72hrs | | | |
| | - | Atmosphere (Gas ratio) | | | |
| | - | Air | $H_2$ : Ar | | |
| | - | 100 | 25:75 | 75:25 | 100 |

### Color change of refractory brick
As shown in specimen "E" of Figure 2, after the specimen's heated in hydrogen atmosphere, the color is changed to dark. And the blackened specimen could be also returned to the bright color like specimen "A" when it is heated in the air. This reversible reaction is considered that some of the refractory brick components, especially, $K_2O$, $Na_2O$, and $Fe_2O_3$, are reduced to metal having dark color and be oxidized in the air to cause a bright color again.

*Fig. 2: Specimen before and after hydrogen heat treatment*

### Strength changes (Modulus of Rupture)

*Fig. 3: Strength changes by heating atmosphere*

Figure3 shows that refractory's strength changes due to hydrogen reduction. Even though the strength of specimen "B" heat-treated in the air decreased slightly by 6% (1MPa), but specimen(C, D, F)'s strength, heated in the hydrogen atmosphere, decreased by more than 15% (2MPa). The strength change among specimen "C", "D", and "F" was similar to one another indicating that the decreasing strength is influenced by lack of oxygen not by hydrogen concentration.

**Phase changes (XRD)**
The XRD analysis shows that $Fe_2O_3$ in the refractory brick component was reduced to $Fe_3O_4$ and Fe after heat treatment. In particular, metal Fe was detected in specimens(C, D, F), and it seems to have caused a color change of the specimen after heat treatment[4].

Tab.3: XRD results of refractory brick (main peak +++, traces +)

| Specimen | A | B | C | D | E |
|---|---|---|---|---|---|
| Mullite | +++ | +++ | +++ | +++ | +++ |
| Andalusite | +++ | +++ | +++ | +++ | +++ |
| Cristobalite | ++ | ++ | ++ | ++ | ++ |
| Quartz | + | + | + | + | + |
| Fe2O3 | + | + | | | |
| Fe3O4 | | + | + | + | + |
| Fe | | | + | + | + |
| Fe(OH)3 | | + | + | + | + |

**Microstructure Changes (SEM)**
Figure 4 shows the microstructure observations before and after heat treatment in hydrogen atmosphere. Cracks were observed between and within the raw materials regardless of the atmosphere.

*Fig. 4: SEM image before and after hydrogen heat treatment*

**CHANGES OF RAW MATERIALS**

**Preparation of Raw Material Specimens**
To identify which material causes the color changes and strength reduction of refractory bricks in hydrogen atmosphere. The raw material specimens are prepared by the same procedures described in refractory brick. Afterwards, these specimens were heat-treated in 100% $H_2$ atmosphere. The six types of raw materials and their compositions are shown in Table 4.

Tab.4: **Raw materials composition of refractory brick**

| Raw material (particle size, mm) | Composition (wt%) | | | | | | |
|---|---|---|---|---|---|---|---|
| | $SiO_2$ | $Al_2O_3$ | $Fe_2O_3$ | $TiO_2$ | $P_2O_5$ | $Na_2O$ | $K_2O$ |
| Mullite chamotte(3-1) | 43.5 | 51.6 | 1.2 | 2.5 | 0.1 | 0.0 | 0.2 |
| Mullite chamotte(1) | 43.9 | 50.8 | 1.4 | 2.5 | 0.1 | 0.0 | 0.2 |
| Mullite chamotte(0.3) | 41.6 | 52.4 | 1.4 | 2.6 | 0.1 | 0.0 | 0.2 |
| Andalusite(1) | 40.7 | 57.1 | 0.8 | 0.2 | 0.0 | 0.1 | 0.2 |
| Andalusite(0.3) | 39.3 | 58.3 | 0.9 | 0.2 | 0.0 | 0.0 | 0.3 |
| Clay (1) | 51.2 | 33.1 | 1.2 | 0.8 | 0.1 | 0.0 | 0.1 |

**Color changes of raw materials**
As shown in Figure5, color changes were observed in all specimens after heat treatment. The color changes were more noticeable in

Mullite chamotte with smaller particle sizes. Referring to Table 4, we found out the fact that the higher $Fe_2O_3$ content caused the darker color. The degree of color change is increased in the order of Mullite chamotte, Clay and Andalusite which can be explained by the $Fe_2O_3$ content.

*Fig.5: Specimen before and after hydrogen heat treatment*

**Weight changes**
Weight changes after heat treatment are shown in Table 5. The weight loss was greater in smaller particle sizes. Weight loss of mullite chamotte and andalusite is attributed to the reduction of silica and $Fe_2O_3$.

Tab.5: Weight changes before and after hydrogen heat treatment

| Raw material (particle size, mm) | Weight (g) | | $\triangle$g (%) |
|---|---|---|---|
| | Before | After | |
| Mullite chamotte (1) | 13.30 | 13.27 | -0.22% |
| Mullite chamotte(0.3) | 9.76 | 9.73 | -0.29% |
| Andalusite (1) | 13.65 | 13.62 | -0.19% |
| Andalusite (0.3) | 8.77 | 8.75 | -0.21% |
| Clay (1) | 6.97 | 6.97 | -0.03% |

**Phase Changes (XPS)**

*Fig.6: XPS of Fe peak in mullite chamotte(0.3)*
*(a)Before hydrogen heat treatment*
*(b)After hydrogen heat treatment*

*Fig.7 XPS of Si peak in mullite chamotte(0.3)*
*(a)Before hydrogen heat treatment*
*(b)After hydrogen heat treatment*

The phase change of mullite chamotte(0.3), which has the largest color change and strength reduction, was observed by XPS. $Fe^{3+}$ and $Fe^{2+}$ were detected in the Fe peak after heat treatment, indicating that Fe and $Fe_3O_4$ were generated through the reduction

reaction of $Fe_2O_3$ impurities in the specimen by hydrogen, resulting in the observed color change. While silica reacts with hydrogen to produce SiO, it evaporates as a gas and none of the reduced Si species such as $Si^{3+}$ or $Si^{2+}$ were detected after heat treatment.

**Changes in silica in hydrogen atmosphere**
To demonstrate the relationship between the generation of SiO through the reaction of silica with hydrogen and the resulting strength reduction, the reaction of silica alone with hydrogen was performed. Amorphous and crystalline silica were compared under the same conditions as the raw material experiments.

Tab.6 Composition and content of silica

| Material | Composition (wt%) | | | |
|---|---|---|---|---|
| | $SiO_2$ | $Al_2O_3$ | $Fe_2O_3$ | LOI |
| Amorphous | 99.90 | 0.04 | 0.01 | 0.00 |
| α-Quartz | 99.05 | 0.34 | 0.13 | 0.13 |

**Color Changes**
Color changes were observed in the specimens after heat treatment in hydrogen atmosphere, both externally and internally. Similarly, color changes were more pronounced with higher $Fe_2O_3$ content.

*Fig.8 Specimen before and after hydrogen heat treatment*
**Weight changes (TGA)**

*Fig.9 TGA results of Silica*

The TGA results representing the volatilization loss of silica shows that the weight of the specimens decreased by approximately 1.0% over time for both amorphous and crystalline specimens (Figure 9). The data is based on isothermal time right after reaching 1100°C. In both cases, the weight loss was greater than the amount of impurities contained in silica. This indicates the generation of SiO through the reduction of iron oxide as well as the reduction of silica. The evaporation of water vapor generated by the reduction reaction of iron oxide and the volatilization of gaseous SiO formed through the hydrogen reaction of silica occurred simultaneously. In accordance with literature[6], assuming an equilibrium state with the Gibbs free energy for the volatilization reaction of silica, the calculated volatilization loss(equilibrium pressure) at 1100°C is very small, approximately $2.14 \times 10^{-3}$Pa. However, as it is proportional to time, the volatilization loss of refractory materials increases linearly with longer exposure to hydrogen reduction [6].

**Microstructure (SEM)**
The microstructure changes of silica particles are shown in Figure 10. For Quartz with a high impurity content (Table 6), exposure to hydrogen for more than 4 hours at 1100°C resulted in a change from the original smooth surface to a rough surface. On the other hand, if the impurity content is low, the degree of surface damage is much milder.

*Fig.10 Microstructure of Silica*

These defects eventually lead to a decrease in strength. Although the calculated volatilization loss (equilibrium pressure) of silica is minimal, even when silica is exposed to hydrogen for 72 hours at 1100°C, it demonstrates the formation of pores and a potential decrease in mechanical strength.

**CONCLUSION**
In hydrogen atmosphere, $SiO_2$ and impurities such as $Na_2O$, $K_2O$, and $Fe_2O_3$ among the refractory material raw materials are reduced under low oxygen partial pressure, resulting in the weakening of refractory bricks.

Refractory bricks show reversible color changes after heat treatment in reduction atmosphere. Since the degree of color change is determined by the impurity content, $Fe_3O_4$ and Fe, the reduction products of $Fe_2O_3$, were observed as major color change factors.

Silica components are prone to damage due to the evaporation of SiO, which leads to the weakening of refractory bricks. The damage to silica in the hydrogen atmosphere is accelerated by the presence of impurities.

In addition, oxides such as $TiO_2$ and $P_2O_5$ are likely to be reduced by hydrogen. The vulnerability of refractories in the hydrogen atmosphere can be also prevented by lowering the content of the impurities.

# CHARACTERIZATION OF REFRACTORIES WITH REGARD TO THE APPLICATION IN H$_2$−CONTAINING ATMOSPHERES

Cristian Daniel Bohorquez-Moreno[1]; Dietmar Gruber[2]; Sido Sinnema[1]

[1]Tata Steel IJmuiden, Ceramics Research Centre, Velsen Noord, Netherlands;

In search of mitigation solutions to avoid the effects of fossil fuel-based production, industries have been encouraged to understand new ways to reduce their carbon footprint during production. As a result, the major trend in the steelmaking industry is the transition from the blast furnace to direct reduction of iron based on the use of hydrogen. Especially the effect of H2-containing atmospheres on the degradation of thermo-mechanical behaviour is less investigated. Existing refractory solutions and designs for the direct reduction process (DRP) reactors use materials that are already available, for which only empirical and no detailed information is known about their interaction with atmospheres rich in hydrogen and water vapour. The present work shows challenges and limitations for testing under H2-containing atmospheres. Furthermore, results for common refractory materials are presented. For this purpose, samples were exposed to H2-rich atmospheres for at least 24 h, 48 h, and 72 h at high temperatures, showing that the prolonged exposure caused changes in the morphological, thermophysical and mechanical properties. The results are expected to serve as a basis for future DRP-reactor design or as preventive measures in the maintenance of existing reactors. This project is part of the cooperation between members of the Concerted European action on Sustainable Applications of REFractories (Cesaref), which aims to give new insights and support in the transition and anticipation of tomorrow's problems related with the green production.

# HYDROGEN INDUCED ATTACK OF AL$_2$O$_3$–SIO$_2$ REFRACTORIES – APPLICATION OF SEM TECHNIQUES AND THERMODYNAMICS

Isabelle Henn[1]; Almuth Sax[2]; Peter Quirmbach[2]

[1]University of Koblenz, Institute for Integrated Natural Sciences – Chair of Technical Chemistry and Corrosion Sciences, Koblenz, Germany; [2]University of Koblenz, Institute for Integrated Natural Sciences – Chair of Technical Chemistry and Corrosion Scie

In order to reduce $CO_2$ emissions, a change is currently taking place within the steel industry towards hydrogen-based steel production. For this purpose, the requirement profile for the refractory materials is thus being extended to include a resistance to hydrogen. The aim of this poster is to characterize the structural changes respectively the corrosion mechanism occurring in an Al2O3-SiO2 refractory material, which experienced a hydrogen induced attack. SEM techniques were applied and the results were verified with thermochemical calculations. First, a corrosion test was conducted. Therefore, the refractory material was exposed to 100 % H2 for 200 h at 1400°C. Subsequently, an elemental analysis by SEM of the hydrogen-induced corrosion zone of the refractory was performed. The corrosion mechanism was described by thermodynamic modeling using the software FactSage.
